FIGURE 307-1. Histopathology in an acute case of gonococcal urethritis with Gram stain technique. This slide is used to demonstrate the nonrandom distribution of gonococci among polymorphonuclear neutrophils. Note that there are both intracellular and extracellular bacteria in the field of view.

FIGURE 307-2. Male with a purulent penile discharge from gonorrhea and an overlying penile pyodermal lesion. Pyoderma involves the formation of a purulent skin lesion, which in this case is located on the glans penis.

recommended evaluation. The major clinical manifestations of gonococcal infection are discussed separately later. Gonococcal ophthalmia, which occasionally results from autoinoculation in individuals with anogenital gonorrhea, presents as an acute, purulent conjunctivitis that can result in corneal ulceration if not treated promptly. This syndrome is now rare and is not discussed further.

DIAGNOSIS

Microscopy

Microscopy of a Gram-stained smear is positive when polymorphonuclear neutrophils are observed to contain intracellular gram-negative diplococci of typical morphology (Fig. 307-1). Gram-stained urethral smears are 90 to 98% sensitive in the diagnosis of symptomatic gonococcal urethritis in men and have a specificity greater than 95%. However, Gram stain is only approximately 50% sensitive for cervical or rectal infection and for asymptomatic urethral gonorrhea. Although Gram stain is often considered highly specific for such infections, the actual performance varies with the skill and experience of the examiner, and rectal and cervical smears are unreliable in many clinical settings. Smears are both insensitive and nonspecific for pharyngeal gonococcal infection and are not recommended.

Culture

Isolation of *N. gonorrhoeae* by culture, generally using antibiotic-containing selective media, is the historic mainstay of the diagnosis of gonorrhea. Ideally, growth media should be inoculated directly and placed promptly into a humid atmosphere with increased carbon dioxide, such as a candle extinction jar. However, standard transport systems (e.g., Culturette) are acceptable if specimens are kept moist, are not refrigerated, and are processed within 6 hours. When testing specimens not likely to be colonized by competing flora (e.g., synovial fluid), nonselective chocolate agar should be used.

Nucleic Acid Amplification Tests

In most settings in the United States, nucleic acid amplification tests (NAATs) have now supplanted culture as the dominant laboratory test used to diagnose gonorrhea. NAATs approved by the Food and Drug Administration (FDA) include polymerase chain reaction (PCR), transcription-mediated amplification (TMA), and DNA strand displacement (SDA). The advantages of NAATs include a slight increase in sensitivity over culture, the ability to test urine specimens and self-obtained vaginal swabs, and the fact that most NAATs are now marketed as combination assays that allow simultaneous testing for *N. gonorrhoeae* and *Chlamydia trachomatis*. The disadvantages of NAATs include the inability to perform antimicrobial susceptibility testing and the poor or inadequately defined positive predictive value of some NAATs when used to test low-prevalence populations. Because the prevalence of *N. gonorrhoeae* in family planning clinics in many parts of the United States and other nations is now well below 1%, the risk of false-positive screening results may be high, and reliable results depend on the use of assays with exquisite specificity. Existing evidence suggests that TMA has a high positive predictive value even in very low-prevalence settings, and the Roche PCR has a low positive predictive value when used as a screening test in low-prevalence populations; the positive predictive value of SDA is not well defined.

Although NAATs have been approved by the FDA only for the testing of genital tract and urine specimens, increasing evidence suggests that at least some NAATs (e.g., TMA, SDA) are substantially more sensitive than culture in detecting *N. gonorrhoeae* in pharyngeal and rectal specimens and that these NAATs are sufficiently specific to screen high-risk populations for rectal and pharyngeal gonorrhea (owing to low specificity, the Roche PCR should not be used to test rectal or pharyngeal specimens). Given the decreasing availability of gonococcal culture, the poor sensitivity of culture on non–genital tract specimens, and the high prevalence of asymptomatic rectal and pharyngeal infections in some populations (particularly MSM), clinicians caring for patients at high risk for nongenital gonococcal infections should be able to use NAATs. Recent studies suggest that self-obtained rectal and pharyngeal specimens yield accurate results and are acceptable to MSM. In the United States, laboratories wishing to use NAATs to test pharyngeal or rectal specimens must perform an internal validation study. Many large commercial laboratories have done such validation studies, making the test available to a growing number of clinicians.

Older nonculture tests, based on nonamplified DNA probe technology or immunochemical detection of gonococcal antigens, are substantially less sensitive and probably less specific than culture or NAATs, and they cannot be used to test urine or anatomic sites other than the urethra and cervix. Such tests have little clinical use today and are no longer recommended.

CLINICAL SYNDROMES

Urogenital Gonorrhea in Males

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Gonococcal urethritis in men is typically characterized by a purulent urethral discharge and dysuria. The usual incubation period is 2 to 6 days. A small minority of men who acquire urethral infection—generally estimated at 1 to 10%, and varying with the auxotype or serotype of the infecting strain—remain asymptomatic.

Physical examination typically reveals a purulent urethral exudate (Fig. 307-2); this is usually readily apparent, but sometimes compression of the urethra is required to express the exudate. Erythema of the meatus is sometimes present. Nongonococcal urethritis (Chapter 293) is typically characterized by less copious and less purulent discharge.

The diagnosis of gonococcal urethritis is usually suspected clinically, confirmed preliminarily by a Gram-stained smear showing leukocytes with intracellular gram-negative diplococci (see Fig. 307-1), and made definitively when *N. gonorrhoeae* is identified by culture or NAAT.

PROGNOSIS

With prompt treatment, urethral gonorrhea seldom results in significant long-term morbidity. Acute epididymitis complicates gonococcal urethritis in less than 1% of cases. *C. trachomatis* is a more common cause of

epididymitis in young men, and *Escherichia coli* and other uropathogens are probably more common in older men and perhaps in men who engage in insertive anal intercourse. Patients with epididymitis usually present with unilateral testicular pain and swelling, often with fever. Posterior urethritis or prostatitis, typically manifesting as pelvic or perineal pain and urinary retention, was once fairly common but is now rare. Urethral stricture, another formerly common complication, is now very rare. Although it is not a direct effect of gonorrhea, having gonorrhea is associated with an elevated risk of future HIV acquisition among MSM, so the diagnosis of gonorrhea should alert clinicians to counsel such patients about their sexual risk and to encourage them to seek frequent HIV testing.

Lower Genital Tract Gonorrhea in Females

CLINICAL MANIFESTATIONS, DIAGNOSIS, AND PROGNOSIS

The primary site of infection in women is the endocervical canal. The proportion of infected women who develop symptoms is not precisely known, although one study of 19 recently infected women found that 50% had symptoms. More certain, however, is that most prevalent infections among women are asymptomatic. Although gonorrhea is sometimes associated with an abnormal vaginal discharge, bacterial vaginosis, trichomonas vaginitis, and candidal vaginitis are much more common causes of this symptom, and gonorrhea does not cause vaginitis in sexually mature women. Lower genital tract gonorrhea in women can be associated with abnormal vaginal bleeding, which typically manifests as metrorrhagia, scant intermenstrual bleeding, or postcoital spotting. *N. gonorrhoeae* sometimes causes dysuria and can be isolated from the urethra in up to 80% of women with gonorrhea; however, the urethra is rarely the only infected site, except in women who have had hysterectomies. In a minority of women, physical examination is notable for a purulent or mucopurulent cervical discharge, cervical edema, or easily induced cervical bleeding, signs of mucopurulent cervicitis. In uncomplicated infections, purulent exudate can sometimes be expressed from a Bartholin's gland duct, near the vaginal introitus laterally, or from Skene's glands, adjacent to the urethral meatus.

Microbiologic diagnosis usually rests on identifying *N. gonorrhoeae* in cervical secretions by culture or NAAT. Gram-stained smears are insensitive and are seldom used.

The most important common complication of lower genital tract gonorrhea in women is PID (see later). Much rarer complications include Bartholin's gland abscess, which manifests as a tender introital mass and may involve superinfection with facultative and anaerobic bacteria.

Pelvic Inflammatory Disease

CLINICAL MANIFESTATIONS

PID refers to an infection of the lower female genital tract and can involve the uterus (endometritis), fallopian tubes (salpingitis), and ovaries (oophoritis), as well as neighboring pelvic structures. An estimated 10 to 40% of women with endocervical gonococcal infections develop PID, and gonorrhea is thought to be the cause of approximately 10 to 30% of all diagnosed cases of PID in the United States, although this percentage varies with overall rates of gonorrhea and other (e.g., chlamydial) infections in the population.

Low abdominal pain is the dominant symptom of PID. Pain is variable in intensity and is often mild; it is usually bilateral, typically present for days to weeks before clinical presentation, and can be exacerbated by coitus. Symptoms often coincide with the onset or cessation of menses. Approximately one third of women have abnormal vaginal bleeding. Fever, chills, anorexia, vaginal discharge, urethritis, and proctitis occur, but they are neither sensitive nor specific in identifying women with PID.

The physical examination is typically notable for diffuse abdominal tenderness that is greatest in the lower quadrants and for tenderness of the pelvic organs on bimanual examination, with or without manipulation of the cervix. Most women have signs of cervicitis or bacterial vaginosis. Fever is present in a minority of cases. Abdominal or adnexal signs are occasionally unilateral, and this finding can cause confusion with appendicitis (Chapter 144), ectopic pregnancy, and other conditions. Right upper quadrant abdominal tenderness is sometimes present due to Fitz-Hugh-Curtis syndrome, in which intra-abdominal extension of infection results in perihepatitis, which can mimic acute cholecystitis or viral hepatitis. Sometimes perihepatitis occurs in the absence of other abdominal or pelvic findings typical of PID, especially when caused by *C. trachomatis*. Severe PID may be accompanied by signs of generalized peritonitis.

DIAGNOSIS

The clinical diagnosis of PID is imprecise. Published studies, which have used somewhat variable criteria in populations with different prevalences of the syndrome, have reported positive predictive values of 65 to 95% compared with the "gold standard" of laparoscopically defined PID. Although nonspecific, the presence of neutrophils on a saline wet mount of vaginal secretions was 91% sensitive for endometritis in one study. The absence of white blood cells on a wet mount, particularly if mucopurulent cervicitis is also absent, should prompt the consideration of alternative diagnoses. The differential diagnosis of PID includes ectopic pregnancy; appendicitis; rupture, bleeding, or torsion of an ovarian cyst; endometriosis; urinary tract infection or pyelonephritis; renal or ureteral stones; inflammatory bowel disease; and, rarely, viral hepatitis or cholecystitis.

Because of the potential seriousness of the infection and the relative simplicity, low cost, and low toxicity of treatment, clinical diagnostic criteria emphasize sensitivity at the cost of specificity. The CDC recommends that all sexually active women with pelvic or lower abdominal pain and uterine, adnexal, or cervical motion tenderness be treated for possible PID if no other cause for their symptoms and signs is readily apparent. Factors such as fever, an elevated erythrocyte sedimentation rate or C-reactive protein, and concurrent bacterial vaginosis or mucopurulent cervicitis further support the clinical diagnosis, but these are frequently absent. Definitive diagnosis requires histologic evidence of endometritis on endometrial biopsy, transvaginal ultrasound or other diagnostic imaging showing thickened or fluid-filled fallopian tubes or tubo-ovarian abscess, or laparoscopic findings of a purulent tubal exudate, erythema, or edema.

PROGNOSIS

Fallopian tube scarring secondary to PID often results in tubal factor infertility (TFI), ectopic pregnancy, and chronic pelvic pain. Previous gonococcal and chlamydial infections are among the most common antecedents of these complications. Each episode of PID, whether due to *N. gonorrhoeae, C. trachomatis,* or neither of these organisms, significantly increases the risk for recurrent salpingitis.

The natural history of clinically apparent PID is well defined. In what is probably the best single study on the subject, TFI occurred in 8% of women following a single episode of laparoscopically proved PID, in 20% after two such episodes, and in 40% after three or more episodes. The first pregnancy after an episode of PID was ectopic in almost 8% of women, and like TFI, the risk of ectopic pregnancy increased with each successive episode of the syndrome. Chronic pelvic pain, sometimes disabling in its severity, occurs in almost 20% of women after one or more episodes of PID. Importantly, these outcomes were best studied in women with clinically apparent PID, and the pertinent studies were undertaken at a time when clinical recognition and treatment were likely delayed. Many women suffer clinically mild or silent PID. The risk of sequelae associated with silent PID is not well defined, but more clinically severe PID is associated with a higher risk of sequelae. Most women with TFI deny a history of PID, and it seems likely that silent PID, particularly silent PID associated with *C. trachomatis*, is responsible for most cases of severe STI-related reproductive tract sequelae. For example, *C. trachomatis* seropositivity is strongly associated with TFI, independent of clinical or historical evidence of PID.

Rectal Infection

CLINICAL MANIFESTATIONS

Gonococcal infection of the rectum is common in women and in MSM. In women, infection is acquired either through perineal contamination with cervicovaginal secretions or by anal intercourse; the latter is the exclusive route of infection in MSM. In women with cervical gonorrhea and in MSM with gonorrhea at any anatomic site, about 40% have rectal infection. More than 80% of infections are subclinical, but symptomatic proctitis sometimes manifests as varying combinations of anal pruritus, mucopurulent discharge (often characterized by the patient as mucus-coated feces), pain, tenesmus, and bleeding. Symptomatic proctitis seems to be more common in MSM than in women with rectal gonorrhea, which suggests that the size of the infecting inoculum or the trauma of anal intercourse may influence the clinical manifestations. Among MSM, rectal gonorrhea, particularly recurrent episodes, is a potent risk factor for the acquisition of HIV.

DIAGNOSIS

Diagnosis of rectal gonorrhea depends on the identification of *N. gonorrhoeae* by culture or, increasingly, by NAAT. The Gram-stained smear is insensitive and nonspecific. The differential diagnosis of symptomatic proctitis includes other traditional STIs, (herpes, syphilis, and chlamydial infection, including lymphogranuloma venereum; Chapter 326), as well as ulcerative colitis, Crohn's colitis, anal fissure, rectal lacerations, and proctocolitis caused by *Shigella, Campylobacter, Yersinia enterocolitica,* and other enteric pathogens. Recent studies using NAAT among STI clinic patients suggest that approximately 5% of tested MSM and 1% of tested women have rectal infections without concurrent genital tract infections, findings that support the routine screening of MSM, but not women, for rectal gonorrhea.

Pharyngeal Infection

CLINICAL MANIFESTATIONS

Pharyngeal gonococcal infection results from orogenital exposure. It is more efficiently acquired by fellatio than by cunnilingus and is typically found in 3 to 7% of heterosexual men, 10 to 30% of women, and 10 to 30% of MSM with genital tract gonorrhea. Asymptomatic infection is the rule, although rare cases may exhibit exudative pharyngitis and cervical lymphadenopathy. Isolated pharyngeal infection is common in MSM and may also be common in at least some populations of heterosexuals. Complications are infrequent, and most cases resolve spontaneously or in response to therapy for genital or rectal infection. Although the modest morbidity associated with pharyngeal infections probably does not justify extensive screening efforts, the oropharynx may be an important reservoir for infection in some populations, particularly MSM. Current guidelines suggest that MSM at risk for STIs be tested periodically for pharyngeal gonorrhea. At present, similar testing in heterosexuals is not recommended, although there may be some populations in which such testing is justified.

Gonorrhea in Children

Gonococcal conjunctivitis may develop in infants born to mothers with gonorrhea, a condition termed *ophthalmia neonatorum.* Formerly a common cause of blindness, gonococcal ophthalmia is now rare in industrialized countries because of both improved control of gonorrhea and routine use of neonatal ocular prophylaxis with topical antibiotics or 1% silver nitrate. Neonates may also acquire pharyngeal or rectal infection and, rarely, gonococcal pneumonia or sepsis. Neonatal vaginal infection is uncommon because, under the influence of maternal estrogen, the glycogen-rich squamous epithelium of the neonatal vagina is resistant to gonococcal infection, just as *N. gonorrhoeae* does not cause vaginitis in sexually mature women. Beyond the neonatal period, purulent vaginitis is the most common manifestation of gonorrhea or chlamydial infection in girls, and rectal or pharyngeal infection is the most common manifestation in prepubertal boys. Most cases are acquired through sexual abuse, but occasional cases in young children may be acquired from fomites or by nonsexual personal exposure in crowded conditions, especially in tropical climates. Legal considerations may require that an organism be isolated and retained for confirmation, and culture should be done in addition to NAAT in all cases of suspected childhood gonorrhea or chlamydial infection. Testing with more than one NAAT, particularly when culture is not available, is also worthwhile when evaluating a child with suspected gonorrhea.

Disseminated Gonococcal Infection

CLINICAL MANIFESTATIONS

Disseminated gonococcal infection (DGI) usually manifests with various combinations of polyarticular tenosynovitis, dermatitis secondary to focal septic embolization, and septic arthritis. Studies undertaken in the 1960s and 1970s estimated that DGI occurred in 1 to 3% of adults with gonorrhea, but the risk depends on characteristics of the particular strains of *N. gonorrhoeae* circulating in the population. Today, DGI probably occurs in well under 1% of gonococcal infections in most geographic areas. Women may be somewhat more susceptible to DGI than men, and the onset often coincides with menstruation. Severity varies from a mild illness with slight joint discomfort, a few skin lesions, and little or no fever to a fulminant illness with overt polyarthritis, innumerable skin lesions, high fever, and prostration. Most persons with DGI have no symptoms of genital gonorrhea, probably because the strains of *N. gonorrhoeae* that are prone to disseminate are also associated with subclinical mucosal infections. The absence of clinical symptoms and signs of mucosal infection in these strains is probably due to their ability to bind complement downregulatory molecules, thereby diminishing the local inflammatory response.

The presentation of DGI can be divided into the clinical syndromes of tenosynovitis-dermatitis or mono- or oligoarticular arthritis, although these presentations sometimes overlap. Tenosynovitis-dermatitis is thought to predominate early in the course of dissemination, and approximately 70% of DGI cases in published series present with this syndrome. These patients usually suffer migratory polyarthralgias without purulent arthritis. There is often tendon inflammation affecting the wrists, fingers, ankles, or toes. Skin lesions are typically painless, are few in number (5 to 30), affect predominantly the extremities, and are pustular or vesiculopustular (Fig. 307-3), although petechiae, hemorrhagic macules, papules, bullae, and nodules rarely occur (see Fig. 449-5 in Chapter 449). Axial skeletal involvement is uncommon, a feature that can help differentiate DGI from reactive arthritis (Chapter 273). The tenosynovitis-dermatitis syndrome often subsides spontaneously, or it may evolve over a period of several days into an overt septic arthritis with purulent synovial fluid, usually involving only one or two joints. Approximately 30 to 40% of persons with DGI present initially with purulent oligoarthritis. A sequential evolution from arthritis-dermatitis syndrome is often not observed, so some patients present initially with septic arthritis. This form of DGI typically affects the knee, ankle, elbow, or wrist, but any joint may be involved.

DIAGNOSIS

Sexually active young persons with arthritis, tenosynovitis, or papulopustular skin lesions should be tested for *N. gonorrhoeae* at all potentially exposed anatomic sites. The diagnosis of DGI is secure when gonococci are identified by culture or NAAT in the blood, a skin lesion, or synovial fluid, but it is often made presumptively when genital, rectal, or pharyngeal gonorrhea is present in a patient with a compatible clinical syndrome that responds promptly to antibiotics.

Blood, synovial fluid, and mucosal tract cultures are positive in approximately 4 to 35%, 10 to 34%, and 80% of patients, respectively. However, the

FIGURE 307-3. Cutaneous gonococcal lesion secondary to disseminated *Neisseria gonorrhoeae* infection. Although gonorrhea is a sexually transmitted disease, if it remains untreated, the *N. gonorrhoeae* bacteria responsible for the infection can disseminate throughout the body and form lesions in extragenital locations (also see Fig. 449-5 in Chapter 449).

yield from culture varies with the clinical presentation. The performance of NAAT versus culture has not been studied in patients with DGI. Patients with tenosynovitis-dermatitis more frequently have bacteremia, whereas patients with septic gonococcal arthritis are seldom bacteremic, and close to 50% have positive synovial fluid cultures; it is reasonable to suspect that the yield might be higher with NAAT. Because bacteremia is intermittent, clinicians should obtain more than one set of blood cultures to maximize the likelihood of isolating the organism. Similarly, culture or NAAT should be obtained from all potentially exposed anatomic sites (genital tract, pharynx, rectum). Cultures of skin lesions are generally negative despite demonstrable gonococci by fluorescent antibody, but NAATs may be positive in persons with negative blood and mucosal site cultures. The peripheral blood leukocyte count is generally elevated but may be normal. The synovial fluid leukocyte count is usually 20,000 to 60,000/mm^3, with higher numbers of white cells seen in persons with clinically apparent arthritis than in those with tenosynovitis-dermatitis. Liver function tests often show elevations in aminotransferase levels, suggestive of mild hepatitis.

The differential diagnosis of DGI includes reactive arthritis (Chapter 273), meningococcemia (Chapter 306), other kinds of septic arthritis (Chapter 280), rheumatoid arthritis (Chapter 272), systemic lupus erythematosus (Chapter 274), acute HIV (Chapter 393), syphilis (Chapter 327), and other rheumatologic conditions and infectious diseases. Reactive arthritis, often triggered by sexually acquired chlamydial infection, is the principal consideration in young adults. The skin lesions of the two conditions, when present, are generally distinct and often pathognomonic for one syndrome or the other. In addition, conjunctivitis and involvement of the axial skeleton (e.g., sacroiliitis) are common in Reiter's syndrome and infrequent in DGI.

PROGNOSIS

Endocarditis, meningitis, and myocarditis have been reported in 0 to 10% of DGI case series. Gonococcal endocarditis usually involves the aortic valve and often progresses rapidly, leading to valve destruction and heart failure. Many cases of arthritis-dermatitis syndrome resolve spontaneously, but untreated septic arthritis can lead to contiguous osteomyelitis or joint destruction.

PREVENTION

Control of gonorrhea depends on prompt diagnosis and effective treatment of infected persons, screening of sexually active women and MSM in settings where gonorrhea is prevalent, treatment of patients' partners, rescreening of persons with a recent history of gonorrhea, and efforts to promote safer sexual behaviors (e.g., condom use, abstinence, fewer partners). Sexually active MSM outside of mutually monogamous relationships, including HIV-infected men, are at high risk for gonorrhea and should be tested at least annually for rectal and pharyngeal gonococcal infection and for other STIs. The value of screening asymptomatic males for urethral infection (by NAAT of urine) is uncertain; the yield is low in most settings. Gonococcal screening criteria for woman are not well defined. However, because virtually all current NAATs for *C. trachomatis* also test for gonorrhea, most young women tested for STIs are tested for gonorrhea.

Public education and personal counseling of persons with gonorrhea or at risk of contracting it should emphasize the effectiveness of mutual monogamy and condoms. Every patient with gonorrhea should be counseled about the risks for HIV infection and should be tested for HIV, *C. trachomatis,* and syphilis. Because accurate epidemiologic data are essential to generate and maintain resources for the prevention and control of STIs, all cases of gonorrhea, chlamydial infection, syphilis, and HIV infection should be promptly reported to the health department in accordance with local laws. Ultimate control of gonorrhea may require immunization, but no effective vaccine is on the horizon, despite intensive research for more than 4 decades.

TREATMENT Rx

Antimicrobial Susceptibility

Gonococci with chromosomal or plasmid-borne mutations that confer relative or absolute resistance to the penicillins, tetracyclines, and sulfonamides are prevalent worldwide, and none of these drugs is acceptable as empirical therapy anywhere in the world. The prevalence of β-lactamase (penicillinase) plasmids, which confer absolute resistance to penicillin, ampicillin, and amoxicillin, varies from about 10% of gonococci in the United States and western Europe to almost 50% in some developing countries. Strains with relative resistance to some but not all cephalosporins are common in parts of Japan, and ongoing surveillance for cephalosporin resistance remains a high priority in all areas. All gonococci were highly susceptible to the fluoroquinolones when these drugs were introduced 3 decades ago, but resistant strains are now widespread. These agents were in common use in the United States until 2007, by which time 7% of gonococcal isolates obtained from heterosexual men and 36% of isolates from MSM in the CDC's Gonococcal Isolate Surveillance Project were resistant to ciprofloxacin. Approximately 5% of gonococcal isolates in the United Kingdom are azithromycin resistant, and azithromycin-resistant *N. gonorrhoeae* has recently been identified in the western United States, although such strains were rare as recently as 2008. Clinicians who treat patients for gonorrhea and other STIs should keep abreast of regional trends in resistance and be alert to modified therapeutic recommendations.

Principles of Treatment

Gonorrhea almost always responds to single-dose treatment with an appropriate antibiotic. Because of the need to curtail transmission, therapy is usually based on clinical or epidemiologic suspicion before the diagnosis is confirmed microbiologically. Even when *N. gonorrhoeae* is isolated by culture, antimicrobial susceptibility testing is generally not performed. Accordingly, routine treatment is dictated by local or regional patterns of antimicrobial susceptibility, without knowledge of susceptibility in individual patients. However, susceptibility testing should be used to guide the treatment of gonococcal septic arthritis, endocarditis, or other serious complications.

In North America, 5 to 10% of MSM, 15 to 25% of heterosexual men, and 35 to 50% of women with gonorrhea are also infected with *C. trachomatis,* so routine treatment of chlamydial infection is advised in addition to specific therapy for gonorrhea.

Treatment Regimens

Ceftriaxone, 250 mg intramuscularly, or cefixime, 400 mg orally, should be given as a single dose for uncomplicated gonorrhea (Table 307-1).[1] Cefpodoxime, 400 mg orally, and cefuroxime, 1 g orally, are also options, but they may be less effective than other regimens, particularly in the treatment of pharyngeal gonococcal infection. Because of the high prevalence of concurrent pharyngeal infection in women and in MSM, and because of concerns related to the possible increased number of *N. gonorrhoeae* isolates with decreased susceptibility to cephalosporins, ceftriaxone is the drug of choice for the routine treatment of gonorrhea. All persons with gonorrhea should routinely be treated with an oral regimen active against *C. trachomatis,* usually azithromycin in a single oral dose of 1 g or doxycycline 100 mg twice daily for 7 days. Such treatment is warranted even in persons who test negative for *C. trachomatis* because observational data suggest that dual therapy may enhance the efficacy of treatment for pharyngeal gonorrhea, and using more than one drug may retard the selection of antimicrobial resistance in *N. gonorrhoeae*. Azithromycin 2 g should be used in persons with β-lactam allergies.

Women with acute PID should be treated with antibiotics active against *N. gonorrhoeae, C. trachomatis,* and a broad range of facultative and anaerobic pathogens, regardless of whether gonococcal or chlamydial infection is documented. Suggested outpatient regimens include an intramuscular dose of a cephalosporin (ceftriaxone 250 mg or cefoxitin 1 g) and doxycycline 100 mg twice daily, with or without metronidazole (500 mg twice daily) for 14

*Treatment of gonorrhea in adults should always include treatment for chlamydial infection, treatment of sex partners, and advice to abstain from sex for 7 days.
†Treat with intravenous therapy until the patient has been clinically improved for 24 to 48 hours. Then switch to cefixime 400 mg orally twice a day to complete a 7-day course.

days.[2] Although oral regimens containing levofloxacin (500 mg once daily) or ofloxacin (400 mg twice daily) plus metronidazole (500 mg twice daily) for 14 days were recommended in the past, the CDC no longer recommends these regimens because of quinolone-resistant *N. gonorrhoeae*. For hospitalized patients or others who require parenteral therapy, the CDC recommends intravenous cefotetan or cefoxitin plus oral doxycycline, or parenteral therapy with clindamycin plus gentamicin. Parenteral therapy is continued until improvement is observed, after which oral therapy is prescribed to complete 14 days' total treatment.

Most persons with DGI should be hospitalized and treated with a parenteral third-generation cephalosporin such as ceftriaxone, cefotaxime, or ceftizoxime, or with ciprofloxacin, ofloxacin, or levofloxacin if the infecting strain is known to be sensitive. Joint irrigation or drainage appears to be unnecessary for septic arthritis, although repeated aspiration of synovial fluid may speed clinical improvement. Oral treatment (e.g., cefixime, cefpodoxime, or a fluoroquinolone) can usually be substituted after improvement begins and then continued to complete 7 days' therapy. More prolonged parenteral treatment and higher doses are indicated for the treatment of gonococcal meningitis or endocarditis, although modern data are lacking. Gonococcal epididymitis, bartholinitis, and other localized complications should generally be treated for 7 to 14 days with drugs active against both *N. gonorrhoeae* and *C. trachomatis*. Gonococcal conjunctivitis in adults can be managed with a single dose of ceftriaxone, 1 g intramuscularly, with optional saline lavage.

Management of Sex Partners

Failure to ensure treatment of patients' sex partners contributes to the continued transmission of gonorrhea and often results in reinfection of the index case. For gonorrhea and chlamydia, all partners in the preceding 2 months should be treated (if the patient has not had sex in the preceding 2 months, the most recent partner should be treated). Because very few U.S. health departments routinely make an effort to ensure that sex partners receive treatment, the responsibility lies jointly with the patient and the diagnosing clinician. Optimally, the partners of persons with gonorrhea should undergo diagnostic testing for gonorrhea, chlamydial infection, syphilis, and HIV infection. However, clinicians should not wait to obtain the results of diagnostic testing before treating a potentially exposed sex partner; all partners of infected persons should be treated when they initially present for evaluation.

In most settings, approximately 50% of potentially exposed sex partners are not treated. In an effort to address this problem, the CDC and several state health departments recommend that clinicians offer heterosexual patients with gonorrhea or chlamydial infection medication to give to their sex partners. This practice, termed patient-delivered partner therapy (PDPT), is supported by three randomized controlled trials showing that treating sex partners without requiring their examination can decrease the risk of reinfection and increase the proportion of partners treated.[3-5] As of 2010, PDPT was legal in most of the United States, and clinicians should offer most heterosexual patients PDPT. The CDC website maintains up-to-date information on the legality of PDPT in U.S. states and territories (*http://www.cdc.gov/std/ept/legal/default.htm*). Clinicians who give patients medication for their sex partners should also provide written information about the medication and STI prevention, as well as advice to seek clinical care in addition to taking the medication provided. Examples of forms that can be dispensed with PDPT can be found at the following websites: *http://www.doh.wa.gov/cfh/std/ept.htm, http://www.cdph.ca.gov/HealthInfo/discond/Pages/SexuallyTransmittedDiseases.aspx*.

Follow-up

The recommended regimens cure 96 to 100% of uncomplicated cases of genital or rectal gonorrhea caused by susceptible strains. Retesting of infected patients to ensure resolution ("test of cure") is not recommended except in pregnant women, when adherence with therapy is in doubt, or when atypical treatment regimens are employed. When test of cure is indicated, culture can be performed a week after treatment is completed, but retesting by NAAT should be delayed at least 3 weeks after treatment to reduce the possibility of detecting persistent gonococcal DNA despite the eradication of viable organisms.

Although test of cure per se is generally not advised, all persons diagnosed with gonorrhea should be rescreened 3 to 4 months after treatment. In prospective studies, 10 to 20% of both men and women with gonorrhea or chlamydial infection are infected when retested in the 3 to 4 months following therapy; however, in one trial, PDPT decreased that risk by 70% in persons with gonorrhea. in Rescreening can be done using urine or self-obtained vaginal swab testing by NAAT and does not require a second visit with a clinician.

HAEMOPHILUS AND *MORAXELLA* INFECTIONS

MICHAEL S. SIMBERKOFF

HAEMOPHILUS INFECTIONS

DEFINITION

The name *Haemophilus* is derived from the Greek nouns *haima*, meaning "blood," and *philos*, meaning "lover." *Haemophilus* species colonize the respiratory tract, cause infections of the respiratory tract, skin, or mucous membranes of humans, and from these sites can invade and cause bacteremia, meningitis, epiglottitis, endocarditis, septic arthritis, or cellulitis.

The Pathogen

Haemophilus species are small, nonmotile, aerobic or facultative anaerobic, pleomorphic, gram-negative bacilli. The prototype of this genus, *Haemophilus influenzae*, was originally recovered from patients with influenza by Pfeiffer in 1893, and it was considered the cause of that disease for many years. Primary isolation of *Haemophilus* species is best accomplished on chocolate agar medium in a CO_2-enriched atmosphere.

EPIDEMIOLOGY

The precise prevalence and incidence of *H. influenzae* infections are unknown. This organism can be detected in the nasopharynx of both children and adults. Before the introduction of an effective vaccine, between 3 and 5% of infants harbored *H. influenzae* type b in their nasopharynx. Children who have been immunized against *H. influenzae* type b are far less likely to be colonized and infected with this organism. However, the risk for infection in nonimmune household contacts of a patient with invasive *H. influenzae* disease is approximately 600-fold greater than the risk in the age-adjusted general population. Nontypeable *H. influenzae* can be detected in the nasopharyngeal cultures of more than 70% of young children, but infection occurs in only a small proportion of colonized individuals.

H. influenzae type b was the most common cause of meningitis in young children before effective vaccines were introduced in the 1980s. Vaccination has had a dramatic impact on the incidence of infection in this group. In a population-based study in Atlanta over a 1-year period, invasive *H. influenzae* disease occurred in only 5.6 per 100,000 children and 1.7 per 100,000 adults. Forty of the 47 strains associated with invasive disease from adult patients in this study were serotyped. Twenty of these isolates (50%) were *H. influenzae* type b, 19 (47.5%) were nontypeable, and 1 (2.5%) was type f. Other studies have shown that the proportion of invasive infections caused by other encapsulated *H. influenzae* serotypes (particularly a and f) and by nontypeable (unencapsulated) *H. influenzae* strains has increased and now exceeds those caused by *H. influenzae* serotype b.

Patients with human immunodeficiency virus (HIV) infection are at increased risk for *H. influenzae* infection. Rates of invasive *H. influenzae* infection in men aged 20 to 49 with HIV infection and acquired immunodeficiency syndrome (AIDS) were 14.6 and 79.2 per 100,000, respectively. The majority of these infections were caused by nontypeable *H. influenzae* strains, although in a second study, 10 of 15 bacteremic *H. influenzae* type b infections observed in adults occurred in patients at risk for HIV infection, and AIDS was documented in 7 of these patients.

Other factors also increase the risk for *H. influenzae* infection, including globulin deficiencies, sickle cell disease, splenectomy, malignancy, pregnancy, cerebrospinal fluid (CSF) leaks, head trauma, alcoholism, chronic obstructive pulmonary disease (COPD), and race. Eskimo, Navajo, and Apache children have *H. influenzae* type b infection rates that are significantly greater than those in comparable non-native populations. In addition, daycare attendance, crowding, the presence of siblings, prior hospitalizations, and previous otitis media have been shown to increase the risk for *H. influenzae* type b disease in young children, whereas breast-feeding decreases this risk.

PATHOBIOLOGY

H. influenzae consists of encapsulated (typable) and nonencapsulated (nontypeable) forms. The former are responsible for most of the invasive infections in children and acute epiglottitis in both children and adults, whereas the latter cause respiratory mucosal infections, conjunctivitis, female genital tract infections, and invasive disease in adults. The capsules of *H. influenzae* consist of polysaccharide antigens. Six capsular serotypes (a through f) exist and are important virulence factors that inhibit opsonization, clearance, and intracellular killing of the organisms. *H. influenzae* type b, formerly the most common cause of meningitis in infancy and childhood worldwide, contains a pentose capsular polysaccharide consisting of polyribosyl ribitol phosphate (PRP). Other serotypes contain hexose polysaccharides. *H. influenzae* type b is more virulent than the other serotypes, probably because it is highly resistant to clearance once bacteremia has been initiated.

Fimbriae are important virulence factors that enhance the adherence of *H. influenzae* to mucosal surfaces. Both typable and nontypeable *H. influenzae* isolates contain fimbriae. The lipo-oligosaccharides (LOSs) of *H. influenzae* also contribute to their virulence. LOSs appear to play a crucial role in facilitating the survival of *H. influenzae* on mucosal surfaces within the nasopharynx and in initiating invasive disease (blood stream invasion) from these sites.

Outer membrane proteins (OMPs) also serve as virulence factors in *H. influenzae* disease. At least 15 different *H. influenzae* OMPs have been identified. One of these (P2, 39 to 40 kD) functions as a porin, and others are associated with iron binding. Successful scavenging of iron within the human host is crucial for multiplication of *H. influenzae*.

Antibodies have been recognized for decades as an important part of host defenses against *H. influenzae* diseases. The classic studies of Fothergill and Wright in 1933 demonstrated that most cases of *H. influenzae* meningitis occur in young children after they lose passively acquired maternal antibodies and before active humoral immunity to the organism develops. These protective antibodies function primarily to opsonize and facilitate clearance of *H. influenzae* rather than to kill virulent organisms directly.

Complement is also an essential component of host defenses against some *H. influenzae* diseases. Children with congenital deficiencies of C2, C3, and factor I have an increased incidence of *H. influenzae* infections. Patients who lack a functional spleen or who have undergone splenectomy

also are at risk for the development of overwhelming infection with *H. influenzae* type b.

CLINICAL MANIFESTATIONS

Meningitis

H. influenzae meningitis commonly occurs in children younger than 5 years and in adults with a history of skull trauma or CSF leaks. *H. influenzae* type b strains cause the overwhelming majority of these cases. A review of 493 episodes of acute bacterial meningitis in adults over a 27-year period showed that 19 cases (4%) were due to *H. influenzae*.

H. influenzae meningitis is clinically indistinguishable from other forms of acute bacterial meningitis. Most patients with *H. influenzae* meningitis have CSF white blood cell counts greater than 1000/mm^3 and hypoglycorrhachia. CSF Gram stain shows pleomorphic gram-negative bacilli in 60 to 70% of untreated cases. In some patients, however, the bipolar staining may result in a mistaken diagnosis of pneumococcal meningitis. Thus, Gram stain is neither sensitive nor specific for diagnosing *H. influenzae* meningitis.

A diagnosis of *H. influenzae* type b meningitis can be rapidly and reliably established by detecting PRP capsular antigens in CSF. The diagnosis can be established in most cases even when antibiotics have been given before CSF is obtained. Other serotypes (most commonly type f) can also cause meningitis in adults. Therefore, serologic tests for type b antigen in CSF cannot be relied on to rule out *H. influenzae* meningitis in all cases.

Epiglottitis

H. influenzae type b is the most common cause of acute epiglottitis in both children and adults. Epiglottitis is a life-threatening infection in children that usually occurs in those younger than 5 years. The symptoms are fever, drooling, dysphagia, and respiratory distress or stridor, which appear over the course of hours. In adults, fever, sore throat, dysphagia, and odynophagia occur. Cervical tenderness and lymphadenopathy can be found at all ages. Laryngoscopy demonstrates a swollen, cherry-red epiglottis. However, this procedure should be avoided or undertaken only by experts because it may precipitate acute airway obstruction and thus make emergency tracheotomy necessary. A lateral radiograph of the neck more safely confirms the diagnosis of acute epiglottitis. The patient must be maintained in an upright position during this procedure, however, to avoid additional compromise of the airway. The cause is usually established by blood culture. Cultures of the pharynx and other mucosal surfaces are less useful because *H. influenzae* may be part of the normal flora. One review suggests that although vaccination has effectively reduced the incidence of this disease in children, it may be increasing in adults.

Pneumonia

H. influenzae is a common cause of pneumonia in both children and adults. These organisms can also cause nosocomial infections, including ventilator-associated pneumonia. The clinical features of *H. influenzae* pneumonia include fever, cough, and signs and radiographic findings of lobar consolidation. Parapneumonic effusions or empyema occur commonly in patients with *H. influenzae* pneumonia. Gram-negative bacilli in sputum suggest the diagnosis, but isolation of *H. influenzae* from sputum culture alone is inadequate to prove a cause because of the high frequency with which this organism colonizes the respiratory tract. A diagnosis can be established by isolating *H. influenzae* from either blood or pleural fluid. Most isolates are nontypeable.

Tracheobronchitis

Tracheobronchitis is a condition characterized by fever, cough, and purulent sputum that occurs in the absence of radiographic infiltrates suggestive of pneumonia. It frequently develops in patients with known chronic lung disease. Blood cultures are rarely positive. A combination of pleomorphic gram-negative bacilli predominating in purulent sputum, antibody titers to *H. influenzae* that rise after infection, and a response, at least transiently, to treatment of *H. influenzae* infection strongly suggests this diagnosis.

Sinusitis

H. influenzae and *Streptococcus pneumoniae* are the most frequent bacterial isolates from antral punctures or surgical specimens of patients with acute purulent sinusitis. Most *H. influenzae* isolates are nontypeable. Although patients may respond initially to treatment directed against *H. influenzae*, the response is transient if the sinus obstruction is not relieved. *H. influenzae* is not an important pathogen in patients with chronic sinusitis.

Otitis Media

H. influenzae is the most frequent cause of otitis media in young children. Approximately 90% of the *H. influenzae* isolates obtained by tympanocentesis are nontypeable; *H. influenzae* type b causes most of the remaining 10% of infections. Patients with otitis media may have ear pain or exhibit irritability. Drainage can be present. An inflamed, opaque, bulging, or perforated tympanic membrane is usually demonstrated. The cause can be proved by Gram stain and culture of purulent fluid obtained by tympanocentesis. Otitis caused by *H. influenzae* type b may occur in association with bacteremia and meningitis.

Cellulitis

H. influenzae type b is the cause of 5 to 15% of cases of cellulitis in young children. Most of the infections occur on the face or neck. *H. influenzae* cellulitis is often described as causing a distinctive blue or violaceous discoloration of the skin. However, the fever, erythema, and tenderness observed may not be distinguishable from those attributable to other causes. The diagnosis is established by culture of blood or tissue aspirates from the involved area, or both.

Bacteremia without a Primary Focus of Infection

H. influenzae causes primary bacteremia in both children and adults. In infants or children, occult meningitis or epiglottitis can be present. Rigorous clinical and laboratory evaluation is essential to avoid missing a diagnosis of life-threatening focal infection in these patients. In adults, primary *H. influenzae* type b bacteremia often occurs in those with underlying diseases such as lymphoma, leukemia, or alcoholism.

Obstetric and Gynecologic Infection

Pregnancy is associated with a significant risk for *H. influenzae* infection. In the Atlanta study, 7 of 47 adult *H. influenzae* invasive infections occurred in pregnant women. Nontypeable *H. influenzae* is also an important cause of tubo-ovarian abscess and salpingitis in women.

Pericarditis

H. influenzae type b is an important cause of primary bacterial pericarditis in children. It rarely causes this infection in adults; however, pericarditis can occur in association with pneumonia, probably as a result of contiguous spread of the infection.

Endocarditis

H. influenzae is a very unusual cause of endocarditis in view of the frequency with which invasive disease occurs. Most infections occur in patients with preexisting valvular heart disease. Because of its slow initial growth in blood culture media, diagnosis of this infection may be delayed or missed. Patients with *H. influenzae* endocarditis are at high risk for arterial embolic phenomena.

Septic Arthritis

H. influenzae type b is a common cause of septic arthritis in young children; it is rare in adults. *H. influenzae* type b arthritis is clinically indistinguishable from other causes of pyogenic arthritis.

Purulent Conjunctivitis and Brazilian Purpuric Fever

H. influenzae, biogroup *aegyptius* (Koch-Weeks bacillus), causes epidemic purulent conjunctivitis in children. This disease commonly occurs in hot climates or in the summer season.

The infection is characterized by conjunctival erythema, edema, mucopurulent exudate, and varying discomfort in the eyes. An unusually virulent clone of *H. influenzae*, biogroup *aegyptius*, causes an invasive infection called Brazilian purpuric fever, which is characterized by petechial or purpuric skin lesions and vascular collapse; it occurs days to weeks after an initial episode of conjunctivitis in infants and children younger than 10 years.

TREATMENT Rx

Third-generation cephalosporins are considered the treatment of choice for serious *H. influenzae* infections, such as meningitis or epiglottitis. Treatment with ceftriaxone (adult dose, 1 to 2 g intravenously every 12 hours) or cefotaxime (adult dose, 2 g intravenously every 6 hours) should be started in patients with proven or suspected *H. influenzae* infection, and it should be continued at least until full susceptibility data are available.

Ampicillin was effective treatment of all *H. influenzae* infections until the mid-1970s. Since the first reports of ampicillin-resistant *H. influenzae* isolates in 1972, however, the prevalence of resistance has increased dramatically. Most resistance is due to a plasmid-mediated, R-factor enzyme (tumor endothelial marker 1 [TEM-1]), β-lactamase, which can be detected rapidly in the laboratory. A small number of isolates, however, have altered penicillin-binding proteins that have decreased binding affinity to penicillin and other β-lactam antibiotics. As a consequence, the isolates may be resistant to some cephalosporins, such as cefaclor, cefamandole, and cefuroxime, in addition to ampicillin. Therefore, patients with proven or suspected *H. influenzae* infections should not be treated with ampicillin or second-generation cephalosporins until susceptibility to these antibiotics has been proved. Chloramphenicol resistance also occurs in *H. influenzae*; an inactivating enzyme, chloramphenicol acetyltransferase, causes resistance. A small number of *H. influenzae* isolates are resistant to both ampicillin and chloramphenicol.

Oral antibiotics are commonly used to treat tracheobronchitis in patients with COPD and otitis media in children, in whom *H. influenzae* isolates are common. Because of resistance, ampicillin and amoxicillin cannot be recommended for the more serious of these infections unless the susceptibility of isolates is known. Most *H. influenzae* isolates are susceptible to amoxicillin-clavulanate. They are also susceptible to azithromycin and clarithromycin, the newer macrolide antibiotics. Fluoroquinolones, such as ciprofloxacin, ofloxacin, levofloxacin, and gatifloxacin, are active against these organisms. Trimethoprim-sulfamethoxazole is also effective for most isolates.

PREVENTION

The first *H. influenzae* type b vaccines were licensed for use in the United States in 1985. They contained purified PRP antigens. However, postlicensing studies of PRP vaccines in the United States showed variable efficacy. The PRP vaccines elicit a type 2, thymus-independent B-cell response, generate few (if any) memory B cells, and fail to stimulate a response in neonates and infants.

Protein-conjugated PRP vaccines were developed to overcome the problem of lack of immune response in the most susceptible infants and some young children. Several are now licensed for use in infants. At present, protein-conjugated PRP vaccines are recommended for use in all infants older than 2 months but not earlier than 6 weeks of age. Recent studies have shown that protein-conjugated vaccines are effective in diverse populations, including adults with COPD.

Antibiotic prophylaxis should be used for the nonimmunized household or daycare contacts of patients with invasive *H. influenzae* type b disease. Rifampin is the treatment of choice. It should be given in a dosage of 10 mg/kg once daily for 4 days to neonates younger than 1 month, 20 mg/kg (up to a maximum of 600 mg) once daily for 4 days to older children, and 600 mg/day for 4 days to adults.

Other *Haemophilus* Species

Haemophilus parainfluenzae can be found as part of the normal flora of the mouth and pharynx (Table 308-1). It is a rare cause of meningitis in children and an even rarer cause of meningitis in adults. It may cause dental infections or dental abscesses. Cases of brain abscess, epidural abscess, liver abscess, osteomyelitis, pneumonia, empyema, epiglottitis, peritonitis, septic arthritis, and bacteremia have been reported to be caused by this organism. *H. parainfluenzae* also causes subacute endocarditis, often in young adults. *Haemophilus* species are responsible for approximately 1% of cases of infective endocarditis in non–drug-abusing patients. *H. parainfluenzae*, *Haemophilus aphrophilus*, and *Haemophilus paraphrophilus* are the species most frequently recovered from these patients. *H. parainfluenzae* forms bulky vegetations on heart valves. Arterial embolization is common in patients with *H. parainfluenzae* endocarditis. Most isolates are sensitive to ampicillin, but some produce β-lactamases.

MORAXELLA INFECTIONS

DEFINITION

Moraxella species are associated with a variety of infections, the most common of which is exacerbation of chronic bronchitis by *Moraxella catarrhalis*.

The Pathogen

Moraxella organisms are small, gram-negative bacteria that grow well on blood or chocolate agar. They are catalase and oxidase positive. These small diplococci are morphologically difficult to distinguish from *Neisseria*. Some *Moraxella* species are gram-negative bacilli. *M. catarrhalis* is the most important pathogen of this genus (Table 308-2).

PATHOBIOLOGY

The organism is isolated exclusively from humans and is found predominantly in the respiratory tract. *M. catarrhalis* adheres to mucosal cells with the aid of pili. Infection is believed to result from contiguous spread of the organism from sites of colonization, possibly as a result of the introduction of new, more virulent strains to which the host lacks immunity.

M. catarrhalis can often be found in respiratory secretions together with *H. influenzae*. Although the mechanism for coexistence of these pathogens is not known, recent evidence suggests that the outer membrane vesicles of *M. catarrhalis* inactivate complement, thus enhancing survival of the latter.

CLINICAL MANIFESTATIONS

M. catarrhalis is associated with exacerbations of chronic bronchitis. Studies indicate that this organism can be isolated from 0.2 to 8.1% of the sputum aspirates of patients with this disease. It is the third most common pathogen isolated from these patients behind *S. pneumoniae* and *H. influenzae*.

M. catarrhalis can cause pneumonia, particularly in elderly patients with COPD and other underlying conditions such as diabetes mellitus. Sir William Osler is believed to have died as a result of *M. catarrhalis* pneumonia. Cases of bacteremic pneumonia have been reported. In addition, *M. catarrhalis* can cause nosocomial pneumonia with evidence of patient-to-patient spread of the organism.

M. catarrhalis is a common cause of otitis media in young children. Microbiologic studies indicate that this organism is present in approximately 15% of the aspirates from such patients. The organism also causes sinusitis and is a rare cause of bacteremia in children and adults.

Serious infections with other *Moraxella* species are uncommon. However, these organisms are associated with chronic conjunctivitis. Furthermore, case

TABLE 308-1 SITES OF COLONIZATION AND INFECTIONS BY *HAEMOPHILUS INFLUENZAE*

SPECIES	NORMAL FLORA	ASSOCIATED DISEASES

H. influenzae type b, *aegyptius*	No	Purulent conjunctivitis Brazilian purpuric fever

TABLE 308-2 SITES OF COLONIZATION AND INFECTION BY *MORAXELLA* SPECIES

SPECIES	NORMAL FLORA	ASSOCIATED DISEASES
M. catarrhalis	Oral cavity and upper respiratory tract	Chronic bronchitis exacerbation Otitis media Pneumonia Sinusitis Bacteremia, endocarditis Arthritis, osteomyelitis, epiglottitis (all extremely rare)
M. lacunata	Upper respiratory tract	Chronic conjunctivitis
Other *Moraxella*	Upper respiratory tract	Rare cases of bacteremia, endocarditis, arthritis, meningitis

reports have documented the rare occurrence of invasive infections, including bacteremia, endocarditis, arthritis, pericarditis, and meningitis. The latter may occur in patients with complement deficiency.

TREATMENT

Rx

Oral antibiotics are sufficient for the treatment of most *M. catarrhalis* infections. Inducible β-lactamases are present in many isolates. Therefore, treatment with a β-lactamase–stable antibiotic such as amoxicillin-clavulanate (usual adult dose, 500 mg every 12 hours), a cephalosporin (e.g., cefaclor, usual adult dose, 500 mg every 8 hours), or a non–β-lactam antibiotic such as trimethoprim-sulfamethoxazole (usual adult dose, 1 double-strength tablet every 12 hours) should be initiated pending susceptibility test results.

309

CHANCROID

STANLEY M. SPINOLA

DEFINITION

Chancroid is a sexually transmitted disease characterized by painful genital ulcers and inguinal lymphadenitis. Chancroid is caused by *Haemophilus ducreyi,* a gram-negative coccobacillus that is not a true *Haemophilus* species. *H. ducreyi, Mannheimia haemolytica,* and *Actinobacillus pleuropneumoniae* form a distinct lineage within the Pasteurellaceae. *H. ducreyi* likely diverged from these animal respiratory pathogens to occupy its niche in the human genital epithelium.

EPIDEMIOLOGY

Chancroid is endemic in resource-poor regions of Africa and Asia and plays a major role in facilitating the transmission of human immunodeficiency virus (HIV-1). In the 1990s the World Health Organization estimated the annual global prevalence of chancroid to be 4 million to 6 million cases. The prevalence of chancroid is now unknown owing to an emphasis on the syndromic management of genital ulcers, which consists of treatment for syphilis and chancroid without diagnostic testing. Chancroid can be maintained only in networks with high sex partner change rates, and female sex workers play an important role in its epidemiology. Where clinical services have been provided to sex workers, chancroid prevalence has declined. However, reports of chancroid persist from several regions. Urban outbreaks of chancroid associated with sex work occurred in the United States in the 1980s and 1990s. Owing to contact tracing and treatment efforts, the number of domestic cases of chancroid has decreased steadily, with a 60-year low of 17 cases in 2005 and 25 cases in 2008.

The male to female ratio of chancroid is 3 : 1. The excess number of male cases is usually attributed to the infection of multiple partners by sex workers. However, human inoculation experiments indicate that men are twice as susceptible to disease progression compared with women.

PATHOBIOLOGY

Much of what is known about the pathogenesis of *H. ducreyi* is derived from experiments in which bacteria are inoculated into the skin of the upper arm of human volunteers. Puncture wounds are required to initiate infection, and the estimated infectious dose is as low as one bacterium. Papules develop within 24 hours and either spontaneously resolve or evolve into pustules in 2 to 5 days. Neutrophils and macrophages surround the organism and form an abscess that erodes the epidermis. Below the abscess, there is a dermal infiltrate of macrophages, CD4 and CD8 T cells, natural killer (NK) cells, Langerhans cells, and myeloid dendritic cells. This histopathology is identical to that of natural ulcers. In both experimental and natural infection, *H. ducreyi* associates with neutrophils and macrophages, which fail to ingest the organism. In addition to revealing the bacterial components required for infection, the human model has shown that different hosts are differentially susceptible to disease progression versus resolution. Differential host susceptibility is associated with distinct dendritic cell responses to the organism, which may shape T-cell and NK-cell responses that influence the ability of phagocytes to ingest the organism.

CLINICAL MANIFESTATIONS

H. ducreyi enters the skin through breaks in the epithelium that occur during intercourse. Papules form within hours to days and evolve into pustules in 2 to 3 days. After a few days to 2 weeks, the pustules ulcerate. Patients typically develop one to four painful ulcers (Fig. 309-1) and do not seek treatment until they have had ulcerative symptoms for 1 to 3 weeks. By this time, 10 to 40% have suppurative inguinal lymphadenopathy or buboes (see Fig. 309-1).

Natural ulcers are classically very painful and nonindurated, with ragged edges. The ulcer may be covered by a yellow or gray necrotic exudate and bleeds when scraped. However, this presentation occurs in a minority of patients, and chancroid is frequently indistinguishable from syphilis and genital herpes. Lesions in men are usually on the foreskin, coronal sulcus, or penile shaft. Lesions in women are usually on the labia, but women may have

FIGURE 309-1. Typical chancroidal ulcer and lymphadenitis in a male. (From Herpes-Coldsores.com. http://www.herpes-coldsores.com/std/chancroid_pictures.htm.)

internal vaginal and cervical ulcers that are painless. Lesions also occur on the thighs and buttocks or at distant sites; extragenital lesions are thought to be due to autoinoculation. Untreated, chancroid persists for months and causes giant ulcers, erosion of the infected area, or fibrosis, leading to phimosis in men.

H. ducreyi also causes chronic limb ulcers in the western Pacific. Close contact with family members with leg ulcers is implicated in these cases. The epidemiology of this syndrome has yet to be defined.

DIAGNOSIS

Diagnosis requires either a positive culture or a polymerase chain reaction (PCR) test. In research settings, PCR has a resolved sensitivity of 95 to 98% and a specificity of 99% for *H. ducreyi*. In comparison, the sensitivity for culture is approximately 75%, but clinical diagnosis is neither sensitive (range, 50 to 75%) nor specific (range, 50 to 75%). Unfortunately, PCR-based tests are not commercially available. Most sexually transmitted disease clinics do not routinely test patients for chancroid, and the diagnosis is typically made by the exclusion of genital herpes and syphilis. If patients with genital ulcers and lymphadenitis or treatment failure for primary syphilis appear in a community, public health authorities should be notified so that specific diagnostic testing can be initiated.

The differential diagnosis includes syphilis, genital herpes, lymphogranuloma venereum, and granuloma inguinale. Mixed infections with herpes simplex virus and/or syphilis are common, occurring in approximately 17% of chancroid cases diagnosed by PCR. Patients with suspected chancroid should be tested for genital herpes and have serologic tests for syphilis and HIV-1 and a dark-field examination.

TREATMENT

Rx

Little is known about the prevalence of antibiotic resistance in *H. ducreyi*. Most strains have acquired plasmid-mediated resistance to ampicillin, tetracyclines, and sulfonamides. The only reliable treatment regimens are macrolides, quinolones, or third-generation cephalosporins. The fact that some Enterobacteriaceae harbor plasmids that encode extended-spectrum ß-lactamases and quinolone resistance is a concern. Current treatment recommendations include single-dose azithromycin 1 g orally or ceftriaxone 250 mg intramuscularly, ciprofloxacin 500 mg orally twice a day for 3 days, or erythromycin base 500 mg orally three times a day for 7 days. Thiamphenicol, which is not available in the United States, is effective as a single 2.5-g dose.

Repeated aspiration of buboes may be required to effect a cure. In a randomized study comparing repeated aspiration versus incision and drainage, the latter was considered preferable. However, incision and drainage may cause excessive scarring, especially in persons of African descent, and should be avoided according to some experts.

Initial reports on coinfection with HIV and chancroid indicated that such individuals have a greater number of ulcers that do not heal as readily after antibiotic treatment compared with patients infected with *H. ducreyi* alone. Antibiotic treatment failures were reported in HIV-seropositive patients given single-dose regimens. Subsequent studies failed to show that HIV status had any influence on the efficacy of single-dose antibiotic regimens.

PROGNOSIS

Clinical cure correlates with a reduction in pain and purulence and re-epithelialization of the ulcer within 7 days. Patients who do not show improvement within 7 days should be regarded as treatment failures and given an alternative agent. Even if *H. ducreyi* is eradicated, ulcers may persist if genital herpes or syphilis is present and not treated. Most ulcers heal in 2 weeks; large ulcers may take 4 weeks to heal.

PREVENTION

Circumcision protects against chancroid in men. Condoms are likely protective. There is no vaccine, although several antigens that may afford protection have been identified. Contacts of patients with chancroid should be treated with an approved regimen.

CHOLERA AND OTHER *VIBRIO* INFECTIONS

EDUARDO GOTUZZO AND CARLOS SEAS

CHOLERA

DEFINITION

Cholera is a feared epidemic diarrheal disease caused by *Vibrio cholerae* serogroup O1 and, since 1992, by the new serogroup O139. The disease is characterized by acute watery diarrhea. In its more severe form, a person may be severely dehydrated and in hypovolemic shock; the patient may die in a matter of a few hours after contracting the infection if treatment is not provided. Cholera is endemic today in Africa and Asia, and cases are also reported from Latin America, North America, and Europe. Seven pandemics have been registered in history since 1816; the most recent has lasted more than 4 decades since its recognition in Indonesia in 1961.

The Pathogen

V. cholerae is a curved gram-negative bacillus that belongs to the family Vibrionaceae and shares common characteristics with the family Enterobacteriaceae. *V. cholerae* O1 can be classified into three serotypes according to the presence of somatic antigens and into two biotypes, classic and El Tor, according to specific phenotypic characteristics. There is no evidence of different clinical spectra among the three serotypes of *V. cholerae*. The classic biotype, responsible for the first six pandemics of cholera, causes an approximately equal number of symptomatic and asymptomatic cases, whereas the El Tor biotype causes more asymptomatic infections. The classic biotype is confined to the south of Bangladesh, and the El Tor biotype is responsible for the current pandemic. The O139 serogroup is composed of a variety of genetically diverse strains, both toxigenic and nontoxigenic; it is genetically closer to El Tor *V. cholerae.*

EPIDEMIOLOGY

Cholera has both a predisposition to cause epidemics with pandemic potential and an ability to remain endemic in all affected areas. People of all ages are at risk to contract the infection in epidemic settings, whereas children older than 2 years are mainly affected in endemic areas. *V. cholerae* lives in riverine, brackish, and estuarine ecosystems, where both O1 and non-O1 strains coexist, with non-O1 and nontoxigenic O1 strains predominating over toxigenic O1 strains. In its natural environment, *V. cholerae* lives attached to algae or to crustacean shells and copepods, with which it coexists in a symbiotic manner. Several conditions, such as temperature, salinity, and availability of nutrients, determine the survival of *V. cholerae*; when these conditions are adverse, vibrios survive in a viable, but nonculturable state. More recent data suggest that cholera phages modulate the abundance of *V. cholerae* in the environment and determine the beginning and end of epidemics. Phages may also play a role in the emergence of new *V. cholerae* serogroups by transferring genetic material to nontoxigenic strains.

From its aquatic environment, *V. cholerae* is introduced to humans through contamination of water sources and food. Once humans are infected, very high attack rates may take place, particularly in previously

naïve populations. Acquisition of the disease by drinking contaminated water from rivers, ponds, lakes, and even tube well sources has been documented. Drinking unboiled water, introducing hands into containers used to store drinking water, drinking beverages from street vendors, drinking beverages to which contaminated ice has been added, and drinking water outside the home are risk factors; these factors contributed to the acquisition of cholera during the large Peruvian epidemic of 1991. Drinking boiled water, acidic beverages, and carbonated water and using narrow-necked vessels for storing water are protective measures. Epidemics of cholera associated with the ingestion of leftover rice, raw fish, cooked crabs, seafood, raw oysters, and fresh vegetables and fruits have been documented. Person-to-person transmission is less likely to occur because a large inoculum is necessary to transmit disease. High transmission rates (approximately 50%) are reported among household contacts of patients with cholera in endemic areas.

Epidemics of cholera tend to occur during the hot season. Factors affecting climate change and climate variability have an impact on the incidence of cholera. The El Niño-southern oscillation (ENSO), a periodic phenomenon representative of global climate variability, affects the transmission of cholera and vector-borne diseases. ENSO causes the warming of normally cool waters in the Pacific coastline of Peru, thereby promoting phytoplankton bloom, zooplankton bloom, and *V. cholerae* proliferation.

Some host factors are important in the transmission of cholera. The chronic gastritis associated with *Helicobacter pylori* predisposes to cholera by inducing hypochlorhydria, which reduces the ability of the stomach to contain the infection. An unexplained predisposition to severe disease in persons with the O blood group has been observed in Asia and more recently in Latin America. Thus, complex associations among climatic, seasonal, bacterial, and human factors affect cholera transmission. Although for the most part developing countries are affected by cholera, several developed countries such as the United States, Canada, and Australia have reported indigenous and imported cases. Figure 310-1 shows the distribution of cholera in the world from 1990 to 2008.

PATHOBIOLOGY

V. cholerae O1 and O139 cause clinical disease by secreting an enterotoxin that promotes the secretion of fluids and electrolytes by the small intestine. The infectious dose of bacteria varies with the vehicle. When water is the vehicle, more bacteria are needed to cause disease (10^3 to 10^6), but when the vehicle is food, lower amounts are needed (10^2 to 10^4). The incubation period varies from 12 to 72 hours. Cholera toxin (CTX) has two subunits, a pentamer B subunit and a monomer A subunit. The B subunit allows binding of the toxin to a specific receptor, a ganglioside (GM_1) located on the surface of cells lining the mucosa along the intestine of humans and certain suckling mammals. The active, or A, subunit has two components, A1 and A2, linked by a disulfide bond. Activation of adenylate cyclase by the A1 component results in an increase in cyclic adenosine monophosphate in intestinal epithelial cells, which blocks the absorption of sodium and chloride by microvilli and promotes the secretion of chloride and water by crypt cells. These events lead to the production of watery diarrhea with electrolyte concentrations similar to those of plasma, as shown in Table 310-1. A few other toxins have been isolated from pathogenic *V. cholerae*, but their roles in genesis of the disease are less clear.

The genetic material of El Tor *V. cholerae* O1 is included in two circular chromosomes, the larger containing 3 megabases and the smaller containing 1.07 megabases. The main virulence genes are *ctx*A and *ctx*B, which encode for CTX subunits A and B, respectively, and *tcp*A, which codes for toxin coregulated pilus. Regulation of expression of these genes is complex. Recent data suggest that vibrios are able to upregulate the expression of CTX in response to intestinal fluid components, as well as in the presence of certain

environmental factors. Genes unique to El Tor *V. cholerae* may encode for specific features that allow this biotype to better survive in the environment, as well as to be more infectious to humans.

CLINICAL MANIFESTATIONS

Cholera is characterized by watery diarrhea and dehydration, which ranges from mild to severe and life-threatening. Patients with mild dehydration cannot be differentiated from those infected by other enteric pathogens causing watery diarrhea. In contrast, patients with severe dehydration secondary to cholera are easy to identify in that their stools have the appearance of rice water and no other clinical illness produces such severe dehydration as quickly (in a matter of a few hours) as cholera. Onset of the disease is abrupt and characterized by watery diarrhea, vomiting, generalized cramps, and oliguria. Physical examination shows a feeble pulse, fever is rarely present, patients look anxious and restless, the eyes are very sunken, mucous membranes are dry, the skin has lost its elasticity and when pinched retracts very slowly, the voice is almost nonaudible, and intestinal sounds are prominent. Although watery diarrhea is the hallmark of cholera, some patients do not have diarrhea but instead have abdominal distention and ileus, a relatively rare type of cholera called cholera "sicca."

Laboratory findings in patients with severe dehydration consist of an increase in hematocrit, urine specific gravity, and total serum protein; azotemia; metabolic acidosis with a high anion gap; normal or low serum potassium levels; and normal or slightly low sodium and chloride levels. The calcium and magnesium content in plasma is high as a result of hemoconcentration. Leukocytosis is observed in patients with severe cholera. Hyperglycemia, caused by high concentrations of epinephrine, glucagon, and cortisol stimulated by hypovolemia, is more commonly seen than hypoglycemia. Acute renal failure is the most severe complication of cholera. Incidence rates of 10.6 cases per 1000 were reported in Peru during the first months of the 1991 epidemic. Patients with acute renal failure almost always have a history of improper rehydration. Cholera in pregnant women carries a bad prognosis. Pregnant women have more severe clinical illness, especially when the disease is acquired at the end of the pregnancy. Fetal loss occurs in as many as 50% of these pregnancies. Cholera in the elderly also carries a bad prognosis because of an increase in complications, particularly acute renal failure, severe metabolic acidosis, and pulmonary edema.

DIAGNOSIS

Chaotic movement under darkfield microscopy and a high number of bacteria in a stool sample from patients with diarrhea are characteristic of *V. cholerae* infection. Specific antisera against the serotype block the movement of vibrios and allow confirmation of the diagnosis. Under epidemic conditions, observing bacteria with a darting movement in a stool sample from a suspected patient under darkfield microscopy is adequate to make the diagnosis. Definitive confirmation requires isolation of the bacterium in culture. Specific medium is needed to isolate *V. cholerae* from stool. Higher sensitivity and specificity have been reported with DNA amplification by polymerase chain reaction for detection of vibrios in stool and environmental samples.

TREATMENT Rx

The objectives of therapy are to restore the fluid losses caused by diarrhea and vomiting, correct the metabolic acidosis, restore potassium deficits, and replace continuous fluid losses. Treatment of patients with milder forms of dehydration is easy, but treatment of patients with severe dehydration requires experience and proper training. The intravenous route should be restricted to patients with some dehydration who do not tolerate the oral route, those who purge more than 10 to 20 mL/kg/hr, and all patients with severe dehydration. Rehydration should be accomplished in two phases: the rehydration phase and the maintenance phase. The purpose of the rehydration phase is to restore normal intravascular volume, and it should last no longer than 4 hours. Intravenous fluids should be infused at a rate of 50 to 100 mL/kg/hr in severely dehydrated patients. Lactated Ringer's solution is preferred, but other solutions may be used as well (see Table 310-1). All signs of dehydration should have disappeared and the patient should pass urine at a rate of 0.5 mL/kg/hr or greater after finishing the rehydration phase. The maintenance phase follows immediately. During this phase the objective is to maintain normal hydration status by replacing ongoing losses. The oral route is preferred during this phase, and the use of oral rehydration solutions is highly recommended. Oral rehydration therapy uses the principle of common transportation of solutes, electrolytes, and water by the intestine not affected by cholera toxin. People with diarrhea can undergo successful rehydration with simple solutions containing glucose and electrolytes. The World Health Organization recommends an oral rehydration solution with reduced osmolarity (245 mOsm/L) to treat all diarrheal diseases. This solution contains lower sodium than the standard oral rehydration solution promoted since 1975 (75 vs. 90 mEq/L). No more symptomatic hyponatremia is observed with the reduced-osmolarity than with the standard solution. The addition of L-histidine to rice-based oral rehydration solutions has recently been shown to reduce the volume and duration of diarrhea and the unscheduled use of intravenous therapy in adult cholera patients.[1] Patients without severe dehydration who tolerate the oral route can be rehydrated with oral rehydration solutions exclusively and discharged promptly from the health center. Recommendations for treating cholera patients are shown in Table 310-2. Treatment of cholera caused by *V. cholerae* O139 is the same as described earlier.

Antimicrobial agents are not life-saving and always need to be accompanied by fluid therapy. Effective antibiotics in patients with severe dehydration decrease the duration of diarrhea and the volume of stool by nearly half. Oral tetracycline and doxycycline are the agents of choice in areas of the globe where sensitive strains predominate A single dose of doxycycline (300 mg) is the preferred regimen. Pregnant women can be treated with erythromycin or furazolidone. Because of the emergence of resistance to tetracyclines and other antimicrobials in many endemic areas, the quinolones and, more recently, azithromycin have been tested in clinical trials. A single-dose regimen of azithromycin (20 mg/kg) showed clinical and bacteriologic results that in children were comparable to a 3-day regimen with erythromycin and, in adults, comparable to a single-dose regimen of ciprofloxacin (1 g).[2,3] The addition of oral zinc (30 mg/day) to an erythromycin regimen in children reduced the duration of diarrhea in 12%, with an additional 11% reduction in the volume of diarrhea in comparison to placebo.[4] Antimotility agents such as loperamide or diphenoxylate, adsorbents, analgesics, and antiemetics are not recommended. Antisecretory drugs, including racecadotril, an encephalinase inhibitor, are not useful in patients with severe cholera. Chemoprophylaxis of household contacts of cholera cases is not routinely recommended.

PREVENTION

Access to potable water and ensuring proper management of excreta to avoid contamination of other water sources are important measures to reduce transmission of cholera. Alternative ways to prevent cholera transmission are necessary in developing countries. Water can be made safer to drink by boiling, adding chlorine, or filtering it with cloth made of cotton. An inability to implement these measures to curtail cholera transmission has prompted a search for vaccines. An ideal vaccine against cholera should elicit a fast and long-lasting immune response with minimal side effects. Parenteral vaccines are no longer recommended. Two oral vaccines, the two-dose regimen of the inactivated vaccine WC-BS (whole cell plus B subunit) and a single dose of the live attenuated CVD 103-HgR vaccine, have been tested extensively in epidemic settings and in field trials in endemic areas. Although the WC-BS vaccine showed good short-term protective efficacy (85% at 6 months), the results at 3 and 5 years were less impressive (60%), particularly in children. A large effectiveness study in Mozambique confirmed the high short-term

TABLE 310-2 RECOMMENDATIONS FOR TREATING CHOLERA PATIENTS

1. Determine the degree of dehydration on arrival.
2. Rehydrate the patient in two phases:
   Rehydration phase—lasts 2 to 4 hours
   Maintenance phase—lasts until the end of the diarrheal episode
3. Register and periodically review input and output in predesigned charts.
4. Use the intravenous route in the following situations:
   In all severely dehydrated patients, in whom the speed of infusion varies from 50 to 100 mL/kg/hr
   Patients with some dehydration who are unable to tolerate the oral route
   Patients with high stool output (>10 mL/kg/hr) during the maintenance phase
5. Use oral rehydration solutions, glucose or rice based, during the maintenance phase to match ongoing losses. Volumes of 800 to 1000 mL/hr are usually required. Low-osmolarity solutions are not recommended.
6. Start an oral antimicrobial agent in patients with severe cholera when full rehydration has been achieved and oral tolerance is confirmed. Single-dose doxycycline, 300 mg, is the preferred regimen. Erythromycin or a quinolone is a suitable alternative.
7. Discharge patients only if oral tolerance is adequate (≥1000 mL/hr), urine output is satisfactory (≥40 mL/hr), and stool volume is low (≤400 mL/hr).

Modified with permission from Seas C, DuPont HL, Valdez LM, et al. Practical guidelines for the treatment of cholera. *Drugs.* 1996;51:966-973.

protection against cholera (80%) by this vaccine, especially against severe dehydration (90%). Additionally, reanalysis of data on this vaccine in field trials has shown that it may also confer herd protection in the unvaccinated population. A large field trial of the live attenuated vaccine showed no protective efficacy. Indications for use of the currently available cholera vaccines include travel to endemic areas and situations in which high attack rates of cholera are expected, such as after environmental disasters, in refugee camps, and in urban slums in highly endemic areas. New oral vaccines including both killed and live *Vibrio* are being evaluated in endemic areas, with promising preliminary reports.

PROGNOSIS

Patients with severe cholera left untreated or improperly treated carry a poor prognosis, with mortality rates higher than 50%. However, case-fatality rates during epidemics may be reduced to values below 1% even in disaster situations, provided that adequate access to health care centers and proper management of patients can be ensured. In contrast, figures higher than 10% have been reported in epidemic settings when patients had no access to health care or received improper treatment.

OTHER *VIBRIO* INFECTIONS

Noncholera vibrios have worldwide distribution and coexist in environments in which *V. cholerae* lives. They cause a spectrum of clinical syndromes, including acute diarrhea, soft tissue infections, and sepsis, especially in immunocompromised hosts. In the United States, 549 patients with disease attributable to non-*cholerae Vibrio* were reported in 2007 to the Cholera and Other Vibrio Illness Surveillance System. Complete information was available for 199 patients; 39% were hospitalized and 7% died. The most frequently reported species were *Vibrio parahaemolyticus*, *Vibrio vulnificus*, and nontoxigenic *Vibrio cholerae*. *Vibrio* illnesses in the United States are seasonal and peak during the summer (Fig. 310-2). The incubation period for noncholeragenic *Vibrio* infection is usually 12 to 72 hours but can be as long as 1 week.

Nontoxigenic *V. cholerae* causes gastroenteritis, but unlike toxigenic *V. cholerae* O1 or O139, nontoxigenic *V. cholerae* does not cause epidemics. Illness ranges in severity from mild diarrhea to severe watery diarrhea. Fever and bloody diarrhea are unusual, but immunocompromised persons and those with liver disease can experience more severe illness, including fever, chills, and septic shock.

V. parahaemolyticus lives in marine environments and is a source of intestinal illness associated with the ingestion of contaminated shellfish. Certain serovars have shown pandemic spread (O3:K6 and O4:K68). It is not well known how this *Vibrio* causes infection in humans, but the clinical illness may mimic cholera, although the vast majority of cases are milder and self-limited forms of acute watery diarrhea. Acute dysentery is reported rarely.

In the United States, *V. parahaemolyticus* and *V. vulnificus*, as well as other noncholeragenic vibrios, caused skin and soft tissue infections in victims and responders affected by the Gulf Coast hurricane disasters in fall 2005. *V. parahaemolyticus* wound infections are generally less severe than those caused by *V. vulnificus*. However, in persons with liver disease or those who are immunocompromised, fatal infections can occur.

V. vulnificus is associated with wound infections in persons in contact with contaminated water, as well as with primary sepsis in immunocompromised hosts. Wound infections follow trauma and are characterized by rapid progression of skin and soft tissue involvement, with necrosis and bulla formation occurring in more severe cases. Fever, chills, and sepsis syndrome may ensue rapidly. Primary sepsis with bacteremia and metastatic lesions on the skin, characterized by disseminated erythematous lesions that may evolve to necrotic lesions, is a distinctive clinical manifestation in patients with chronic liver illnesses, alcoholics, and patients with blood disorders such as thalassemia. A history of seafood ingestion, usually oysters, is typical. Patients are acutely ill with high fever and need to be managed aggressively with fluid resuscitation, surgical débridement, general supportive care, and antibiotic coverage. An intravenous combination of cefotaxime, 2 g four times a day, plus doxycycline, 100 mg two times a day, is recommended. This combination is synergistic in vitro. Alternative antimicrobials are ceftazidime and ciprofloxacin.

CAMPYLOBACTER INFECTIONS

BAN MISHU ALLOS

DEFINITION

Campylobacter jejuni is one of the most commonly recognized bacterial causes of diarrhea in developed nations. More than 95% of the campylobacters isolated in developed countries are *C. jejuni* or *Campylobacter coli.* However, other *Campylobacter* species are also associated with human disease.

The Pathogen

Campylobacters are motile, curved, gram-negative rods that are found in domestic and wild animals—especially poultry—all over the world. *C. jejuni* is microaerophilic, requires 3 to 15% oxygen for growth, and is oxidase and catalase positive. It grows best at 42° C; however, other *Campylobacter* species that may also be pathogenic grow best at 37° C. Currently, the entire genome sequences for eight *Campylobacter* species have been determined.

EPIDEMIOLOGY

C. jejuni infections are endemic in young children in developing nations, where they may be isolated in up to 20% of children younger than 5 years with diarrhea. In developed nations, *Campylobacter* infections are among the most common bacterial causes of diarrhea in children and adults, but the incidence of *C. jejuni* infection in the United States fell by more than 40% from 21.7 per 100,000 population in 1998 to 12.7 in 2008. The actual burden of disease caused by *Campylobacter* is probably much higher because even

active surveillance systems substantially underreport the true incidence of infection. Epidemiologic studies have estimated that more than 2 million people in the United States are infected with *C. jejuni* each year. For reasons that are not clear, the incidence is highest in western states such as California and Hawaii. Similarly high rates of infection are observed in Europe. In the United States, Europe, and Australia, *C. jejuni* infections show a substantial peak in warmer months. Such seasonality is not observed in tropical developing countries, perhaps because of the absence of extreme temperature variations.

The incidence of *Campylobacter* infections is highest in early childhood—an epidemiologic feature common to many food-borne bacterial pathogens. However, in the United States and other industrialized countries, the incidence of *Campylobacter* infections peaks again in early adulthood. The incidence of infection is also higher in men, a gender difference most pronounced in young adults.

Most human *C. jejuni* infections occur sporadically, with only a tiny fraction occurring as part of outbreaks. The dominant source of sporadic infections in both developed and developing countries is consumption or handling of poultry. Other sources of transmission in developed nations include foreign travel, contact with pets and other animals, contaminated drinking water, and consumption of unpasteurized milk. Cross-contamination within a kitchen (e.g., use of the same utensils or cutting boards to prepare uncooked chicken and to chop fruit) has led to a variety of foods being implicated as sources of human *C. jejuni* infection. In contrast to sporadic infections, the most common source of *C. jejuni* outbreaks is unpasteurized milk; occasionally, large waterborne outbreaks occur. Transmission of *C. jejuni* infection from ill food handlers is uncommon. Even in households in which an individual has culture-proven *C. jejuni* gastroenteritis, secondary transmission to other family members is unusual.

PATHOBIOLOGY

Persons become infected with *C. jejuni* as a result of orally ingesting the organism, usually in food or water. Factors that affect whether *Campylobacter* infection leads to illness include the dose of bacteria ingested, the virulence of the organism, and the specific immunity of the host to the ingested organism. The minimum number of bacteria needed to cause illness varies between people, but it may be quite low, especially in water; because *C. jejuni* is susceptible to gastric acidity, ingestion of very few organisms may cause illness if gastric pH is elevated as a result of illness or medication. The median incubation period is 2 to 4 days, although it may range from 1 to 7 days.

In early infection, *C. jejuni* multiplies in the bile-rich upper intestines; subsequently, tissue injury is seen in the jejunum, ileum, and colon. Gross inspection of the bowel shows a diffuse, bloody, edematous enteritis. Microscopic examination reveals an inflammatory infiltrate consisting of neutrophils, mononuclear cells, and eosinophils in the lamina propria. The mucosal epithelium is ulcerated, and crypt abscesses may be seen. The pathologic appearance is nonspecific and may mimic ulcerative colitis or Crohn's disease.

Invasion of the epithelium by *C. jejuni* appears to be central to its pathogenesis, and many factors influence how *C. jejuni* adheres to and invades intestinal tissues. A superficial conserved antigen, PEB1, appears to be a major adhesin and is a target of the immune response to *C. jejuni* infection. Other factors that contribute to *C. jejuni*'s invasiveness and pathogenicity, which may be encoded by a virulence plasmid, include type IV secretion systems and mechanisms that disrupt microtubules in host cells. The presence of the plasmid pVir in clinical isolates is significantly associated with bloody stools. Glycolipids and glycoproteins on the surface of *C. jejuni* are important for the organism's survival in the intestinal lumen and in pathogenesis because they have an impact on cell-to-cell interactions, as well as the host's immune response to infection. The bacterium's flagella facilitate its ability to colonize the gastrointestinal tract by promoting motility and chemotaxis of the organism. *C. jejuni* may produce extracellular toxins, but their role in pathogenesis has not been confirmed, with the possible exception of the cytoskeletal distending toxin (cdt), which may facilitate intracellular activities that lead to apoptosis.

Regardless of the organism's virulence, host factors are pivotal in affecting the clinical outcome of infection. In healthy volunteers fed a fixed dose of a single *C. jejuni* strain, a spectrum of illnesses develops. Patients infected with *C. jejuni* excrete the organism in feces for 2 to 3 weeks. In developing nations, where the level of immunity to *C. jejuni* is higher because of recurrent exposure, the period of convalescent excretion of *C. jejuni* is shorter.

After recovery from *Campylobacter* infection, at least short-term immunity develops. The decreasing illness-to-infection ratio with age seen in developing nations also suggests that individuals are acquiring immunity. Specific IgA, IgG, and IgM antibodies in serum and IgA antibodies in intestinal secretions develop in patients infected with *C. jejuni*. Patients with congenital or acquired hypogammaglobulinemia are at risk for severe or recurrent *C. jejuni* infections. Because the incidence of *C. jejuni* infection is markedly higher in persons infected with human immunodeficiency virus (HIV), cell-mediated immunity might also play a role in preventing and terminating infection.

CLINICAL MANIFESTATIONS

The clinical consequences of *Campylobacter* infection range from complete absence of symptoms to fulminant sepsis and death. In most cases, however, illnesses are brief and do not require hospitalization. In developed nations, detection of *C. jejuni* in the stool of asymptomatic persons is rare. However, in developing nations, where infections are endemic and recurrent infections occur frequently, asymptomatic infections are more common. In both developing and developed nations, persons infected with *C. jejuni* typically contract a diarrheal illness that resolves within a week. The case-fatality rate associated with this infection is low, about 0.05 deaths per 1000 infections, and not surprisingly is highest in the elderly and persons with comorbid conditions.

The gastroenteritis that is caused by infection with *C. jejuni* is clinically indistinguishable from that caused by other enteric bacterial pathogens, such as *Salmonella* (Chapter 316), *Shigella* (Chapter 317), and *Escherichia coli* O157:H7 (Chapter 312). The most common symptoms are diarrhea, malaise, fever, and abdominal pain (Table 311-1). Most patients with *C. jejuni* gastroenteritis experience at least 1 day with 10 or more stools; the diarrhea may be loose, watery, or bloody. Nausea is reported by some patients, but vomiting is less common. More than half the patients describe subjective fever. The abdominal cramping may be severe and is sometimes the predominant symptom. Although in most patients the symptoms resolve within 7 days, symptoms may persist in 10 to 20% of patients, and another 5 to 10% may experience a relapse.

Almost regardless of the nature of the symptoms, fecal leukocytes are found in 75% of infected patients; gross or occult blood is seen in 50%. Peripheral white blood cell counts may be elevated, but liver function test results, the hematocrit, and serum electrolytes are usually normal. Sigmoidoscopic examination reveals diffuse colonic inflammation, which is nonspecific.

Local complications of *C. jejuni* gastroenteritis are rare. In its most severe form, infection may lead to massive gastrointestinal hemorrhage or toxic megacolon. Infection of the biliary tract may result in obstructive hepatitis, cholecystitis (Chapter 158), or pancreatitis (Chapter 146). Other reported local complications include peritonitis (Chapter 144), splenic rupture, and exacerbations of inflammatory colitis. Bacteremia is detected in 1.5 per 1000 intestinal infections, with higher rates in persons who are immunocompromised or elderly, but transient bacteremia may be more common because blood cultures are infrequently obtained in patients with diarrhea and the bacteria are killed rapidly by normal human serum. Other extraintestinal complications such as meningitis, endocarditis, osteomyelitis, and purulent arthritis are rare.

TABLE 311-1 CLINICAL FEATURES OF *CAMPYLOBACTER* ENTERITIS DERIVED FROM OUTBREAKS IN WHICH MORE THAN 50 PATIENTS WERE INFECTED

SYMPTOM	MEDIAN FREQUENCY (%)	RANGE (%)
Fever	50	6-75
Diarrhea	84	52-100
Headache	41	6-69
Abdominal pain	79	56-99
Myalgia	42	28-59
Vomiting	15	1-42
Blood in feces	15	0.5-32

Modified from Blaser MJ, Engberg J. Clinical aspects of *Campylobacter jejuni* and *Campylobacter coli* infections. In: Nachamkin I, Szymanski CM, Blaser MJ, eds. *Campylobacter*, 3rd ed. Washington, DC: ASM Press; 2008:99-121.

Guillain-Barré syndrome (Chapter 428), which is a postinfectious complication of *C. jejuni* infection, occurs about once in every 2000 infections; between 30 and 50% of all cases may be triggered by a preceding *C. jejuni* infection. Because the onset of neurologic symptoms occurs about 1 to 3 weeks after the onset of gastrointestinal symptoms, cross-reactivity between antibodies formed against the lipopolysaccharide and capsule of *C. jejuni* and proteins in peripheral nerve myelin or other glycolipids in peripheral nerves is probably the cause. Certain *C. jejuni* serotypes (O type 19, O type 41) are overrepresented in patients in whom Guillain-Barré syndrome develops after culture-documented *C. jejuni* infection. Other postinfectious complications of *C. jejuni* infection include reactive arthritis (seen mostly in persons with HLA-B27 histocompatibility antigens), uveitis, hemolytic-uremic syndrome, erythema nodosum, encephalitis, carditis, and hemolytic anemia.

DIAGNOSIS

The diagnosis of *C. jejuni* infection should be considered in any patient with an acute febrile diarrheal illness. The diagnosis is established by culturing the organism from stool or tissue. Primary isolation of *Campylobacter* species from blood may take up to 14 days.

The presence of curved gram-negative rods on a Gram stain of stool is specific but only 50 to 75% sensitive for detecting *C. jejuni*. Examination of fecal specimens by darkfield microscopy is useful if done within 2 hours of passage; the characteristic darting motility of *Campylobacter* provides a presumptive diagnosis. Serum serologic studies and polymerase chain reaction of stool are currently available only as research tools.

Differential Diagnosis

In patients with acute colitis and bloody diarrhea, especially those whose symptoms last longer than 1 week, *Campylobacter* enteritis may be mistaken for ulcerative colitis or Crohn's disease (Chapter 143). In such cases, it is critical to exclude infectious colitis before starting immunosuppressive therapy. In patients with severe abdominal pain, appendicitis may be suspected and unnecessary appendectomy may result (Chapter 144).

PREVENTION

Because the most common source of transmission of *C. jejuni* infection to humans in developed countries is through the consumption and handling of poultry, interrupting this route of infection will probably have the greatest effect on reducing the burden of disease caused by *Campylobacter*. The nearly universal colonization of poultry flocks with *C. jejuni* makes eradication of the organism in chickens unlikely, but improvements in slaughtering plants appear to be reducing the level of contamination of products reaching humans. For the consumer, careful food preparation methods are critical; chicken must be cooked thoroughly. To avoid cross-contamination in the kitchen, cutting boards, knives, and other utensils used to prepare raw chicken should be washed with hot soapy water before being used to prepare foods eaten uncooked such as fruits or vegetables. Person-to-person transmission of *Campylobacter* is not common; nevertheless, all persons with diarrhea, especially those who handle food, should wash their hands after using the bathroom. Travelers and campers should be cautioned against drinking untreated water. Many outbreaks of *C. jejuni* infection might also be avoided if persons abstain from drinking unpasteurized milk. Antibiotic prophylaxis for travelers is not advised. An effective anti-*Campylobacter* vaccine has not yet been developed.

TREATMENT

Rx

As is true of most patients with infectious or noninfectious diarrhea, the most important principle of treatment of *Campylobacter* gastroenteritis is restoration of proper hydration and electrolyte balance, typically with oral fluids. Occasionally, intravenous fluids are needed, especially in elderly patients or young children. Most *C. jejuni* infections are self-limited and resolve without specific antibiotic treatment. Furthermore, treatment with antibiotics shortens the duration of illness by less than 48 hours.■ Prompt antimicrobial therapy is indicated for patients with high fever (>38.5°C), prolonged illness (>1 week), bloody stools, or worsening symptoms or for those who have relapsed. Antimicrobial treatment is also warranted in the elderly, infants, pregnant women, and persons who are immunocompromised, including those infected with HIV.

The antibiotic of choice for the treatment of *C. jejuni* gastroenteritis is erythromycin (500 mg twice daily for 5 days); azithromycin and clarithromycin are equally effective but considerably more expensive. One concern with erythromycin, which is primarily metabolized by CYP3A4, is the risk for sudden cardiac death. The risk is increased five-fold when erythromycin is given with medications that inhibit CYP3A4. In patients taking one or more of these medications, azithromycin may be substituted for erythromycin.

Fluoroquinolones, carbapenems, aminoglycosides, and clindamycin may also be effective, but resistance to quinolones is now common in many parts of the world. In general, rates of resistance to ampicillin, amoxicillin, and cephalosporins are too high for them to be useful in the treatment of *C. jejuni* infections.

Critically ill or septic persons with *Campylobacter* infection may benefit from imipenem or aminoglycosides, agents to which campylobacters are exquisitely susceptible, with resistance rates consistently less than 1%. In contrast, persons with persistent or relapsing infection, especially those who are immunocompromised, may require prolonged use (sometimes months) of antibiotics. In the absence of continuing sepsis, oral agents may be used.

OTHER *CAMPYLOBACTER* SPECIES

Campylobacter fetus may cause systemic and diarrheal illnesses in compromised hosts and diarrheal illnesses in normal hosts. Most *C. fetus* strains, unlike *C. jejuni*, are not susceptible to the lethal effect of normal human serum because they possess a protein capsule (S layer). In immunocompromised persons, *C. fetus* can cause extraintestinal illnesses such as bacteremia, vascular infections, and meningitis. *C. fetus* infection may also cause perinatal infection and fetal loss. Prolonged treatment with erythromycin plus either imipenem, meropenem, an aminoglycoside, or a third-generation cephalosporin is indicated for serious *C. fetus* infections.

Campylobacter upsaliensis may cause acute or chronic diarrhea in healthy or immunocompromised persons. The organism is frequently isolated from dogs with diarrhea, which could be a source of transmission to humans. Some *C. upsaliensis* strains are resistant to erythromycin, but most are susceptible to fluoroquinolones, doxycycline, third-generation cephalosporins, and amoxicillin-clavulanate.

Campylobacter hyointestinalis was first recognized as a cause of proliferative enteritis in swine; *Campylobacter lari* is most often cultured from gulls and other birds. Both organisms have now been identified as rare causes of watery diarrhea and abdominal cramping in immunocompetent children and adults. Most infected patients do not require antimicrobial therapy; all isolates studied in vitro have been susceptible to erythromycin.

Helicobacter cinaedi and *Helicobacter fennelliae*, once called "*Campylobacter*-like organisms," are causes of proctocolitis or enterocolitis and have also been reported to cause bacteremia in immunocompromised patients. The organisms are frequently resistant to erythromycin; fluoroquinolones are considered the treatment of choice in patients who require antimicrobial therapy. The organisms are also susceptible to third-generation cephalosporins, aminoglycosides, and carbapenems.

Other *Campylobacter* or related species that have been associated with human illness include *Campylobacter mucosalis*, *Campylobacter doylei*, *Campylobacter curvus*, *Campylobacter concisus*, *Campylobacter insulaenigrae*, *Campylobacter rectus*, *Campylobacter helveticus*, *Arcobacter butzleri*, and *Arcobacter cryaerophila*. Illnesses include diarrhea and localized infections, presumably as a result of transient bacteremia from intestinal sources. New pathogenic species of *Campylobacter* are being identified with some regularity.

PROGNOSIS

Even in critically ill patients, 1 week of therapy is generally sufficient to eradicate infection.

Campylobacter infections in HIV-positive patients may be more severe, persist, recur, and be resistant to antibiotics. More severe and extraintestinal illness is also more likely to occur in patients with acquired or congenital hypogammaglobulinemia. Most *C. jejuni* gastrointestinal infections in pregnant women are mild and self-limited, with no severe consequences for the mother or baby. However, if bacteremia develops in the mother, placental infection and fetal death may ensue. Infection during the third trimester can also cause neonatal sepsis and death if the woman is excreting *Campylobacter* in her stool at the time of delivery.

312 *ESCHERICHIA COLI* ENTERIC INFECTIONS

THEODORE S. STEINER AND RICHARD L. GUERRANT

DEFINITION

Escherichia coli, which is the predominant aerobic coliform species in the normal colon, can be an enteric pathogen and cause intestinal disease, usually diarrhea. The diarrhea associated with *E. coli* may be watery, inflammatory, or bloody, depending on the organism's genetic codes for virulence traits. These virulence traits and the clinical syndromes that they cause form the basis for six major categories of *E. coli*: enterotoxigenic (ETEC), enteroinvasive (EIEC), enterohemorrhagic (EHEC), enteropathogenic (EPEC), enteroaggregative (EAEC), and diffusely adherent (DAEC). Each of these categories can be further defined by the type of enterotoxin (e.g., the cholera-like heat-labile toxin [LT] or the heat-stable toxin [ST]) or adherence (e.g., localized and effacing, aggregative, or diffuse) that it produces. Taken together, the various types of diarrheagenic *E. coli* not only constitute the major category of bacterial enteric pathogens but also illustrate the many ways in which enteric pathogens can cause disease.

The Pathogen

E. coli is a small catalase-positive, oxidase-negative, gram-negative bacillus in the family Enterobacteriaceae. It characteristically reduces nitrates, ferments glucose and usually lactose, and is either motile (with peritrichate flagella) or nonmotile. It exhibits a positive methyl red reaction and negative reactions with Voges-Proskauer, urease, phenylalanine deaminase, and citrate agents. *E. coli* is the predominant facultative gram-negative bacillus in the intestinal tract of humans and other mammals. As with other gram-negative organisms, the lipopolysaccharide cell wall contains lipid A and 2-keto-3-deoxyoctanate, a core glycolipid that has been used to develop vaccines that provide cross-protection against systemic infections with other gram-negative organisms. Smooth (S) forms of *E. coli* have O-specific carbohydrate chains attached to this core glycolipid to produce 173 O serogroups, as well as at least 56 heat-labile protein flagellar (H) antigens, by which strains are currently serotyped. Historically, some 80 variably heat-labile capsular (K) antigens have also been described (L, B, and A), not including the numerous adherence, enterotoxic, cytotoxic, and invasiveness factors that may be gained or lost by a particular serotype because they are characteristically encoded on transmissible genetic elements such as plasmids or bacteriophages. Consequently, this common inhabitant of the normal human intestinal tract becomes a pathogen when it houses one or more specific traits contributing to its colonization and virulence in the intestinal tract. Other traits such as the O and H serogroups may also be important for certain enteropathogenic and enteroinvasive organisms. For reasons that remain obscure, only a few O serogroups tend to predominate in the normal human colon (O groups 1, 2, 4, 6, 7, 8, 18, 25, 45, 75, and 81), whereas others (Table 312-1) tend to be associated with specific virulence traits and thus different types of pathogenesis in the intestine.

Well-established mechanisms of *E. coli* pathogenesis include cholera-like intestinal fluid secretion because of at least three different types of enterotoxins (ETEC), *Shigella*-like tissue invasion (EIEC), and epithelial necrosis as a

TABLE 312-1 DIFFERENT TYPES OF ENTERIC *ESCHERICHIA COLI* INFECTIONS

TYPE	MECHANISM	PREDOMINANT O SEROGROUPS	GENETIC CODE	DETECTION	CLINICAL SYNDROMES
ENTEROTOXIGENIC *E. COLI* (ETEC)					
1. Heat-labile toxin (LT)	Activates intestinal adenylate cyclase	6, 8, 11, 15, 20, 25, 27, 63, 80, 85, 139	Plasmid	Gene probe, PCR	Watery diarrhea, traveler's diarrhea
2. Heat-stable toxin (STa: STh or STp)	Activates intestinal guanylate cyclase	12, 78, 115, 148, 149, 153, 155, 166, 167	Plasmid (transposon)	ELISA, suckling mice, 6-hr ileal loop assay, gene probes, PCR	Watery diarrhea, traveler's diarrhea
3. Heat-stable toxin (STb)	Calcium-dependent HCO_3^- secretion and cytotoxicity		Plasmid	Piglet loops, gene probe	Colibacillosis (diarrhea) in piglets, ?human infections
ENTEROINVASIVE *E. COLI*					
4. Enteroinvasive (EIEC)	Cell invasion and spread	11, 28ac, 29, 124, 136, 144, 147, 152, 164, 167	Plasmid (140 Md, pWR110)	Sereny test, gene probe, (lys^-, NM, often $lactose^-$)	Inflammatory dysentery
ENTEROHEMORRHAGIC *E. COLI*					
5. Enterohemorrhagic (EHEC)	Shiga-like toxin(s) (SLT) and attaching/effacing ability	26, 39, 113, 121, 128, 139, 145, 157, occ 55, 111	Phage(s) and adhesin plasmid(s); type III secretion system	ELISA for SLT, serotype, HeLa, Vero cells, cytotoxicity, sorbitol agar, SLT or *eae* gene probes	Afebrile, bloody diarrhea, hemolytic-uremic syndrome
ENTEROPATHOGENIC *E. COLI*					
6. Focal attaching and effacing (EPEC)	Attach, then efface the mucosa	55, 111, 119, 125, 126, 127, 128, 142, 158	Plasmid (60 Md, pMAR2) + chromosomal type III secretion system and effectors	Serotype, focal HEp2 adhesion, gene probes for *EAF* or *eae*	Infantile diarrhea
ENTEROADHERENT *E. COLI*					
7. Enteroaggregative (EAEC)	Colonize; toxins (EAST, Pet), biofilm formation	3, 15, 44, 51, 77, 78, 91	Plasmid (AA) chromosome (Pic/ShET)	HEp2 cell adherence; AA probe; PCR for *aggR* or other virulence genes; biofilm formation	Endemic persistent diarrhea, acute traveler's diarrhea, sporadic acute diarrhea
8. Diffusely adherent (DAEC)	Colonize (F 1845 afimbriate adhesin)	75 (F 1845), 15 (57-1), ?(189)	Chromosomal/ plasmid	HEp2 cell adherence; DA gene probe/PCR	Persistent diarrhea in children >18 mo old

AA = aggregative adherence; DA = diffuse adherence; ELISA = enzyme-linked immunosorbent assay; NM = nonmotile; PCR = polymerase chain reaction.

result of *Shiga*-like toxins (SLTs) causing food-borne hemorrhagic colitis (EHEC) (see Table 312-1). By comparison, the classically recognized EPEC serotypes are neither enterotoxigenic nor invasive but rather attach and efface the epithelium. Still other types of enteroadherent *E. coli* exhibit aggregating (EAEC) or diffuse adherence (DAEC) traits, and the former in particular is associated with prolonged diarrhea in children in tropical developing areas, in patients infected with human immunodeficiency virus (HIV), and in acute diarrhea in outbreak settings and travelers from developed areas.

EPIDEMIOLOGY

Enteric *E. coli* infections are acquired by the fecal-oral route, although the fecal sources differ among the pathotypes. It is believed that a human reservoir is required for most recognized types of EPEC and ETEC. ETEC is also an important veterinary pathogen, especially in calves and piglets. However, the attachment traits of animal strains are different from those of strains that infect humans. EHEC colonizes commercial livestock but does not infect them; human cases can originate from food or water contaminated by manure or through person-to-person spread in secondary cases. The natural reservoir of EAEC is not known, but outbreaks have been traced to contaminated food, and live organisms can be found in drinking water, table salsa, and other consumable items.

The infectious doses of ETEC, EIEC, and EAEC have been determined in volunteers to be 10^6 to 10^{10}, numbers that usually require multiplication in contaminated food or water vehicles for their transmission. Heavy contamination with ETEC has been documented in foods prepared in homes and restaurants and by street vendors, as well as in drinking water in many tropical areas, and contaminated water and food probably represent the major sources of their acquisition, primarily in warm or wet seasons. In the United States, a large waterborne outbreak of diarrhea at a popular national park was caused by ETEC, and a widespread outbreak of EIEC enteritis was traced to the consumption of French Camembert cheese. Many EHEC (O157:H7 and others) infections have been attributed to eating undercooked hamburgers, and large outbreaks have been associated with contamination of unpasteurized apple juice, spinach, or seed sprouts. Approximately 600 people were infected in a large outbreak caused by contamination of the domestic water supply in Walkerton, Ontario, in 2000. EHEC infections are especially alarming because they are increasing in frequency and may cause hemolytic-uremic syndrome (HUS) (Chapter 175). HUS can be fatal despite antimicrobial therapy, which in some instances may actually induce phage and toxin production. Patients (generally children) who recover from HUS may also suffer chronic kidney injury as a result. Occasional nosocomial outbreaks of EAEC, ETEC, and EPEC serotypes have also occurred in hospitalized infants in the United States and other industrialized countries.

As with most diarrheal illnesses, the highest age-specific attack rates of ETEC are found in young children, especially at the time of weaning, when ETEC accounts for 15 to 50% of illnesses. Like immunologically inexperienced young children, a traveler visiting tropical areas has a 30 to 50% chance of acquiring traveler's diarrhea (Chapters 142 and 291) over a 2- to 3-week stay unless untreated water or ice and uncooked foods such as salads are strictly avoided. The most commonly recognized pathogen associated with traveler's diarrhea in most tropical areas of the world is ETEC that produces either the heat-stable toxin STa, the heat-labile toxin LT, or both. A close second to ETEC as a cause of traveler's diarrhea is EAEC, now reported in 19 to 33% of affected travelers to India or Mexico.

Of potential immunologic significance is the continued occurrence of symptomatic infections with *E. coli* that produce the less immunogenic STa in adult residents of tropical or other areas endemic for ETEC infection. In contrast, adult residents in endemic areas often carry LT-producing *E. coli* asymptomatically, thus suggesting that they may be protected from symptoms, if not from colonization.

Limited data on invasive *E. coli* suggest that infectious doses are relatively high. As with ETEC infections, such large numbers have readily been spread in food with high attack rates. EPEC has been recognized primarily in urban areas, especially among hospitalized infants in their first year of life, with apparent cross-infection in hospital nurseries. Although sporadic cases still occur, nosocomial outbreaks of EPEC diarrhea during the summer appear to have become less common and less severe in industrialized countries in the past few decades. EAEC increasingly appears to be an important cause of persistent diarrhea and malnutrition, especially in children in tropical areas and in patients with HIV infection. It was also recently shown in several studies to be a major cause of sporadic diarrhea in the United States and the United Kingdom.

PATHOBIOLOGY

The pathogenesis of enteric *E. coli* infection begins with ingestion of the organism in contaminated food or water, which then faces the normal gastric acid barrier. Both ETEC and EIEC appear to be sensitive to gastric acid; neutralization of gastric acid reduces the infectious dose by 100- to 1000-fold. Ingestion is followed by an incubation period of 2 to 7 days, during which colonization of the involved part of the intestinal tract, toxin production, and invasion or other disruption of cell function take place. For example, colonization by ETEC in the upper portion of the small bowel involves one of at least five major colonization factor antigen groups (which are fimbriate or fibrillar protein structures on the surface of the organism). The colonization fimbriae bind the organism to cell surface receptors in the upper part of the small bowel, where the enterotoxin is delivered to reduce normal absorption and cause net electrolyte and water secretion. LT, with a molecular weight of about 86,000, has a binding and active subunit and, like cholera toxin, binds to a monosialoganglioside (GM_1) receptor. Also like cholera toxin, the active subunit adenosine diphosphate ribosylates the regulatory subunit of adenylate cyclase to activate adenylate cyclase. The consequently increased chloride secretion and reduced sodium absorption combine to cause net isotonic electrolyte loss that must be replaced to prevent severe dehydration, hypotension, and their potential consequences. Other strains produce the heat-stable toxin (STa), which is a much smaller molecule than LT (18 to 19 amino acids) and activates intestinal particulate guanylate cyclase. Like cyclic adenosine monophosphate, the cyclic guanosine monophosphate thus formed also causes net secretion. The roles of other enterotoxins such as LTII, EAST, EIET, and others seen in ETEC, EAEC, and EIEC, respectively, are unclear at present. Both the colonization traits and production of enterotoxin are encoded on transmissible plasmids. Besides the complications of dehydration, the only significant pathologic change with ETEC is depletion of mucus from intestinal goblet cells.

EIEC, often of certain serogroups (see Table 312-1), has the capacity, analogous to *Shigella*, to invade and multiply in epithelial cells, cause conjunctivitis in guinea pigs (Sereny test), and produce inflammatory colitis and dysenteric or bloody diarrhea. As seen with shigellosis, a striking inflammatory response occurs, with numerous polymorphonuclear leukocytes in stool. The colon shows patchy, acute inflammation in the mucosa and submucosa with focal denuding of the surface epithelium, usually without deeper invasion or systemic spread. Although epithelial cell invasiveness in both EIEC and *Shigella* appears to be encoded on a large 120- to 140-Md plasmid, several chromosomal determinants, including the O antigen, are crucial for full invasive virulence.

The classically recognized EPEC serotypes often fail to produce known enterotoxins or to be invasive. Nevertheless, they are well-established causes of infantile diarrhea and exhibit a remarkable array of chromosome- and plasmid-encoded traits that orchestrate their initial attachment and subsequent effacement of the brush border epithelium. The majority of classically recognized EPEC serotypes, such as O55 and O111, exhibit both plasmid-encoded localized adherence to epithelial cells (via specialized bundle-forming pili) and chromosomally mediated attachment and effacement of microvilli. The latter is characterized by the formation of pedestals that hold the bacteria intimately to the cell surface and is mediated via effectors secreted directly into host cells by a specialized type III secretion system. There is also villous atrophy, mucosal thinning, inflammation in the lamina propria, and variable crypt cell hyperplasia. These morphologic changes are associated with a reduction in mucosal brush border enzymes and may contribute to the impaired absorptive function and diarrhea.

EHEC, most notably serotype O157:H7 but also serogroups O26, O39, and others, cause type III secretion–dependent intimate adherence and microvillous effacement like EPEC, but they also produce SLTs that are responsible for the characteristic colonic mucosal disruption and hemorrhage, as well as the complication of HUS. Organisms that produce SLTs without intimate adherence and pedestal formation are known as STEC or VTEC (Shiga-toxigenic or verotoxigenic *E. coli*), and their clinical importance remains uncertain. However, the terms EHEC, STEC, and VTEC were often used interchangeably in the older literature.

EAEC is defined by a characteristic aggregative adherence pattern to cells and the substrata associated with biofilm formation. This adherence requires a large plasmid known as the AA plasmid, which encodes specialized aggregative adherence fimbriae and other virulence genes, including a serine protease autotransporter toxin known as Pet and an antiaggregative protein called dispersin. Chromosomal virulence traits include a mucinase, Pic, and a

second enterotoxin, ShET. Limited studies on human infections with EAEC suggest that the organisms do not intimately adhere or invade but reside within a biofilm and that secreted factors contribute to a damaging host inflammatory response.

The fundamental pathogenesis of DAEC is still an area of active investigation but appears to depend on direct interactions between specialized adhesins (Afa/Dr) with host CD55 (decal accelerating factor).

Host risk factors for diarrheagenic *E. coli* infection differ among the various bacterial pathotypes but in general include age, recent antibiotic use, and loss of gastric acid. Recent studies suggest that specific single nucleotide polymorphisms in the lactoferrin, osteoprotegerin, and interleukin-8 genes are associated with traveler's diarrhea caused by ETEC, EAEC, or both.

CLINICAL MANIFESTATIONS

The clinical manifestation of enteric *E. coli* infections vary among the pathotypes. ETEC infections generally produce watery diarrhea, particularly in young children and travelers to tropical or developing areas. Diarrhea may range from mild to severe and cholera-like; it may be life-threatening, especially in small children and elderly patients, who are particularly prone to dehydration, undernutrition, and electrolyte imbalance (especially hypokalemia and acidosis). Other characteristic symptoms include malaise, abdominal cramping, anorexia, and occasionally nausea, vomiting, or low-grade fever. The illness is generally self-limited to 1 to 5 days and rarely extends beyond 10 days or 2 weeks. Infections with *E. coli* that produce both ST and LT or ST alone may be more severe than those caused by *E. coli* strains that produce only LT. The persistence of impaired mucosal absorptive capacity for 1 to 3 weeks may further compound the cycle of malnutrition that complicates diarrheal illnesses in children in developing, tropical areas.

Infection with EIEC is characterized by inflammatory colitis, often with abdominal pain, high fever, tenesmus, and bloody or dysenteric diarrhea, essentially like that seen with *Shigella*, to which this organism is closely related. The incubation period is usually 1 to 3 days, with the duration generally self-limited to 7 to 10 days.

Outbreaks of EPEC infection in newborn nurseries have ranged from mild transient diarrhea to severe and rapidly fatal diarrheal illnesses, especially in premature or otherwise compromised infants. The more severe illnesses appear to have been more common in industrialized countries before 1950. However, more recent outbreaks and sporadic cases are well documented.

Hemorrhagic colitis associated with EHEC is characterized by grossly bloody diarrhea, often with remarkably little fever or inflammatory exudate in stool but with significant abdominal pain. Although this diarrheal illness is self-limited, potentially fatal HUS or thrombotic thrombocytopenic purpura subsequently develops in a significant number of children and older adults (Chapter 175). Outbreaks of hemorrhagic colitis secondary to EHEC in nursing homes or other institutions may be common and quite severe. The incubation period in two outbreaks has been 3 to 4 days (range, 1 to 7 days), and the illness is characteristically self-limited to 5 to 12 days (mean, 7.8 days).

EAEC has been associated with persistent diarrhea and malnutrition in children in developing areas, in HIV-positive patients, and in travelers who experience diarrhea (especially those genetically predisposed to greater inflammatory responses). Elevated inflammatory markers in stool are fairly common. DAEC has also been associated with diarrhea with no particular identifying features in children older than 18 months.

DIAGNOSIS

With the exception of EHEC (which should be sought by enzyme-linked immunosorbent assay or other testing for SLT and growth of sorbitol-negative EHEC O157:H7 in all patients with bloody diarrhea), definitive etiologic diagnosis of *E. coli* diarrhea requires documentation of a specific virulence trait—such as enterotoxin, invasiveness, enteroadherence—or serotype, which requires specialized immunologic tests, tissue culture, animal bioassay, or gene probes that are usually available only in research and reference laboratories. Other than for EHEC, such tests are rarely cost-effective or clinically indicated, except in outbreak or research situations. Fortunately, a probable diagnosis can often be suspected by the clinical and epidemiologic setting.

In the case of EHEC, sigmoidoscopy, which is rarely indicated, generally reveals only moderately hyperemic mucosa, and barium enema may show a thumbprint pattern of submucosal edema in the ascending and transverse colon. Some patients have superficial ulceration with mild neutrophil infiltration in the edematous submucosa. These changes are not pathognomonic.

Differential Diagnosis

Numerous other causes of diarrhea must be considered, depending on the clinical circumstances (Chapters 142 and 291). For example, self-limited, noninflammatory diarrhea in tropical, developing areas is most likely due to ETEC, rotaviruses (young children), or noroviruses (older children and adults) (Chapter 388). Noninflammatory diarrhea in older children or younger adults in the winter months in temperate areas is more likely to be due to noroviruses. *Vibrio* infections (Chapter 310) are common in areas endemic for cholera or in any coastal area where inadequately cooked seafood may be eaten. If noninflammatory diarrhea persists, especially with weight loss, other possibilities include *Giardia lamblia* (Chapter 359), *Cryptosporidium* (Chapter 358), *Cyclospora* (Chapter 361), and microsporidial infection (Chapter 361). In outbreaks of food poisoning, *Staphylococcus aureus* (Chapter 296), *Clostridium perfringens* (Chapter 304), and *Bacillus cereus* should be considered.

Inflammatory colitis with high fever and tenesmus, as well as leukocytes, mucus, and blood in the stool, may well be due to EIEC but should prompt a stool culture for more common invasive pathogens such as *Campylobacter jejuni* (Chapter 311), *Shigella* (Chapter 317), *Salmonella* (Chapter 316), *Yersinia enterocolitica* (Chapter 320), or noncholera *Vibrio* (Chapter 310). Any patient with a history of recent antibiotic use, gastrointestinal surgery, or parturition should be screened for toxigenic *Clostridium difficile* (Chapter 304). EHEC should be strongly considered in any case of bloody diarrhea, particularly in the absence of fever; many laboratories now routinely screen for this pathogen in all stool cultures, and most will screen any grossly bloody samples.

TREATMENT

Rx

As with all diarrheal illnesses, the primary treatment is replacement and maintenance of water and electrolytes, usually with a simple oral rehydration solution that uses the intact, sodium-coupled glucose or amino acid absorption (or both) to replace the fluid losses. Oral rehydration solution should be given ad libitum with free water, and in breast-fed infants, continued breast-feeding and early refeeding can compensate for the nutritional losses. Zinc supplementation is also recommended for diarrhea in infants in developing areas.

Because most *E. coli* diarrhea is self-limited, the role of antimicrobial agents is debated and remains of secondary importance to rehydration. In areas where ETEC remains sensitive, early initiation of sulfamethoxazole-trimethoprim, tetracycline, azithromycin, rifaximin, or a quinolone antibiotic may reduce a 3- to 5-day illness to a 1- to 2-day illness if the agent is started with the first loose stool in travelers to endemic, tropical areas. The use of antimotility agents should be tempered by the potential added risk of worsening or prolonging inflammatory diarrheas and increasing the risk for HUS (Chapter 175) with EHEC infections and their lack of effectiveness in reducing fluid loss, even though abdominal cramping and overt diarrhea may be temporarily reduced. Bismuth subsalicylate may reduce symptoms in traveler's diarrhea but should be used with caution to avoid toxic doses of salicylate.

PREVENTION

Prevention of many *E. coli* enteric infections is ultimately related to basic economic development, adequate sanitary facilities, and sufficient availability of safe water. In the interim, especially in areas where adequate water supplies and sanitary facilities are not available, measures such as breast-feeding for at least 6 to 12 months and handwashing reduce the likelihood of acquiring *E. coli* enteric infections. Travelers to developing or tropical areas should avoid drinking untreated or unboiled water or ice and eating uncooked fruits or vegetables that may have been "freshened" with highly contaminated water. Although a number of antimicrobial agents are effective over short periods when taken prophylactically, their effectiveness is sharply limited by rapidly emerging resistance to antimicrobial drugs, as well as by the potential side effects of their indiscriminate, widespread use. For example, tetracycline resistance among ETEC is common, and resistance to trimethoprim-sulfamethoxazole and even some quinolones is rapidly emerging around the world. More useful is the inactivated *Vibrio* cholera toxin B subunit vaccine (Dukoral), which provides transient protection against ETEC in travelers. EHEC infections can be reduced by adequately cooking beef, especially hamburger, and by careful handwashing and other hygienic measures in daycare centers and nursing homes.

PROGNOSIS

The overall prognosis of the various types of *E. coli* diarrhea is generally excellent if they are treated adequately. However, the impact of *E. coli* and other common diarrheas on mortality and morbidity (particularly with repeated infections compounding malnutrition in young children) remains one of the major health problems on a global scale. The one exception is EHEC-associated HUS, which causes significant morbidity and even mortality.

INFECTIONS DUE TO OTHER MEMBERS OF THE ENTEROBACTERIACEAE, INCLUDING MANAGEMENT OF MULTIDRUG-RESISTANT STRAINS

DAVID L. PATERSON

DEFINITION

The Pathogens

The Enterobacteriaceae is a family of gram-negative bacilli that are responsible for a broad range of infections in humans and animals. They may be motile or nonmotile, depending on the species. They are aerobic or facultatively anaerobic in growth and have a predilection for inhabiting the gastrointestinal tract. Only extra-gastrointestinal manifestations of disease are discussed in this chapter. Enteric infections caused by *Escherichia coli* are discussed in Chapter 312.

From a microbiologic perspective, members of the Enterobacteriaceae ferment sugars. They grow on a variety of solid media and are usually readily identified by clinical microbiology laboratories. A number of subtleties can arise in the detection of antibiotic resistance mechanisms, however, sometimes affecting the reporting of antibiotic susceptibilities. There is a worldwide trend toward the development of multidrug resistance in all gram-negative bacilli, including the Enterobacteriaceae. This chapter emphasizes the treatment and prevention of these multidrug-resistant strains.

Medically important members of the Enterobacteriaceae are listed in Table 313-1. Infections due to *Salmonella, Shigella*, and *Yersinia* are discussed in Chapters 316, 317, and 320, respectively.

EPIDEMIOLOGY

Members of the Enterobacteriaceae are among the most common pathogens that infect humans worldwide. They are responsible for community-acquired, hospital-acquired, and health care–associated infections. Examples of the last category include infections acquired in nursing homes and those associated with outpatient management of cancers or hematologic malignancies. It is also important to note that, as resident components of the gastrointestinal tract flora, isolates of Enterobacteriaceae may represent colonization rather than true infection. This applies to isolates from rectal swabs, urine, or respiratory secretions. Although most infections due to the Enterobacteriaceae arise sporadically, outbreaks of infection may occur. This is most common in hospitals or nursing homes with *Klebsiella* species. Less commonly, outbreaks may be due to *E. coli*, *Enterobacter* species, or *Serratia marcescens*. Typically, outbreaks are due to multiply resistant strains, compounding the difficulties of infection control.

E. coli is the most common cause of urinary tract infection (UTI), accounting for more than 80% of isolates from urine in most clinical situations. Any of the remaining members of the Enterobacteriaceae can cause this infection, with *Klebsiella* species and *Proteus mirabilis* being other common causes of UTI. *Providencia stuartii* is a notable cause of UTI among chronically catheterized patients. The Enterobacteriaceae can cause uncomplicated UTI in healthy women, acute pyelonephritis, and UTI complicating renal tract abnormalities or catheterization. As previously mentioned, the Enterobacteriaceae may colonize the urine or be found in contaminated, improperly collected samples.

Antibiotic-resistant, uropathogenic *E. coli* may spread clonally. In other words, *E. coli* isolates from multiple people with UTIs may be identical or closely related at a genetic level. Trimethoprim/sulfamethoxazole–resistant *E. coli* is notable for its spread in a clonal fashion in the United States (e.g., "clonal group A" and *E. coli* O15:K52:H1). A widely spread *E. coli* clone, defined serologically as O25:H4 and by multilocus sequence typing as sequence type (ST) 131, is associated with the production of extended-spectrum β-lactamases (ESBLs). This clone is typically associated with community-acquired UTI. It has been detected in every inhabited continent and is particularly prominent in the United Kingdom, Canada, and India. In evaluations from New Zealand and Canada, the isolation of ESBL-producing ST131 *E. coli* has been associated with travel to India, Bangladesh, or Pakistan. The presence of ST131 *E. coli* has been confirmed in the United States.

Given the niche of most Enterobacteriaceae in the gastrointestinal tract, it is not surprising that these bacteria are prominent as causes of peritonitis. *E. coli* is the most common cause of both spontaneous bacterial peritonitis (occurring in cirrhotic patients) and bacterial peritonitis arising from visceral perforation. Pyogenic liver abscess and intra-abdominal abscess may be due to *E. coli* as well. Other members of the Enterobacteriaceae may also cause these intra-abdominal infections, especially in patients with "tertiary" peritonitis occurring after prior surgery for intra-abdominal pathology.

Enterobacteriaceae members may also be the causative pathogens of pneumonia. They are more frequently the cause of hospital-acquired and health care–associated pneumonia than community-acquired pneumonia. *Klebsiella pneumoniae* was once a renowned cause of community-acquired pneumonia in alcoholics, but it has declined in significance over the past few decades. One exception is the finding of pneumonia, liver abscess, or meningitis in Asia due to highly mucoid strains of *K. pneumoniae*. Hospital-acquired pneumonia due to the Enterobacteriaceae may be ventilator associated. Enterobacteriaceae members rank as some of the most common causes of ventilator-associated pneumonia, after *Staphylococcus aureus, Pseudomonas aeruginosa*, and *Acinetobacter baumannii*. The Enterobacteriaceae may also cause hospital-acquired pneumonia in non–mechanically ventilated patients, such as those with neurologic impairment from head injury or cerebrovascular accident.

Outbreaks of antibiotic-resistant *K. pneumoniae* infection in hospitals have been prominent for more than 3 decades. In the hospital setting, *K. pneumoniae* is usually the cause of peritonitis, pneumonia, or complicated UTI. Blood stream infection arising from these sites of infection, from vascular catheters, or associated with neutropenia may also occur. In the 1970s, outbreaks occurred due to gentamicin-resistant strains. In the 1980s and 1990s,

hospital outbreaks of ESBL-producing *K. pneumoniae* became commonplace. Finally, in the past decade, *K. pneumoniae* carbapenemase (KPC)–producing *K. pneumoniae* became a substantial infection control issue. The KPC-producing organisms are discussed in detail later in this chapter.

PATHOBIOLOGY

The virulence factors associated with *E. coli* causing enteric infections are discussed in detail in Chapter 312. At least 40 different virulence genes have been described in *E. coli* causing extraintestinal infections. Among the virulence properties of these strains is the renowned ability of *E. coli* to adhere to uroepithelial cells. It is noteworthy that the ST131 *E. coli* clone is typically highly virulent. It belongs to phylogenetic group B2, which is known for extraintestinal pathogenic infections. In an evaluation of the ST131 clone, 46 extraintestinal virulence genes were assessed, and 35% of these genes were found in at least one isolate. Five virulence genes were uniformly present in ST131 *E. coli*. A recently published clinical case documented the occurrence of severe recurrent pyelonephritis with multiple renal abscesses in a man whose daughter was infected with the same ST131-positive *E. coli* strain. The daughter developed emphysematous pyelonephritis with bacteremia and septic shock. Enterobacteriaceae other than *E. coli* also possess a number of virulence mechanisms.

As previously noted, many members of Enterobacteriaceae are now multidrug resistant. Their resistance to aminoglycosides is usually mediated by the production of aminoglycoside-modifying enzymes. However, 16S ribosomal RNA methylation is a more recently described mechanism that results in resistance to gentamicin, tobramycin, and amikacin. Resistance of the Enterobacteriaceae to fluoroquinolones is a growing problem. In most areas, more than 20% of *E. coli* strains are resistant to fluoroquinolones. Resistance is usually mediated by mutation at target sites. However, other mechanisms, such as efflux pump overexpression or expression of the plasmid-mediated *qnr* genes, may play a role. The mechanisms of resistance of the Enterobacteriaceae to β-lactam antibiotics are worthy of detailed description (Table 313-2).

Narrow-Spectrum β-Lactamases

Ampicillin was introduced into clinical practice in the early 1960s. Enterobacteriaceae, with genes encoding β-lactamases inherent to their chromosome, were found to be intrinsically resistant to this antibiotic. Examples include the production of the SHV-1 β-lactamase by *K. pneumoniae* or the AmpC β-lactamase by *Enterobacter cloacae*. Other Enterobacteriaceae (e.g., *E. coli*, *P. mirabilis, Salmonella*) did not produce substantial amounts of chromosomally encoded β-lactamase. However, within months of the release of ampicillin, a plasmid-mediated β-lactamase, leading to *E. coli*'s resistance to the antibiotic, was discovered. This β-lactamase was called the *TEM β-lactamase*, in honor of the patient (Temoneira) from whom it was first isolated. Plasmids encoding resistance to ampicillin have now become widespread, with at least 40% of *E. coli* in most parts of the world being TEM β-lactamase producers.

TABLE 313-2 ANTIBIOTIC RESISTANCE ISSUES IN ENTEROBACTERIACEAE

ORGANISM	β-LACTAMASE	COMMENTS
NARROW-SPECTRUM β-LACTAMASES		
Escherichia coli	TEM-1	Present in at least 40% of strains globally
Klebsiella pneumoniae	SHV-1	Found universally
EXTENDED-SPECTRUM β-LACTAMASES		
E. coli	CTX-M-15	International clone causing community-acquired urinary tract infection
K. pneumoniae	SHV, TEM, CTX-M	Hospital outbreaks
AmpC β-LACTAMASES		
Enterobacter cloacae	AmpC	Found universally
E. coli	AmpC	Occasional plasmid-mediated strains
CARBAPENEMASES		
K. pneumoniae	KPC	Hospital outbreaks in the United States
K. pneumoniae	NDM	Hospital outbreaks in India

Extended-Spectrum β-Lactamases

Third-generation cephalosporins (e.g., ceftriaxone) were active against Enterobacteriaceae producing narrow-spectrum β-lactamases. However, mutant genes encoding β-lactamases capable of inactivating third-generation cephalosporins were discovered in the 1980s. The genes encoding these β-lactamases were identical to TEM or SHV, except for point mutations that led to an altered amino acid sequence. The subsequent structural change led to an ability to hydrolyze and thus inactivate third-generation cephalosporins. In view of the extended antibiotic-hydrolyzing abilities compared with the parent TEM and SHV enzymes, these β-lactamases were called *extended-spectrum β-lactamases*. In addition to the TEM- and SHV-type ESBLs, many new ones have now been described, most notably the CTX-M–type ESBL.

Typically, the ST131 *E. coli* clone mentioned earlier produces a CTX-M–type ESBL (especially CTX-M-15). Although ESBLs are typically susceptible to β-lactamase inhibitors (e.g., clavulanic acid), many ST131 *E. coli* isolates produce an additional β-lactamase (OXA-1) that confers resistance to β-lactamase inhibitors. The antibiotic resistance phenotype of the ST131-positive *E. coli* means that the organisms are typically resistant to ceftriaxone, cefotaxime, fluoroquinolones, trimethoprim, trimethoprim/sulfamethoxazole, penicillin/β-lactamase inhibitor combinations, and tetracyclines. Resistance to aminoglycosides is variable. The clone confers multidrug resistance by the presence of multiple antibiotic resistance genes. These are usually encoded on plasmids.

AmpC β-Lactamases

A number of genera within the Enterobacteriaceae have a chromosomally encoded β-lactamase capable of producing resistance to all penicillins and all cephalosporins except cefepime. Additionally, these β-lactamases are not affected by β-lactamase inhibitors such as clavulanic acid or tazobactam. These β-lactamases are known as *AmpC β-lactamases*. They are not derived from narrower spectrum parent β-lactamases, so it is not correct to call them ESBLs. These AmpC β-lactamases may be overproduced in the presence of certain antibiotics (i.e., the genes encoding the AmpC β-lactamases are "inducible"). *Enterobacter* species, *Citrobacter freundii*, *S. marcescens,* and *Morganella morganii* have inducible, chromosomally encoded AmpC β-lactamases. The genes encoding these β-lactamases have now been found on plasmids in *E. coli*, *Salmonella,* and other gram-negative bacteria.

Klebsiella pneumoniae Carbapenemase and Other Carbapenemases

In 2001, a novel carbapenem-hydrolyzing β-lactamase from a carbapenem-resistant strain of *K. pneumoniae* was first described: KPC. KPC-producing organisms are typically resistant to penicillins, cephalosporins, and carbapenems and are not inhibited by clavulanic acid or other commonly used β-lactamase inhibitors such as sulbactam and tazobactam. KPC production has been documented in *E. coli* and in many genera of the Enterobacteriaceae, such as *Enterobacter*, *Citrobacter*, *Proteus,* and *Salmonella.*

The epicenter of KPC-producing *K. pneumoniae* has been New York City. By 2004, approximately one quarter of *K. pneumoniae* isolates in a surveillance study in Brooklyn, New York, were KPC producing. The Centers for Disease Control and Prevention has reported KPC-producing organisms in numerous cities across the United States. International spread of KPC-producing organisms has been well described, with outbreaks in Israel and Greece being particularly problematic. Individual patients with KPC-producing organisms in France and the United Kingdom had traveled in the United States, Israel, or Greece. Investigators in China and South America have also reported KPC-producing organisms.

Other β-lactamase types have been linked to resistance of the Enterobacteriaceae to carbapenems. The most significant have been metallo-β-lactamases. These also result in resistance to penicillins and cephalosporins. A new metallo-β-lactamase (termed the *New Delhi metallo-β-lactamase,* or NDM) in *K. pneumoniae* from India, with subsequent spread to the United Kingdom, Sweden, and Australia, is particularly concerning.

CLINICAL MANIFESTATIONS

The clinical manifestations of UTI, peritonitis, pneumonia, and blood stream infection due to the Enterobacteriaceae are described in other chapters devoted to specific microbial pathogens.

DIAGNOSIS

Infection with Enterobacteriaceae is readily diagnosed in clinical microbiology laboratories after the collection of appropriate specimens. Examination of the Gram stain enables the rapid differentiation of gram-negative bacilli from other pathogens. However, it is frequently difficult to differentiate infection with the Enterobacteriaceae from infection with other gram-negative bacilli, such as *P. aeruginosa*, based on clinical findings and Gram stain results.

Once a member of the Enterobacteriaceae has been identified, it is important to perform appropriate antibiotic susceptibility testing. In some instances, specialized tests need to be performed by the clinical microbiology laboratory to detect ESBL or KPC production. Molecular epidemiologic assessment may be required to determine whether an isolate belongs to an outbreak strain.

TREATMENT

Rx

Treatment depends on the site of infection and the extent of antibiotic resistance. Empirical antibiotic choices for orally administered therapy for UTI due to *E. coli* and the other Enterobacteriaceae may include fluoroquinolones, trimethoprim/sulfamethoxazole, amoxicillin/clavulanate, or nitrofurantoin. It is noteworthy that *P. mirabilis* is resistant to nitrofurantoin. Empirical parenteral choices may include third-generation cephalosporins, penicillin/β-lactamase inhibitor combinations, aminoglycosides, fluoroquinolones, or carbapenems.

The advent of antibiotic resistance in the Enterobacteriaceae may have a huge impact on the treatment of common infections. UTI is a pertinent example. Orally administered drugs such as fluoroquinolones, trimethoprim/sulfamethoxazole, and amoxicillin/clavulanate are typically inactive against the ST131 *E. coli* strain. Because of this resistance, some patients may need to be admitted for parenteral antibiotics. Worse still, some patients with hospital-acquired infections may need "last-line" antibiotics such as colistin or polymyxin B. Specific treatment choices for antibiotic-resistant Enterobacteriaceae are given in the following paragraphs and in Table 313-3.

Treatment of ESBL-Producing Organisms

In vitro, the carbapenems (including imipenem, meropenem, doripenem, and ertapenem) have the most potent activity against ESBL-producing organisms. This is not surprising, given that these antibiotics are not inactivated by ESBLs. Carbapenems should be regarded as the drugs of choice for serious infections with ESBL-producing organisms, based on extensive positive clinical experience. No randomized trials have been performed comparing carbapenems with other antibiotic classes against ESBL producers. Prospective, observational studies have shown a significantly lower mortality from carbapenem-treated blood stream infections due to ESBL-producing *K. pneumoniae* compared with other antibiotic classes. Although synergy has occasionally been exhibited between carbapenems and other antibiotic classes, there is no evidence that combination therapy is superior to the use of a carbapenem alone.

The choice among the different carbapenems for serious infections with ESBL producers is difficult. In general, minimal inhibitory concentrations (MICs) are slightly lower for meropenem and doripenem than for imipenem and ertapenem, although the clinical significance of this in vitro difference is not clear. The ability to administer ertapenem once daily makes it potentially useful for serious infections due to ESBL producers in nursing home residents or patients continuing parenteral therapy outside the hospital. However, some ESBL-producing strains are resistant to ertapenem.

The advent of KPC, NDM, and other carbapenemases threatens the future utility of the carbapenems. Tigecycline and colistin are active against most ESBL-producing strains and, as non-β-lactams, are not inactivated by β-lactamases. Clinical experience with tigecycline or colistin to treat ESBL producers is sparse. Fluoroquinolones and aminoglycosides are obviously not affected by β-lactamases either, but the coexistence of resistance mechanisms affecting these antibiotics and ESBLs is frequent. Three observational clinical studies have assessed the relative merits of quinolones and carbapenems for serious infections due to ESBL-producing organisms. Two of these studies found that carbapenems were superior to quinolones, and one study found that they were equally effective. It is possible that suboptimal dosing of quinolones in the presence of strains with elevated quinolone MICs (yet remaining in the "susceptible" range) accounts for these differences.

Nitrofurantoin is an option for the oral treatment of cystitis due to ESBL-producing *E. coli* or *Klebsiella* species. It is important to note that nitrofurantoin is not useful in patients with upper tract infections or with moderate to severe renal impairment. Oral pivmecillinam and fosfomycin are available in some countries for the treatment of cystitis due to ESBL producers.

Treatment of KPC Producers

Treatment of KPC-producing organisms is difficult because they may lack susceptibility to all β-lactam antibiotics, fluoroquinolones, and aminoglycosides. KPC-producing organisms sometimes appear to be susceptible to carbapenems such as meropenem and imipenem (although they are always recognized as resistant to ertapenem), but these antibiotics should not be used against KPC producers.

Susceptibility to polymyxins (colistin, polymyxin B) and tigecycline is typically present. However, neither of these drug classes is a perfect solution. The pharmacokinetics of the polymyxins is not well understood, especially in critically ill or renally impaired patients. Nephrotoxicity and neurotoxicity are potential adverse effects of the polymyxins, although they are less common than they were 30 to 50 years ago, when the polymyxins first came into widespread use. Of concern is that increased polymyxin MICs have been observed during the treatment of KPC producers. Tigecycline attains low serum, urine, and cerebrospinal fluid concentrations relative to MICs of the drug with KPC producers. For this reason, tigecycline should be used with great caution in blood stream infection, UTI, and meningitis.

Antibiotics that may not be widely available, such as fosfomycin and temocillin, may have activity against KPC producers. Clinical experience with these antibiotics against KPC-producing organisms is limited. Combination therapy (e.g., colistin plus a carbapenem or rifampin) is an option, but it has not been evaluated in randomized controlled trials. Novel inhibitors of KPC may hold some promise, but their clinical availability is years away.

TABLE 313-3 TREATMENT OPTIONS FOR MULTIPLY RESISTANT ENTEROBACTERIACEAE

ESBL PRODUCERS
Carbapenems (first choice, serious infections)
Piperacillin/tazobactam, cefepime (second choice, serious infections)
Nitrofurantoin, fosfomycin (first choice, UTI)
Ciprofloxacin, amoxicillin/clavulanate (second choice, UTI)
KPC PRODUCERS
Colistin, polymyxin B, tigecycline

ESBL = extended-spectrum β-lactamase; KPC = *Klebsiella pneumoniae* carbapenemase; UTI = urinary tract infection.

PREVENTION

Prevention of hospital-acquired outbreaks caused by ESBL or KPC producers rests on a number of basic infection control principles (Chapter 290). First, if a focus of infection exists in the hospital environment, it should be removed. Examples include contamination of ultrasonography coupling gel or bronchoscopes. Outbreaks have been dramatically curtailed when these sources of contamination have been properly cleaned or removed.

Evidence suggests that transient carriage on the hands of health care workers is the most important means of transferring ESBL- or KPC-producing Enterobacteriaceae from patient to patient. The hands of health care workers are presumably colonized by contact with the colonized skin of patients or by contact with a contaminated environment around the patient. It is important to recognize that many patients may have asymptomatic colonization with ESBL- or KPC-producing organisms and thus exhibit no signs of overt infection. These patients represent an important reservoir of organisms. In some hospital wards with ongoing issues related to ESBL or KPC producers, more than 30% of patients have gastrointestinal tract colonization with these organisms at any given time. These patients should be subject to contact precautions. Hand carriage by health care workers is usually eliminated by hand hygiene with alcohol-based agents. Compliance with contact isolation precautions and hand hygiene must be high to maximize the effectiveness of these interventions.

Changes in antibiotic policy may play a role in controlling outbreaks attributed to ESBL and KPC producers, but this concept remains controversial. In one reported outbreak of ESBL producers, no effort was made to change infection control procedures. Instead, ceftazidime use decreased, and piperacillin-tazobactam was introduced to the hospital's formulary. This coincided with curtailment of the outbreak. In another institution, the entire class of cephalosporins was removed to gain control over endemic ESBL producers. The difficulty with this approach is that the replacement of one antibiotic class with another may result in the replacement of one antibiotic resistance issue with another. No study has demonstrated that removing carbapenems from a hospital formulary leads to the elimination of KPC producers. This is not surprising, because no study has shown an independent association between prior carbapenem use and the isolation of KPC producers. These

organisms are resistant to multiple antibiotic classes, and it is more common for patients to receive β-lactam/β-lactamase inhibitor combinations and fluoroquinolones than carbapenems prior to colonization or infection with KPC producers. Prudent use of all antibiotic classes, with an emphasis on reducing the duration of antibiotic use, may be more useful than the restriction of individual antibiotic classes.

PROGNOSIS

The prognosis of infection with the Enterobacteriaceae depends on multiple factors, including site of infection, presence of underlying diseases, and adequacy of empirical antibiotic therapy. At one extreme, inadequate orally administered antibiotic therapy for uncomplicated UTI due to an ESBL producer may have no impact on mortality, although it may have an impact on the duration of symptoms and the need for parenteral therapy due to treatment failure. At the other extreme, patients in the intensive care unit with serious infections due to KPC producers may have an in-hospital mortality rate exceeding 70%. In contrast, comparable patients without infection due to a KPC producer have in-hospital mortality rates of 20 to 30%.

PSEUDOMONAS AND RELATED GRAM-NEGATIVE BACILLARY INFECTIONS

GERALD B. PIER

DEFINITION

The *Pseudomonas*-related group of organisms comprises a set of gram-negative rods, including *Pseudomonas aeruginosa*, the most commonly encountered human pathogen in the family Pseudomonadaceae. Also included in this group are relatively low-virulence, uncommon pathogens such as members of the genera *Burkholderia* and *Stenotrophomonas* and two highly pathogenic species, *Burkholderia mallei* and *Burkholderia pseudomallei*, which can cause serious infections in the limited parts of the world where they occur naturally. On occasion, some non–*P. aeruginosa* organisms in the genus *Pseudomonas* or the related genus *Ralstonia* cause human infection, although such infection is almost always due to improper decontamination of a medication or device used to treat humans.

The Pathogen

P. aeruginosa is readily identified as a gram-negative, straight or slightly curved rod with a length ranging from 1 to 3 μm and a width of 0.5 to 1.0 μm. Major morphologic characteristics on laboratory media include the production of pigments, notably a soluble blue phenazine pigment called *pyocyanin.* Some strains produce red or black colonies because of synthesis of the pigments pyorubin and pyomelanin, respectively. Another diffusible yellow-green to yellow-brown pigment produced by *P. aeruginosa* is called *pyoverdin,* which when produced along with pyocyanin gives rise to a typical green to green-blue colony on solid media. The name *aeruginosa* stems from the green-blue hue seen within colonies of many clinical isolates.

EPIDEMIOLOGY

In adult clinical medicine, *P. aeruginosa* is primarily encountered as a nosocomial pathogen. However, as patients with cystic fibrosis (CF) survive longer and their medical care as adults is increasingly shifted away from pediatric providers, treatment of chronic *P. aeruginosa* CF lung disease by adult practitioners has become common (Chapter 89). This organism is able to survive in environments that have only minimal nutritional components. Within the hospital, *P. aeruginosa* can colonize moist surfaces of the axilla, ear, and perineum. It is also isolated from other moist, inanimate environments, including water in sinks and drains, toilets, and showers, with the source being *P. aeruginosa*–containing biofilms formed in plumbing fixtures. Pathogenic strains have likewise been isolated from the water used for flowers in patients' rooms. Hospital equipment that comes in contact with water, such as mops, respiratory ventilators, cleaning solutions, and food and food-processing machines, can be sources of *P. aeruginosa*.

Infections with *P. aeruginosa* have remained relatively constant in terms of incidence and tissue sites of occurrence over the past 30 to 40 years, and relative frequencies of hospital-acquired pneumonia and ventilator-associated pneumonia (VAP) can vary significantly among health care settings in different countries. In intensive care units in the United States in 2003, *P. aeruginosa* accounted for 18.1% of hospital-acquired pneumonias and a significant percentage of urinary tract infections (16.3%), surgical site infections (9.5%), and blood stream infections (3.4%). With increasing problems because of infections with strains of *P. aeruginosa* resistant to multiple antibiotics, it can be anticipated that therapeutic difficulties with this organism will remain a major cause of morbidity and mortality for some time to come.

Though much less of a problem than nosocomial infection, community-acquired *P. aeruginosa* infection does occur in certain settings, and such infection is often associated with exposure to moist environments. *P. aeruginosa* infections in the community are related to the use of hot tubs, whirlpools, swimming pools, and other types of baths, as well as the use of contact lenses, particularly the extended-wear variety. It is also a cause of otitis externa. Puncture wounds through tennis shoes can give rise to serious *P. aeruginosa* infection. *P. aeruginosa* endophthalmitis after surgery or eye trauma can result in serious visual compromise, and *P. aeruginosa* endocarditis is frequently found in injection drug users, a problem that often recurs within individual communities as a result of sharing of contaminated needles and drugs.

PATHOBIOLOGY

Host Factors in Pathogenesis

Although many factors contribute to host susceptibility to *P. aeruginosa* infection, one overarching factor for community-acquired and nosocomial *P. aeruginosa* infection appears to be neutropenia. Even in settings in which polymorphonuclear neutrophil (PMN) numbers are normal but their recruitment and activation in responses to infection are impaired, such as those associated with the constitutive inflammation in the lung of patients with CF, *P. aeruginosa* infections readily develop. Other host factors known to be associated with increased susceptibility to infection include dead or poorly perfused tissue in burns and wounds, loss of mucosal barrier function, such as occurs in the tracheobronchial tree of mechanically ventilated patients, and disruption of the normal bacterial flora in the gastrointestinal tract and oropharynx. The panoply of cytokines and chemokines that humans can produce in response to infection, with their additive, synergistic and complementary, or antagonistic effects, makes it difficult to ascribe a role in resistance to *P. aeruginosa* infection to a single cytokine. In transgenic mice, some cytokines and chemokines serve as key elements in both resistance and enhancement of pathology related to *P. aeruginosa* infection.

Although all known monocytic, granulocytic, and lymphocytic cell types have shown some effect in having an impact on *P. aeruginosa* infection in both human and experimental animal infections, it is clear that the major cellular mediators of resistance to *P. aeruginosa* infection are PMNs. Even though the incidence of serious *P. aeruginosa* infection in neutropenic hosts seems to have declined in the past 10 to 15 years when compared with the incidence in the 1970s, neutropenia in humans is still a major risk factor for *P. aeruginosa*

infection. Signaling via the MyD88 adaptor protein used by such cytokine receptors as those for interleukin-1 and tumor necrosis factor-α to induce translocation of nuclear factor κB is essential for PMN recruitment to the lung. In the absence of MyD88, lethal pneumonia and sepsis can be induced by fewer than 60 bacterial cells applied to the noses of mice. Thus, MyD88-mediated cellular responses provide essentially all of the resistance to *P. aeruginosa* lung infection.

Epithelial cells, particularly in the lung, are among the first cell types to encounter *P. aeruginosa* after exposure. Principally through studies directed at elucidating why CF patients are so commonly infected with *P. aeruginosa* (>80% of patients are infected by 15 to 20 years of age), much has been learned about the role of epithelial cells in orchestrating innate immunity to *P. aeruginosa* infection (Chapter 89). The major challenge has been to correlate the genetic defect leading to the synthesis of either no cystic fibrosis transmembrane conductance regulator (CFTR) protein or dysfunctional CFTR to the pathogenesis of *P. aeruginosa* infection. Lack of functional CFTR compromises the host's ability to respond rapidly to *P. aeruginosa* with a protective inflammatory response involving such diverse factors as epithelial uptake of bacteria via binding to CFTR, which in turn leads to rapid cytokine responses and PMN infiltration to protect against further bacterial spread within the bronchial mucosa. Delays in these responses, particularly the rapid recruitment of PMNs to the site of infection, could underlie the ability of *P. aeruginosa* to survive in the lung of CF patients and ultimately lead to destructive inflammation.

Bacterial Factors in Pathogenesis

P. aeruginosa is a formidable pathogen in humans because of the multitude, diversity, and complexity of its virulence factors. Virtually all major classes of bacterial virulence systems are found in this organism (Table 314-1), including exotoxins, endotoxins, type III secreted toxins, pili, flagella, proteases, phospholipases, iron-binding proteins, exopolysaccharides, the ability to form biofilms, and elaboration of toxic small molecules such as pyocyanins. The potential of *P. aeruginosa* to cause infection in virtually any body site is probably due to the array of factors that it can call on from its large genome to establish itself at a specific site and use a wide variety of nutrients for growth, along with the ability to produce a panoply of factors to counteract host defenses.

Bacterial factors produced to counter host defenses include the expression of long O side chains on bacterial lipopolysaccharide to prevent lysis by complement and production of a variety of proteases that can inactivate host immune effectors and kill immune effector cells, as well as degrade tissue components, thereby allowing the organism to advance the infectious process. *P. aeruginosa* uses typical siderophore systems to acquire iron, specifically involving factors referred to as *pyoverdin* and *pyochelin.*

A major cellular toxin is exotoxin A, an adenosine diphosphate–ribosylating toxin with activity very similar to that of diphtheria toxin. Purified exotoxin A is lethal to experimental animals in small doses, and its production is affected by iron levels. *P. aeruginosa* can induce hemolysis of red blood cells as a result of the production of PlcHR, a hemolytic phospholipase C. A second, nonhemolytic phospholipase C, PlcN, is also made by *P. aeruginosa* strains. Type III secretion systems are highly conserved features of bacterial pathogens, including *P. aeruginosa*. This system allows direct injection of bacterial toxins into eukaryotic cells, which disrupts cellular trafficking by inhibiting the actin cytoskeleton and also by affecting protein synthesis. For *P. aeruginosa*, clinical isolates expressing type III toxins are isolated significantly more frequently from patients who have poor clinical outcomes. Four major effector proteins are known: ExoS, ExoT, ExoU, and ExoY.

As bacterial counts increase in a tissue, the organisms reach a critical mass that is thought to allow them to effectively communicate with each other through the system of quorum sensing (QS). For *P. aeruginosa*, three major, interrelated QS systems are known to date, designated the las, rhl, and *Pseudomonas* quinolone system (PQS). The molecular mediators of the QS system are known as autoinducers because of their self-regulatory effects on bacterial responses to the environment. These three systems, along with some other regulatory factors, have a complex interaction in the context of regulation of gene transcription and production of virulence factors.

Another major bacterial phenotype regulated by the QS system is the formation of *P. aeruginosa* biofilms, a well-studied area but with some important limitations in terms of applicability to clinical infection and disease. Although biofilms are thought to play a role in chronic infections such as osteomyelitis or CF lung infection, the structured communities typical of biofilms are not really observed in infected tissues, notably the CF lung. Rather, microcolonies or aggregates of bacteria are present, and these microcolonies contain not only bacterial factors but also host factors, including host DNA, mucus, actin, and probably other products from dead and dying bacterial and host cells. How these in vivo microcolonies are actually related to the QS-controlled biofilms studied in vitro on abiotic surfaces is still unclear.

CLINICAL MANIFESTATIONS

Bacteremia

The clinical manifestations of *P. aeruginosa* blood stream infection are rarely different from those of bacteremia in general. Patients are usually febrile, but more severely ill patients in shock may be hypothermic. The only point differentiating this entity from other causes of gram-negative sepsis may be the occurrence of distinctive skin lesions known as *ecthyma gangrenosum* (Chapter 449), which occur almost exclusively in markedly neutropenic

TABLE 314-1 VIRULENCE FACTORS FOR *PSEUDOMONAS AERUGINOSA*

LOCATION OR CLASS	EXAMPLES	ACTIVITY/EFFECTS ON HOST
Cell surface	Alginate	Antiphagocytic, resists opsonic killing
	LPS	Endotoxic, antiphagocytic, evades preformed antibody to previously encountered O antigens
	Pili (produced by type IV secretion)	Twitching motility, biofilm formation, adherence to host tissues
	Flagella	Motility, biofilm formation, adherence to host tissues and mucin components
	Injection of type III secretion factors	PcrG, PcrV, PcrH, PopB, and PopD proteins form injection bridge for type III effectors
Outer membrane	Siderophore receptors	Provide iron for microbial growth and survival
	Efflux pumps	Remove antibiotics
Secretion systems		
Type II	Elastase, lipase, phospholipases, chitin-binding protein, exotoxin A, and others	Variety of proteolytic, lipolytic, and toxic factors. Degrade host immune effectors
Type III	ExoS, ExoT, ExoU, ExoY	Intoxicate cells (ExoS/ExoT); cytotoxic (ExoU), disrupt actin cytoskeleton
Type VI	Cytoplasmic and membrane-associated proteins, ATPases, lipoproteins, Hcp1 protein	Poorly characterized but found in animal studies to be needed for optimal virulence, particularly in chronic infection
Iron acquisition	Pyoverdin, pyochelin	Scavenge iron from the host for bacterial use
Secreted toxins	Exotoxin A, leukocidin, phospholipases, hemolysins, rhamnolipid phospholipases	Kill leukocytes, hemolysis of red cells, degrade host cell surface glycolipids
Secreted oxidative factors	Pyocyanin, ferripyochelin	Produce reactive oxygen species: H_2O_2, O_2^- Inflammatory, disrupts epithelial cell function
Quorum sensing	LasR/LasI, RhlR/RhlI, PQS	Biofilm formation, regulation of virulence factor secretion

ATPases = adenosine triphosphatases; LPS = lipopolysaccharide; PQS = *Pseudomonas* quinolone signal.

patients. These small, painful, reddish, maculopapular, well-circumscribed lesions have a geographic margin and begin pink, darken to purple, and finally become black and necrotic. Histopathology indicates that the lesions are caused by vascular invasion after bacteremia and are teeming with bacteria.

Acute Pneumonia

The respiratory tract remains the most frequent site of infection by *P. aeruginosa*. This organism ranks either first or second in most lists as the causative pathogen in VAP. However, much debate centers on the actual role of the organism in VAP because the conclusion that *P. aeruginosa* plays a major role in VAP is based on results of cultures of sputum or endotracheal tube aspirates. Frequently, these culture results represent only nonpathogenic colonization of the tracheobronchial tree, formation of an innocuous biofilm on the endotracheal tube, or simple tracheobronchitis. In the absence of radiologic evidence of pneumonia, the question remains whether *P. aeruginosa* is the cause of anything more than purulence in tracheobronchial secretions (i.e., tracheobronchitis). At the current time there is an emerging consensus that an invasive procedure such as bronchoalveolar lavage or protected brush sampling of the distal airways should be used to perform quantitative culture of the lung to substantiate the occurrence of *P. aeruginosa* pneumonia in a ventilated patient. However, the results of treatment when endotracheal aspirates are used as the diagnostic procedure appear to be just as good as those when bronchoalveolar lavage is used.

Chronic Respiratory Tract Infections

P. aeruginosa is responsible for chronic infections of the airways associated with a number of underlying or predisposing conditions, the most prevalent being CF. A description and management of *P. aeruginosa* infection in patients with CF can be found in Chapter 89. A somewhat similar state of chronic colonization is seen in some Asian populations in a disease of unknown cause called *chronic* or *diffuse panbronchiolitis.* The disease is most often described in Japan but is not restricted to that country. However, not unlike CF, there is a chronic relapsing infection by *P. aeruginosa* that is characterized by increased sputum production, fever, and focal lung infiltrates. Strains of *P. aeruginosa* isolated from these patients also undergo the same type of mucoid conversion as do strains from patients with CF, which reflects overproduction of an exopolysaccharide called *alginate,* a clear pathogenic factor in chronic CF lung disease.

Bone and Joint Infections

P. aeruginosa is not a frequent cause of bone or joint infections. Such infections result from at least three different mechanisms: bacteremia, direct inoculation into bone, or spread from contiguous infection. Bacteremia secondary to either injection of contaminated illicit drugs or infective endocarditis in the addict population has been well documented to cause vertebral osteomyelitis and septic arthritis of then sternoclavicular joint. The clinical manifestation of vertebral *P. aeruginosa* osteomyelitis is more indolent than that of staphylococcal osteomyelitis. The duration of symptoms in the addict population with vertebral osteomyelitis is from weeks to months. Fever is not uniformly present but, when present, tends to be low grade. Sternoclavicular septic arthritis from *P. aeruginosa* is seen almost exclusively in intravenous drug addicts. It may occur with or without endocarditis, but a primary site of infection is often not found.

Pseudomonas osteomyelitis of the foot most frequently follows puncture wounds through sneakers. The organism has been found between the rubber sole layers of sneakers in many cases. Most of these cases are reported in children, but it is also seen in adults. The main manifestation is pain in the foot, and there may be superficial cellulitis around the puncture wound and tenderness on deep palpation of the wound.

Central Nervous System Infections

Primary central nervous system (CNS) infections by *P. aeruginosa* are a relative rarity. Involvement is almost always secondary to a surgical procedure or head trauma and is occasionally noted following bacteremia. The entities seen most often are postoperative or post-traumatic meningitis and occasionally subdural or epidural infections resulting from initial contamination of access areas. Brain abscess secondary to embolic disease from endocarditis has also been described in intravenous drug addicts. The cerebrospinal fluid (CSF) profile of *P. aeruginosa* meningitis is no different from that of pyogenic meningitis. Other forms of *P. aeruginosa* CNS infection, such as brain abscess and epidural and subdural empyema, generally require surgical drainage in addition to antibiotics.

Eye Infections

Eye infections by *P. aeruginosa* occur from direct inoculation into tissue as a result of trauma or surface injury caused by contact lenses. Keratitis is the most frequent type of disease seen, and its association with contact lens wear, especially extended-wear lenses, is well established. However, any form of trauma may predispose to this type of infection, including surgery and burns. Keratitis can be slowly or rapidly progressive, but the classic description is that of disease progressing over a 48-hour period and leading to involvement of the entire cornea with opacification and sometimes perforation. *P. aeruginosa* keratitis should be considered a medical emergency because of the rapidity with which it can progress and lead to loss of sight. Prevention of contact lens–associated infections by proper use of daily-wear disposable lenses would probably drastically reduce the incidence of keratitis in lens users.

P. aeruginosa endophthalmitis is one of the most feared of *P. aeruginosa* infections. Loss of sight or very much reduced visual acuity is the most common outcome of these infections. This entity may result from penetrating injuries, surgery, perforation of a corneal ulcer, or seeding from bacteremia. The disease is fulminant, with severe pain, chemosis, decreased visual acuity, anterior uveitis, vitreous involvement, and panophthalmitis. *P. aeruginosa* also causes a number of uncommon eye infections, including orbital cellulitis in neutropenic patients and gangrene necrosis of the eyelids, both of which result from bacteremia.

Ear Infections

P. aeruginosa ear infections vary from the mild swimmer's ear, to chronic persistent draining ears, to serious life-threatening infections that lead to neurologic sequelae or even death. Swimmer's ear is commonly seen in children and results from infection of moist, macerated skin of the external ear canal. The source of the organism is likely to be hot tubs or swimming pools, particularly if not sufficiently chlorinated. The natural history of most of these cases is resolution without sequelae, but chronic drainage occurs in some patients. Systemic symptoms such as fever develop in a small minority of patients. The diagnosis is made easily as long as there is a high index of suspicion, which should be the case in diabetics and patients with acquired immunodeficiency syndrome.

Another poorly understood form of *P. aeruginosa* ear infection is a chronic middle ear drainage called *chronic suppurative otitis media. P. aeruginosa* is isolated from a large percentage of these draining middle ears. Frequently, it is found in mixed culture, but in about 30% of cases it is the sole organism isolated from aerobic cultures. The pathogenesis of this condition is unclear. It is possible that it begins with external otitis similar to swimmer's ear, with subsequent middle ear involvement followed by chronic mastoiditis.

Urinary Tract Infections

P. aeruginosa urinary tract infections generally occur as a complication of the presence of a foreign body such as a stone, stent, or catheter in the urinary tract or an obstruction within the genitourinary system or after instrumentation or surgery on the urinary tract. Paraplegic patients are at high risk for *P. aeruginosa* urinary tract infections, and frequent use of antibiotics in this setting may select for *P. aeruginosa*. Notwithstanding the relationship between obstructive lesions and *P. aeruginosa* urinary tract infections, there have been descriptions of *P. aeruginosa* urinary tract infections in outpatient children without stones or evident obstruction. *P. aeruginosa* urinary tract infection frequently serves as the nidus for *P. aeruginosa* bacteremia by ascending infection.

Skin and Soft Tissue Infections, Including Burns

P. aeruginosa causes ecthyma gangrenosum in neutropenic patients, an entity described earlier in this chapter. Secondary infection of chronic skin ulcers or burns (see later) can also occur. Maceration of normal skin, such as from soaking in a hot tub, can lead to superficial infection. Folliculitis and other papular or vesicular lesions attributed to *P. aeruginosa*, collectively called *dermatitis,* have now been described extensively. Multiple outbreaks have been linked to whirlpools, spas, and swimming pools. Thus, control of growth of this organism in the home or recreational environment by proper antibacterial treatment of water is essential, comparable to the control commonly practiced in hospitals.

Burn wound infections by *P. aeruginosa* constituted one of the most significant problems caused by this organism during the 1960s and 1970s in countries with advanced medical care. A specific clinical picture of sepsis, with high colony counts of *P. aeruginosa* exceeding 10^5 organisms per gram of

tissue, was the defining feature. Patients generally exhibited progressive formation of a black necrotic eschar and sepsis, with or without bacteremia. The occurrence of *P. aeruginosa* burn wound sepsis does not appear to be as frequent as reported in the past in countries with advanced medical care, when as many as 10% of burn patients had *P. aeruginosa* sepsis. However, *P. aeruginosa* remains a major pathogen in settings where burn patients have high rates of infection. The diagnosis may be made by culture of blood or by the pathognomonic clinical picture of an expanding burn lesion caused by infection with *P. aeruginosa*. Clinicians usually rely on isolation of *P. aeruginosa* from wounds or blood along with the finding of sepsis in diagnosing burn wound sepsis secondary to *P. aeruginosa*.

Endovascular Infections

P. aeruginosa may cause endovascular infections, including infective endocarditis. In intravenous drug addicts, the source is generally contaminated paraphernalia or illicit drugs. This organism has also been reported to cause prosthetic valve endocarditis. Outbreaks of *P. aeruginosa* endocarditis on native heart valves have been described in drug addicts residing in particular cities, probably resulting from local contamination of illicit drugs. The manifestations of *P. aeruginosa* endocarditis resemble those of other forms of acute endocarditis in addicts except that it appears to be more indolent than *Staphylococcus aureus* endocarditis.

Febrile Neutropenia

P. aeruginosa infections during febrile neutropenia occupy a historical place as the organism against which empirical coverage must always be included. Currently, the organism does not appear to be as common in neutropenic patients as it once was. However, the importance of *P. aeruginosa* infection in neutropenic patients has not diminished simply because when it does cause pneumonia or bacteremia, mortality is likely to be high if not appropriately treated by empirical therapy. Additionally, in some parts of the world, *P. aeruginosa* continues to be responsible for the largest proportion of infections caused by a single organism in neutropenic patients. The classic clinical syndromes in febrile neutropenic patients were bacteremia, pneumonia, and soft tissue infection, mainly manifested as ecthyma gangrenosum.

Uncommon *P. aeruginosa* Infections

In addition to the entities just described, *P. aeruginosa* can cause a number of infrequently seen syndromes, including noma neonatorum, a necrotizing mucosal and perianal infection of newborns, toe web infections (especially in the tropics), and the "green nail syndrome" caused by *P. aeruginosa* paronychia as a result of frequent submersion of the hands in water. In the last entity, the green discoloration results from diffusion of pyocyanin into the nail bed.

TREATMENT

Treatment of Bacteremia

Removal of an infected vascular catheter may be needed to control device-related bacteremia. The standard of care for *P. aeruginosa* bacteremia is usually an effective β-lactam antibiotic combined with an aminoglycoside. Monotherapy with an aminoglycoside has generally resulted in very poor outcomes. There have been at least four studies, none of which have been prospective, double-blinded studies, indicating that *P. aeruginosa* bacteremia has the same outcome when treated with a single antipseudomonal β-lactam or such an agent combined with an aminoglycoside.

Depending on the antibiotic susceptibility of *P. aeruginosa* isolates routinely found in a specific setting, one of the following regimens would be appropriate for *P. aeruginosa* bacteremia, pending return of susceptibility testing results. Adult, nonazotemic patients may be given ceftazidime, 2 g intravenously every 8 hours, cefepime, 2 g intravenously every 12 hours, meropenem, 1 g every 8 hours, or imipenem, 0.5 g every 6 hours. Aztreonam, 1.5 to 2.0 g every 6 to 8 hours, has been used for patients with serious β-lactam allergy. If piperacillin-tazobactam is used empirically, it should be given at a dose of 3.375 g every 4 hours, or if administration of a second drug is indicated, amikacin, 15 mg/kg every 24 hours, may be added to the piperacillin-tazobactam therapy. The addition of an aminoglycoside to the other regimens is perhaps less critical and probably depends on the level of resistance to β-lactam antibiotics seen in any given institution. At the current time, the highest levels of susceptibility are to amikacin in most regions of the world.

Treatment of Pneumonia

Optimal therapy for *P. aeruginosa* pneumonia has not been determined by rigorous studies.[1] As with bacteremia, high failure rates were seen when aminoglycosides were used as single agents. The drugs of choice for *P. aeruginosa* pneumonia would appear to be similar to those just mentioned for bacteremia. A strong case cannot be made for inclusion of the aminoglycoside component for the treatment of fully susceptible organisms, given the evidence that aminoglycosides are not optimally active in the lungs at concentrations normally used for intravenous administration. Aerosolized aminoglycoside might provide adequate drug levels in the tracheobronchial tree, but there is no reason to believe that the drug would penetrate into the consolidated lung. The usually recommended drug is tobramycin, 300 mg inhaled daily. Inhaled aztreonam lysine (75 mg three times daily for 28 days) has shown safety and efficacy for CF patients with moderate to severe lung disease.[2] Patients with nosocomial pneumonia may have *P. aeruginosa* isolates resistant to many of the usual drugs, a problem that appears to be becoming progressively worse. Doripenem is a new carbapenem reportedly with a lower rate of seizures and with activity against a small percentage of meropenem- or imipenem-resistant *P. aeruginosa* isolates. Doripenem has been shown to have activity for treating lower respiratory tract infections if given as a 500-mg dose every 8 hours via a 1-hour infusion, with adjustments in dose needed in patients with impaired renal clearance. A longer infusion time (up to 4 hours) shows somewhat improved pharmacodynamic profiles.

Patients with diffuse panbronchiolitis respond clinically to antipseudomonal therapy, but the organism is not eradicated. Significant advances have, however, been made in its management with the long-term use of macrolides, a class of drugs that have no antibacterial activity against *P. aeruginosa* but are thought to suppress the inflammatory response and perhaps suppress production of *P. aeruginosa* virulence factors. The most commonly used agents have been clarithromycin and azithromycin. Recent clinical studies in *P. aeruginosa*–infected patients with CF have demonstrated benefits in clinical status from the use of macrolides, with a single weekly dose based on weight showing efficacy over a placebo-treated group.[3]

Treatment of Other Infections

With the exception of osteomyelitis after puncture wounds, which occurs mainly in children, antibiotic therapy for other *P. aeruginosa* infections is difficult. The choices are single-drug therapy with an antipseudomonal β-lactam antibiotic or ciprofloxacin. However, resistance of *P. aeruginosa* to ciprofloxacin has increased dramatically worldwide and may preclude its use in many cases.

For the treatment of meningitis, the general principles involved in the treatment of this infection apply, that is, the need for high doses of bactericidal agents to attain high levels within CSF. The agent with which there is some published experience for *P. aeruginosa* meningitis is ceftazidime, but other antipseudomonal β-lactam agents that achieve high CSF concentrations, such as cefepime and meropenem, have also been used successfully.

The usual therapy for keratitis is topical antibiotics. Fortified aminoglycoside preparations or fluoroquinolones are recommended. In cases in which involvement is extensive, ceftazidime or gentamicin may be given by subconjunctival injection.

Therapy for endophthalmitis includes both systemic antibiotics at high doses to achieve better concentrations in the eye and intravitreal antibiotics. Ceftazidime has been the most frequently used antibiotic for this entity, but little is written about outcomes. Its penetration into the vitreous is excellent. Aminoglycosides are also injected subconjunctivally and by intraocular routes and sometimes given intravenously. Adjunctive surgery is generally performed to remove infected vitreous.

Management of otitis externa involves the use of topical antibiotic agents (otic solutions). Aminoglycoside-containing solutions are the most frequently used. Recurrences are frequent and can lead to chronically draining ears that may require more intensive topical therapy.

Treatment of malignant external otitis has undergone significant changes since it was first described in 1960. At the current time, the approach appears to be débridement of the ear canal, including any necrotic tissue cartilage and adjacent bone, rather than extensive bone débridement or facial nerve decompression. Treatment with a single agent, usually ceftazidime or ciprofloxacin, has been successful.

Most *P. aeruginosa* urinary tract infections fit into the category of complicated urinary tract infections, with therapy being more prolonged than the usual course recommended for cystitis. There are no real comparative data on proper therapies. Foley catheters, stents, or stones should be removed if possible to prevent relapse. Generally, 7 to 10 days of antibiotic treatment will suffice, with up to 2 weeks for pyelonephritis. Antipseudomonal β-lactams, ciprofloxacin, levofloxacin, gatifloxacin, and aminoglycosides given once daily are all equally acceptable, given their normally high levels of urinary excretion. Alternative antibiotics that may be used for the oral treatment of *P. aeruginosa* urinary tract infections include doxycycline, to which many strains are sensitive; in cases of multiple antibiotic resistance or in patients with very low urinary output, bladder irrigation with 0.25% acetic acid may be useful. Relapse is common, and it may not be due to antibiotic resistance but to host factors.

Management of *P. aeruginosa*–infected burn wounds is both surgical and medical. Extensive débridement of colonized eschar or necrotic tissue is required. The general principle is to reduce the organism count, which would probably diminish the sepsis response, but importantly, it would reduce the

risk of resistance developing during therapy given the extremely high microbial burden of such wounds. At the current time, true burn wound sepsis secondary to *P. aeruginosa* is probably best managed with a combination of antibiotics.

For treatment of *P. aeruginosa* infections in febrile, neutropenic patients, antipseudomonal β-lactams such as cefepime, ceftazidime, or a carbapenem can be used either alone or in combination with an aminoglycoside. Alternatively, an antipseudomonal penicillin such as piperacillin can be used in combination with an aminoglycoside if so preferred.

Antibiotic Resistance and Antibiotic Therapy for Multiresistant *Pseudomonas* Infections

P. aeruginosa strains that occur worldwide and carry multiple resistance determinants that mediate β-lactam multiresistance, along with fluoroquinolone and aminoglycoside resistance, have emerged as significant causes of infection. The medical community is now turning to drugs such as colistin and polymyxin, which were discarded decades ago but are now being considered as antimicrobials for the "21st century." Alternative approaches to the management of multiresistant *P. aeruginosa* began some time ago because of the complexity of management of such organisms in patients with CF. Colistin (polymyxin E) is used intravenously, not withstanding its toxicity. Use of this agent—or the related peptide antibiotic polymyxin B—is now rapidly becoming the therapy of choice of last resort in non-CF patients infected with multiresistant *P. aeruginosa*. The dose of either agent needs to be adjusted for renal insufficiency. One recommended schedule for colistin is as follows: for patients with creatinine clearance greater than 20 mL/min, 75 to 100% of the daily dose given in two divided doses; for creatinine clearance of 5 to 20 mL/min, 50% of the daily dose given in two divided doses; and for creatinine clearance less than 5 mL/min, 30% of the daily dose given in two divided doses every 12 to 18 hours. Addition of rifampicin to colistin has been suggested to have a synergistic effect.

Infections Caused by Organisms at One Time Classified As Pseudomonads

Most of these infections are due to members of the genus *Burkholderia*, including *Burkholderia cenocepacia*, a complex of about 10 related species previously referred to as *genomovars* that are phenotypically similar but distinguished primarily by nucleic acid sequences, as well as *B. mallei* and *B. pseudomallei*, causes of glanders and melioidosis, respectively. Infections caused by members of the genus *Ralstonia* and non–*P. aeruginosa* pseudomonads such as *Pseudomonas fluorescens* are generally rare and often iatrogenically induced by accidental contamination of solutions or medications delivered to patients. *Stenotrophomonas maltophilia* is an uncommon cause of a variety of diseases and often occurs as part of a polymicrobial infection; it can be involved in pneumonia, endocarditis, bacteremia, and urinary tract infections. This organism is generally resistant to many types of common antibiotics used for *P. aeruginosa* but is frequently sensitive to trimethoprim-sulfamethoxazole, ticarcillin-clavulanate, many fluoroquinolones, and rifampin.

Organisms in the *B. cenocepacia* complex are usually pathogenic for immunocompromised hosts and individuals with long-standing underlying serious disease. It infects the lungs of about 4% of CF patients, most commonly after many years of tissue destruction from chronic *P. aeruginosa* infection. Some strains of *B. cenocepacia* and *Burkholderia dolosa* are known to cause precipitous deterioration in the clinical condition of CF patients who acquire these hypervirulent strains and, though relatively rare, can still cause focal outbreaks in CF centers. Outside of CF, *B. cenocepacia* infection can either be acquired from hospital surfaces or be brought in from outside the hospital because of its ubiquity in the environment. As with *P. aeruginosa*, *B. cenocepacia* is found in moist or water-based environments. Pseudobacteremia caused by contamination of blood culture bottles has to be suspected when *B. cenocepacia* organisms are reported. Treatment of *B. cenocepacia* infections can be highly problematic because the organisms are at times naturally resistant to almost all commonly used antibiotics. Nonetheless, combinations of meropenem with ciprofloxacin and tobramycin appear to be successful, and in CF patients with β-lactam hypersensitivity, meropenem monotherapy has been effective. In vitro susceptibility profiles can be used to guide initial therapy.

Melioidosis from *B. pseudomallei* can occur in humans and animals and is endemic in parts of Southeast Asia and northern Australia. Findings range from asymptomatic infection to localized skin infections, chronic lung infection, and even fulminant septicemia with multiple organ failure. *B. pseudomallei* infections can occur in individuals who have recently traveled to endemic areas and is also a category B bioterrorism agent. Infection with *B. pseudomallei* can remain latent for long periods and then become reactivated, so lack of recent exposure or travel to an infected area may be insufficient to exclude a diagnosis of melioidosis. Underlying conditions such as diabetes, excessive alcohol consumption, and renal disease are found in more than half of such patients. Initial intensive therapy for 10 to 14 days can include ceftazidime, meropenem, or imipenem, to which trimethoprim-sulfamethoxazole can be added. For eradication therapy, 3 months or more of trimethoprim-sulfamethoxazole with or without doxycycline is used.

Glanders, caused by *B. mallei*, is primarily a disease of horses and is thus an occupational risk for those who come in contact with these animals. Glanders has been eliminated from enzootic foci in most countries, but some pockets remain in South America, Asia, Africa, and the Middle East. A history of contact with horses or similar species such as donkeys in one of these areas is consistent with a diagnosis of glanders. Incubation periods can be short (1 to 2 days after inhalation) or up to a few months, and as with *B. pseudomallei*, latent foci can be reactivated years after primary exposure. Clinical manifestations include an acute febrile illness and necrosis in the tracheobronchial tree accompanied by mucopurulent discharge from the eyes, nose, or lips. Systemic infections along with lymphadenopathy, respiratory tract involvement, and skin lesions are also manifestations of this disease. Untreated, the infection is lethal within 10 to 14 days. Antibiotic susceptibility and treatment are similar to that for *B. pseudomallei*, although newer macrolides appear to be effective against glanders, but they are not effective against melioidosis, as is gentamicin. *B. mallei* is also a category B bioterrorism agent and was used during World War I by German agents to infect and incapacitate horses in the United States, Europe, and Argentina.

DISEASES CAUSED BY *ACINETOBACTER* AND *STENOTROPHOMONAS* SPECIES

ROBERT BONOMO

ACINETOBACTER SPECIES

DEFINITION

The Pathogen

Acinetobacter species are gram-negative aerobic bacteria that are coccobacillary in shape and are generally described as aerobic, non–lactose fermenting, nonfastidious, nonmotile, catalase positive, and oxidase negative. Unique among microbial pathogens, the appearance of *Acinetobacter* species is highly dependent on the life cycle. In the early growth phases, *Acinetobacter*

species appear rod shaped. In the stationary phase, they acquire a coccobacillary morphology.

There are now more than 30 different species in the genus *Acinetobacter,* and their classification and identification remain problematic for clinicians. Automated and biochemical systems are sometimes inaccurate for the identification of *Acinetobacter* species. In the context of this chapter, the term *Acinetobacter* species refers specifically to *Acinetobacter baumannii* and *Acinetobacter baumannii-calcoaceticus* complex. A full list of *Acinetobacter* species is provided in E-Table 315-1. Molecular methods used to identify and classify *Acinetobacter* are listed in E-Table 315-2.

An increasing number of strains of *Acinetobacter* species are resistant to all antibiotics, and these strains are often responsible for outbreaks in large hospitals. These multidrug-resistant (MDR) strains are often resistant to three or more classes of antibiotics. Among the resistance genes found in *Acinetobacter* species are a large collection of genes for β-lactamase, aminoglycoside-modifying enzymes, and many efflux pumps. Unfortunately, resistance to "last-line" agents, such as the cationic antimicrobial peptides colistin (polymyxin E) and its close relative polymyxin B, also occurs.

CLINICAL MANIFESTATIONS

Acinetobacter species can colonize all body surfaces and cause infection in almost any organ system. Consequently, there are a number of common clinical syndromes associated with infection by *Acinetobacter.* The most common infections are respiratory (pneumonia), blood stream (bacteremia), urinary tract, wound, skin and soft tissue, and burn infections; osteomyelitis secondary to trauma; and meningitis. In general, infection is observed only in immunocompromised or injured hosts. Overall, there are few distinguishing features of *Acinetobacter* infection except for skin manifestations.

Pneumonia

Because of colonization of the oropharynx and tracheostomy tubes in patients on ventilators, the upper respiratory tract is the most common site for infection by *Acinetobacter* species. The distinct syndromes associated with respiratory tract infection due to *Acinetobacter* are community-acquired pneumonia (CAP) and hospital-acquired pneumonia (HAP). In tropical regions of China, Asia, Australia, and the South Pacific, CAP due to *Acinetobacter* species is increasingly recognized. In some locations the incidence can be as high as 10%. The common comorbid conditions seen in CAP due to *Acinetobacter* species are mainly chronic obstructive pulmonary disease (emphysema), renal disease, diabetes mellitus, and alcoholism. CAP due to *Acinetobacter* species appears to be associated with a high incidence of bacteremia, acute respiratory distress syndrome, sepsis, and death (mortality rates ≥50%). The reasons for these fulminant presentations are still unknown. Rarely, CAP due to *Acinetobacter* species can present with consolidation and multiple lung abscesses.

More frequently, *Acinetobacter* species are a cause of HAP. In the United States, *Acinetobacter* species are the third leading cause of nosocomial pneumonia. This disease largely resembles the clinical spectrum of gram-negative pneumonias (bilateral infiltrates, pleural effusion, cavitations, hypoxemia, and bacteremia). Most cases are described in patients on ventilators. The main factors associated with HAP due to *Acinetobacter* species are intubation, previous antibiotic use, intensive care unit stay, surgery, and underlying pulmonary disease. Moreover, *Acinetobacter* species can be acquired occupationally. The major challenge complicating nosocomial pneumonia due to *Acinetobacter* species is the frequent recovery of MDR strains. When isolates are MDR, the options for treatment are limited, and complications quickly arise. *Acinetobacter* HAP is associated with excess length of stay and excess mortality.

Bacteremia

Blood stream infection due to *Acinetobacter* species is often a consequence of infection or colonization of intravenous catheters or of HAP. Less commonly, wound infections cause bacteremia. In most series, mortality associated with blood stream infection ranges from 17 to 46%.

Urinary Tract Infection

Commonly, urinary tract infections are caused by enteric gram-negative bacilli; only rarely are these infections caused by *Acinetobacter* species. The indwelling bladder catheter has been implicated as the major risk factor for urinary tract infection (cystitis and pyelonephritis) due to *Acinetobacter* species.

Wound, Burn, and Skin and Soft Tissue Infections

In most clinical series to date, traumatic or postoperative wounds, burns, and skin and soft tissue infections (SSTIs) are the most common causes of *Acinetobacter* infections. Most likely, the combination of antibiotic use, colonization, and compromised or devitalized tissues is responsible. The spectrum of infection can extend from cellulitis to necrotizing fasciitis.

As a result of the outbreak of *A. baumannii* among military personnel in Iraq and Afghanistan, reports of severe wound infections and SSTIs caused by this pathogen are increasing in frequency. Necrotizing SSTI associated with *A. baumannii* occurs in hosts with underlying comorbidities (e.g., trauma, cirrhosis) and is often accompanied by bacteremia. Multiple drug resistance and the presence of co-pathogens frequently complicate treatment. Most cases require surgical débridement and lead to substantial mortality (≈30%). In addition, the use of central venous catheters and total parenteral nutrition is more common among patients with SSTIs. *Acinetobacter* species–associated SSTIs can present with a peau d'orange appearance, with overlying tiny vesicles (Fig. 315-1) and, when untreated, progress to necrotizing infection with bullae (hemorrhagic and nonhemorrhagic).

Osteomyelitis

The conflicts in Iraq and Afghanistan highlighted the first cases of osteomyelitis due to *Acinetobacter* species. Before this time, rare cases of osteomyelitis occurring in soldiers were reported during the Korean and Vietnam wars. Most of the initial reports from the Middle East described "contiguous focus" osteomyelitis. These patients had open fractures or exposed bone, with gross findings of infection: purulence, necrotic tissue, or environmental contamination with exposed bone; temperature higher than 38° C; leukocyte count greater than 12,000/μL; and *Acinetobacter* species identified from culture of deep wound tissue obtained intraoperatively. Antibiotic treatment of these infections also requires multiple surgical débridements of necrotic bone.

Meningitis

Acinetobacter meningitis is usually found in the post-neurosurgical setting, with mortality exceeding 15%. Although an uncommon cause of meningitis from the community, the frequency is almost 4% in cases of hospital-acquired meningitis. Treatment is problematic because cephalosporins do not achieve high enough levels in cerebrospinal fluid to be effective (see later).

FIGURE 315-1. Cellulitis caused by *Acinetobacter baumannii*. There is characteristic edematous peau d'orange erythema, with associated vesicles that may coalesce to form nonhemorrhagic bullae. (From Guerrero DM, Perez F, Conger NG, et al. *Acinetobacter baumannii*–associated skin and soft tissue infections: recognizing a broadening spectrum of disease. *Surg Infect [Larchmt].* 2010;11:49-57.)

TREATMENT

Rx

Increasing resistance to a variety of antimicrobial agents complicates the treatment of *Acinetobacter* species infections. Evidence is emerging that mortality in patients with *Acinetobacter* blood stream infection is significantly greater than that due to other gram-negative pathogens, *Pseudomonas*, *Staphylococcus aureus,* and *Candida* species. In addition, infection with MDR *Acinetobacter* species is associated with increased mortality and length of hospitalization.

Infection with MDR *Acinetobacter* species is often treated, largely empirically, with colistin (2.5 to 5 mg/kg/day IV, which is equivalent to 6 to 12 mg/kg/day colistimethate sodium), sulbactam (ampicillin/sulbactam 3 g IV every 6 hours), imipenem (500 to 1000 mg IV every 6 hours), or tigecycline (100 mg loading dose, then 50 mg every 12 hours). The duration of treatment is generally similar to that for infections caused by other gram-negative pathogens and is dependent on the site of infection. Often clinicians add rifampin (10 mg/kg/day, not to exceed 600 mg) to either colistin or sulbactam. Unfortunately, too few patients have been studied properly, and animal models may have significant limitations in helping to determine the best form of therapy. In cases of meningitis due to *Acinetobacter* species, treatment should be intravenous meropenem (2000 mg every 8 hours) plus the intraventricular administration of an aminoglycoside (gentamicin, depending on susceptibilities, or amikacin). Intraventricular gentamicin is administered at a dose of 4 mg once daily every 1 to 3 days until clinical and microbiologic improvement occurs. Amikacin can be used in place of gentamicin at the dose of 30 mg once a day, if required. For cases of meningitis due to carbapenem-resistant *Acinetobacter*, intravenous colistin supplemented with intraventricular or intrathecal administration of 5 to 10 mg in 1 to 2 mL sterile normal saline, after the removal of a greater or equal volume of cerebrospinal fluid, plus removal of infected neurosurgical material, appears to be the therapeutic strategy most likely to succeed.

STENOTROPHOMONAS MALTOPHILIA

DEFINITION

S. maltophilia has attracted significant attention because it is often MDR owing to intrinsic and acquired factors, and it contributes significantly to morbidity, but usually not mortality, in immunocompromised patients. The role of *S. maltophilia* in infections in patients with cystic fibrosis (Chapter 89) increases with age and appears to be linked to antibiotic exposure history.

The Pathogen

S. maltophilia are gram-negative bacteria that need methionine for growth and, like *Pseudomonas aeruginosa* and *Acinetobacter* species, are non–lactose fermentors. *S. maltophilia* possess flagellae that are multitrichous (more than one flagellum arising from the pole) and are distinguished from *P. aeruginosa* as oxidase negative. Colonies of *S. maltophilia* may appear pale yellow or lavender-green on blood agar plates. The organism emits a mild ammonia-like odor that is used for preliminary identification.

CLINICAL MANIFESTATIONS

Despite harboring many resistance genes, little is known about the virulence of *S. maltophilia*. Nevertheless, a number of risk factors are associated with infection by *S. maltophilia* (Table 315-1). Although *S. maltophilia* is regarded as primarily a nosocomial pathogen, community-acquired infection can occur.

TABLE 315-1 RISK FACTORS FOR INFECTION BY *STENOTROPHOMONAS MALTOPHILIA*

Central venous catheters
Prolonged hospitalization or intensive care unit stay
Neutropenia or cytotoxic chemotherapy
Mechanical ventilation
Malignancy
Corticosteroids
Antibiotic exposure
Exposure to other patients with *S. maltophilia*

Respiratory Tract

The respiratory tract is the most common site of isolation of *S. maltophilia* in hospitalized patients, accounting for the origin of 70% of isolates. Nosocomial pneumonia due to *S. maltophilia* is often associated with significant pulmonary disease such as emphysema, bronchiectasis, lung transplantation, or endobronchial obstruction. In addition, many of these patients are on mechanical ventilators, have tracheostomy tubes in place, or are receiving broad-spectrum antibiotics. Respiratory tract involvement with *S. maltophilia* is associated with significantly increased mortality; late-onset ventilator-associated pneumonia due to *S. maltophilia* has a mortality rate of 65%. In patients with neutropenia, mortality is as high as 40%; however, CAP due to *S. maltophilia* is very rare.

The incidence of respiratory tract infection due to *S. maltophilia* in patients with cystic fibrosis (Chapter 89) is increasingly being reported. There may be clear links with antipseudomonal antibiotics (tobramycin, imipenem, ceftazidime) used to treat these patients and the duration of hospitalization. The prognostic significance of *S. maltophilia* in the respiratory tract of patients with cystic fibrosis is unclear. Although some studies have shown progressive deterioration in pulmonary function, particularly in patients who are chronically colonized, recent data show that patients who acquire *S. maltophilia* have more advanced disease than those who do not. Moreover, detection of this species in sputum culture does not independently affect the rate of deterioration or survival.

Blood Stream Infection and Endocarditis

Bacteremia may be secondary to a respiratory, urinary, or gastrointestinal source or to an indwelling intravascular device. In many cases, except for those involving intravenous catheters, the portal of entry is not apparent. Despite the inability to demonstrate virulence, attributable mortality in blood stream infection is between 40 and 60%. On occasion, an environmental reservoir or contaminated vascular access device is linked to the presence of bacteremia. Intravenous drug users are at especially high risk for contaminating prosthetic valves with S. *maltophilia*. In the case of endocarditis, favorable outcomes are reported with antimicrobial therapy, but surgery may also be required.

Urinary Tract Infection

Although *S. maltophilia* is frequently recovered from urine specimens in patients with urinary catheters, the role of this organism is unclear.

Meningitis

Rarely, cases of central nervous system infection are reported due to *S. maltophilia*. Often these are associated with central nervous system devices or antecedent neurosurgery.

Skin and Soft Tissue Infection

S. maltophilia can be isolated form postoperative wounds, but its role in this setting is unclear. In contrast, *S. maltophilia* can cause burn wound sepsis, presenting as a syndrome very similar to ecthyma gangrenosum (Chapter 449) in immunocompromised oncology patients.

TREATMENT

Rx

As a pathogen that is an increasingly important cause of nosocomial infections, *S. maltophilia* exhibits intrinsic resistance to many antibiotics. The complexity of resistance genes and mechanisms is summarized in Table 315-2. Resistance to imipenem, piperacillin/tazobactam, ceftazidime, and aminoglycosides is very common. Despite significant resistance to many agents, trimethoprim-sulfamethoxazole remains the drug of choice (one DS tablet orally twice a day, or 12 to 15 mg/kg/day IV, based on the trimethoprim dose). Treatment duration is uncertain, but it is usually 14 days or longer. In addition, in vitro studies indicate that ticarcillin–clavulanic acid (3.1 g every 6 hours), minocycline (200 mg followed by 100 mg every 12 hours, not to exceed 400 mg in 24 hours), some of the new fluoroquinolones (ciprofloxacin 400 mg IV every 8 hours), and tigecycline may be useful agents. Colistin and rifampin (see earlier) may serve as alternatives in the face of resistance to trimethoprim-sulfamethoxazole. Aztreonam is effective against strains exhibiting resistance to β-lactams by metallo-β-lactamases.

TABLE 315-2 MECHANISMS OF RESISTANCE IN *STENOTROPHOMONAS MALTOPHILIA*

DRUG	MECHANISM OF RESISTANCE
β-lactams, including imipenem	L1 and L2 β-lactamases Outer membrane permeability/efflux
Aminoglycosides	Aminoglycoside-modifying enzymes, transport

SALMONELLA INFECTIONS (INCLUDING TYPHOID FEVER)

JOHN A. CRUMP

DEFINITION

A member of the family Enterobacteriaceae, *Salmonella enterica* subspecies *enterica* includes more than 2400 serotypes found in humans and other warm-blooded animals. These serotypes may be associated with human asymptomatic intestinal carriage, intestinal infection, and invasive disease with extraintestinal infection. Each serotype designation follows the species name (e.g., *Salmonella enterica* subspecies *enterica* serotype Typhmurium) and is frequently abbreviated as simply *Salmonella* followed by the serotype name (e.g., *Salmonella* Typhimurium).

The Pathogen

Salmonellae are gram-negative, non–spore-forming bacilli. They are differentiated from other Enterobacteriaceae by biochemical tests. They ferment glucose, maltose, and mannitol but typically not lactose or sucrose. They reduce nitrates and do not produce cytochrome oxidase. Almost all salmonellae produce acid and gas with fermentation. Most *Salmonella* serotypes cannot be distinguished by biochemical reactions. However, *S.* Typhi may be preliminarily identified by its production of only trace amounts of hydrogen sulfide and diminished biochemical activity compared with other serotypes.

Salmonellae can be differentiated into more than 2400 serotypes (also called *serovars*) by their somatic (O) antigens, which are composed of lipopolysaccharides and are part of the cell wall, and by their flagellar (H) and capsular (Vi) antigens. *Salmonella* serogroups were traditionally designated by letters based on O antigens (e.g., A, B, C1, C2). More recently, the growing number of serogroups has made it necessary to move to a numeric designation. During the transition, the traditional letter-based serogroup may be retained in brackets after the numeric designation (e.g., O:2 [A], O:4 [B], O:6,7 [C1], O:8 [C2]). Some of the important serotypes and their serogroups are Typhi (group O:9 [D1]), Choleraesuis (group O:7 [C1]), Typhimurium (group O:4 [B]), and Enteritidis (group O:9 [D1]). *Salmonella* Enteritidis and Typhimurium are the most common nontyphoidal serotypes causing human disease.

EPIDEMIOLOGY

S. Typhi, *S.* Paratyphi *A*, *S.* Paratyphi *B*, *S.* Paratyphi *C*, and *S.* Sendai are either solely or almost exclusively pathogens of humans; they cause primarily enteric fever rather than diarrhea, and human-to-human transmission is important. As a result of modern sewage and water treatment facilities and improved food safety practices, typhoid fever and paratyphoid fever have become rare in developed countries but remain a problem in countries that lack adequate sanitation and a safe water supply. There are usually fewer than 500 cases of typhoid fever each year in the United States, mainly acquired abroad; in contrast, an estimated 21 million cases occur elsewhere in the world.

Other serotypes of *Salmonella* (described here as nontyphoidal *Salmonella*) have reservoirs in warm-blooded animals and cause human food-borne illness following the consumption of contaminated meat or animal products, contamination of produce or water by animal feces or animal products, or contact with animals and their environments. Some nontyphoidal *Salmonella* serotypes appear frequently in particular animal species, and human illness is often associated with exposure to these animals and their products. For example, *S.* Enteritidis has a reservoir in chickens, and infection is often linked to the consumption of undercooked eggs, poultry products, or exposure to live chicks. Such a relationship is less clear for some other nontyphoidal serotypes (e.g., *Salmonella* Typhimurium). The annual incidence of nontyphoidal *Salmonella* infections in the United States is estimated at 16.2 per 100,000 persons, and most infections are sporadic (i.e., not linked to outbreaks). A disproportionate number of infections occur in July through October, probably related to warm weather. *Salmonella* infections are most common in infants and children younger than 5 years.

Antimicrobial Resistance

Salmonellae have become increasingly resistant to antimicrobial agents, usually by acquiring resistance transfer factors (e.g., plasmid mediated). It is thought that antimicrobial resistance in the human-restricted salmonellae (e.g., *S.* Typhi) is driven primarily by antimicrobial use in humans, whereas antimicrobial resistance among the nontyphoidal salmonellae (e.g., *S.* Typhimurium) is associated with the widespread use of antimicrobial agents in farm animals. A multidrug-resistant strain of *S.* Typhimurium (definitive phage type 104 [DT 104]) has emerged as an important cause of infection in the world. These salmonellae are resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. In addition, decreased susceptibility and, more recently, resistance to fluoroquinolones has been increasing worldwide, particularly in Asia.

Etiology

Salmonellae are transmitted by the ingestion of fecally contaminated food or water; contact with animals, their environments, and other fomites; and, rarely, close contact with infected persons (e.g., oral-anal intercourse). The ultimate sources of contamination are humans or animals that are acutely ill or are asymptomatic carriers.

Contaminated Animal Products

Nontyphoidal *Salmonella* are widely spread in the animal kingdom. *Salmonella* infection in humans usually occurs from ingesting contaminated animal food products, most often eggs, poultry, and meat. *S.* Choleraesuis is associated with pig products, *S.* Dublin with cattle and unpasteurized milk from cattle, and *S.* Enteritidis is associated with poultry and poultry products, including eggs. Eggs may become contaminated from feces on the surface of the eggshell that enter through small cracks; by infection of the ovary, resulting in primary incorporation of salmonellae into the egg; or by penetration of the intact shell. Fecal material on poultry and other animal carcasses can spread at slaughterhouses, such as when many poultry carcasses are placed in the same hot water tank to remove feathers. *Salmonella* contaminating carcasses can multiply to high levels if meat or other animal products are not refrigerated. Human illness may result if such animal products are inadequately cooked or if utensils or other uncooked foods are cross-contaminated during preparation. A wide range of foods can be contaminated with animal or human feces, from production on the farm through consumption in the home. Reports of produce-associated *Salmonella* outbreaks, due to contamination by animal or human feces during production, are increasing. *Salmonella* outbreaks have occurred from contaminated cheese, ice cream, vegetables, fruit, juice, and alfalfa sprouts.

Contaminated Food and Water

CONTAMINATION BY PETS. *Salmonella* infections may be acquired after contamination of food or water with the feces of pet turtles, chicks, ducks, birds, dogs, cats, and many other species.

CONTAMINATION BY HUMANS. *Salmonella* infection can also be acquired by eating food or by drinking water contaminated by human carriers who have not adequately washed their hands. Infection has been spread by the fecal-oral route among children, by contaminated enema and fiberoptic instruments, by diagnostic and therapeutic preparations made from animal or insect products (e.g., pancreatic extract, carmine dye), and from intentional or unintentional contamination of restaurant salad bars. Outbreaks of salmonellosis may occur in institutionalized patients, who are probably more prone to the development of *Salmonella* infections for three reasons. First, within institutionalized populations there is an increased prevalence of underlying diseases that decrease host defense mechanisms against salmonellae, such as disorders of gastric acidity and intestinal motility; second, the use of antimicrobial agents modifies the normal, protective intestinal flora; and third, institutional food prepared in bulk is more likely to be contaminated than are individually prepared meals. Outbreaks in nurseries and among the elderly in nursing homes are associated with the highest mortality rates (>5%).

Contact with Animals and Their Environments

Both healthy and sick animals may harbor and shed *Salmonella*. Transmission of *Salmonella* from animals and their environment to humans occurs primarily by the fecal-oral route. Animal fur, hair, skin, and saliva often harbor fecal organisms, and transmission can occur when persons pet, touch, feed, or are licked by animals. Transmission has also been associated with contaminated animal bedding, flooring, barriers, other environmental surfaces, and clothing and shoes. Contact with calves, turtles and other reptiles, rodents, and young poultry and their environments have all been associated with *Salmonella* outbreaks. Humans may also become infected when animals come into contact with their food or water. Both animals and humans can acquire nontyphoidal *Salmonella* from pet food or animal feed. Infections can be prevented by education, supervision of animal contact, provision and promotion of handwashing facilities, and separation of food handling and consumption from animal areas.

Contact with Infected Persons

Close contact with persons shedding *Salmonella* is an occasional source of infection. Transmission has been documented among persons handling feces (e.g., parents changing the diapers of an infected infant) and is associated with certain sexual practices (e.g., oral-anal intercourse).

PATHOBIOLOGY

After the ingestion of organisms, the likelihood of infection developing, as well as the severity of infection, is related to the dose, the virulence of the *Salmonella* strain, and the status of host defense mechanisms. Usually at least 10^2 to 10^3 bacteria are required to produce clinical infection in a normal host. Higher inocula are associated with increased disease severity, whereas smaller inocula are more likely to result in transient intestinal carriage. Gastric acid serves as a host defense mechanism by killing many of the ingested organisms, and intestinal motility is probably another host defense mechanism. In the absence of or a decrease in gastric acidity (e.g., in infants and the elderly; following gastrectomy, vagotomy, or gastroenterostomy; or with the use of drugs that reduce gastric acidity) and with decreased intestinal motility (e.g., the use of antimotility drugs), much smaller inocula can produce infection, and the infection tends to be more severe.

Administration of antimicrobial agents before the ingestion of salmonellae can markedly reduce the size of the inoculum needed to produce infection, presumably by reducing the concentration of protective bowel flora.

Although any *Salmonella* serotype can produce any of the *Salmonella* syndromes (transient asymptomatic carrier state, enterocolitis, enteric fever, bacteremia, and chronic carrier state), each serotype tends to be associated with certain syndromes much more frequently than others. For example, *S.* Anatum usually causes asymptomatic intestinal infection, whereas *S.* Typhimurium generally causes enterocolitis. *S.* Choleraesuis is more likely to produce bacteremia (often with metastatic infection) than asymptomatic infection or enterocolitis, and some serotypes such as *S.* Typhi and *S.* Paratyphi are most likely to cause enteric fever as well as the chronic carrier state. Fortunately, most *Salmonella* serotypes are of relatively low pathogenicity for humans. Therefore, although food products are commonly contaminated, large outbreaks tend to involve the more virulent serotypes.

To produce infection, invasion must occur across the mucosa of the intestine. When the organisms reach the lamina propria, an influx of polymorphonuclear leukocytes serves as a host defense mechanism to prevent invasion of the lymphatics. Certain serotypes seem to have a greater ability than others to invade the lymphatics and subsequently produce bacteremia (e.g., *S.* Choleraesuis and *S.* Dublin, which commonly produce bacteremia after intestinal infection). Both the small intestine and the colon are involved in the inflammatory process.

In the case of *S.* Typhi and other causes of enteric fever, salmonellae invade the mononuclear phagocytes in Peyer's patches in the ileum and mesenteric lymph nodes, multiply intracellularly, and are carried through the lymphatic system and blood stream to the liver, spleen, bone marrow, and other parts of the reticuloendothelial system. Once in the reticuloendothelial system, they multiply intracellularly in mononuclear phagocytes and produce the systemic manifestations of enteric fever. The onset of fever is associated with bacteremia and the release of cytokines (e.g., tumor necrosis factor and interleukins) from mononuclear phagocytes. Ulcerations over Peyer's patches are responsible for the intestinal manifestations of enteric fever such as pain, perforation, and bleeding.

In *Salmonella* enterocolitis, the organisms remain localized in the intestinal mucosa, and diarrhea results from the inflammation produced by polymorphonuclear leukocytes. In addition, watery diarrhea may occur, apparently the result of the secretion of water and electrolytes by small intestinal epithelial cells in response to an enterotoxin secreted by some of the *Salmonella* strains, or in response to tissue mediators of inflammation.

Patients with diseases that impair host defense mechanisms seem to have an increased frequency of severe *Salmonella* infection. For many years, a striking association has been recognized between diseases producing hemolysis and *Salmonella* bacteremia. Specifically, *Salmonella* bacteremia is common in patients with sickle cell disorders, malaria, and bartonellosis. In fact, because of the frequency of *Salmonella* bacteremia in sickle cell diseases and the underlying bone disease in these patients to which salmonellae localize, these organisms are the most common cause of osteomyelitis in patients with sickle cell disorders (Chapter 166). Prolonged *Salmonella* bacteremia may occur in patients with hepatosplenic schistosomiasis, possibly related to localization on and in the intravascular schistosomes. Patients with lymphoma and leukemia are also more prone to the development of *Salmonella* bacteremia. A markedly increased frequency and severity of *Salmonella* infections in general have been observed in patients with human immunodeficiency virus (HIV) infection, particularly those with $CD4^+$ T-lymphocyte counts less than 200 cells/mm^3. Prolonged and recurrent, refractory *Salmonella* bacteremia is common among these patients. Other risk factors that increase the frequency and severity of *Salmonella* infection are extremes of age, immunocompromised states (e.g., from immunosuppressive agents), malnutrition, and probably diabetes. Nontyphoidal *Salmonella* species are a leading cause of community-acquired blood stream infection in sub-Saharan Africa, where children younger than 3 years and HIV-infected adults carry most of the burden of invasive disease.

CLINICAL MANIFESTATIONS

Asymptomatic Intestinal Carrier State

The asymptomatic intestinal carrier state may result from inapparent infection (which is the most common form of *Salmonella* infection), or it may follow clinical disease (in which case the patient becomes a convalescent carrier). The carrier state is usually self-limited to several weeks to months, with the incidence of positive stool cultures rapidly decreasing over time. By 1 year, far less than 1% of carriers still have positive stools. The main exception is *S.* Typhi; about 3% of those infected excrete the organism for life. Women and older men are most likely to become chronic carriers of *S.* Typhi, related to the presence of biliary tract disease, especially calculi. A patient who has had salmonellae in stool for 1 year (chronic carrier) is likely to become a lifelong carrier; the reservoir is in the biliary tree, usually in calculi in the gallbladder. Patients with *Schistosoma haematobium* infection are predisposed to become chronic urinary carriers of salmonellae.

Enterocolitis

After an incubation period of usually 12 to 48 hours, the illness starts suddenly with crampy abdominal pain and diarrhea. Nausea and vomiting may occur but are usually not prominent or persistent. The diarrhea may be watery

and of large or small volume. Stools may contain mucus and are occasionally bloody. Polymorphonuclear leukocytes are present in the stool. Diarrhea may be mild or severe, with up to 20 to 30 stools a day. Fever is present in most patients, and the temperature may reach 40° C (104° F) or higher. The abdomen is tender to palpation. Transient bacteremia may occur and is most commonly seen in infants, the elderly, and patients with impaired host defense mechanisms.

Symptoms generally improve over a period of days, with fever lasting no more than 2 to 3 days and diarrhea lasting no more than 5 to 7 days. However, these symptoms occasionally persist for up to 14 days. More severe disease is seen with malnutrition, inflammatory bowel disease, and HIV infection. Reactive arthritis may follow enterocolitis in up to 7% of cases, especially among those with the HLA-B27 phenotype.

Enteric Fever

Enteric fever is produced by *S.* Typhi (typhoid fever), *S.* Paratyphi *A, B,* and *C* (paratyphoid fever), and occasionally other serotypes. Sometimes it immediately follows classic enterocolitis caused by the same organism. The syndrome is characterized by prolonged, sustained fever and may be associated with relative bradycardia, splenomegaly, rose spots, and leukopenia.

Therapy aborts the course of the disease. The following is a description of untreated illness. After an incubation period of 5 to 21 days (generally 7 to 14 days), fever and malaise develop, often associated with cough. A small proportion of patients may have diarrhea during the incubation period. The fever tends to rise in a stepwise fashion over the first few days to a week and then becomes sustained, usually at 39.4 to 40° C (103 to 104° F) or higher. Relative bradycardia is seen in up to half of patients. Apathy, confusion, delirium, and even psychosis may occur. Abdominal distention, pain, and tenderness may occur in the first week and may be associated with diarrhea or constipation; these symptoms are generally more pronounced during the second week of fever. Most patients have abdominal tenderness during the course of the illness.

In about 30% of patients, rose spots develop on the abdomen or chest (or both) toward the end of the first week or during the second week of fever. These faint, salmon-colored maculopapular lesions are subtle and may be difficult to see, particularly in dark-skinned patients. Salmonellae can be cultured from punch biopsies of these lesions. Hepatosplenomegaly occurs in about half of patients. Leukopenia and neutropenia are seen in about 20%. Abnormal liver function test results are common.

After 2 weeks of illness, the severe complications of intestinal hemorrhage or perforation related to necrosis of Peyer's patches may be observed in about 5% of patients. These perforations may require surgical as well as medical therapy and can occur even in a patient treated with antimicrobials. Intestinal perforation is the leading cause of death from enteric fever.

The illness usually resolves by the end of the fourth week in an untreated patient. Relapse may occur in untreated as well as treated patients, but the illness is milder than the original episode.

Rarely, some of the following complications may occur: pancreatitis, cholecystitis, infective endocarditis, meningitis, pneumonia, hepatic or splenic abscess, orchitis, or focal infection at virtually any site.

Bacteremia

Patients with the syndrome of *Salmonella* bacteremia usually complain of fever and chills lasting days to weeks. Gastrointestinal symptoms are unusual, but in some patients the syndrome of *Salmonella* bacteremia follows classic enterocolitis. Other symptoms are nonspecific, such as malaise, anorexia, and weight loss. Metastatic infection of bones, joints, aneurysms (particularly of the abdominal aorta), meninges (mainly in infants), pericardium, pleural space, lungs, heart valves, cysts, uterine myomas, malignancies, and other sites is common, and symptoms may be related to the site of metastatic infection. Stool cultures are often negative for salmonellae, but blood cultures are positive.

Although any *Salmonella* serotype can produce bacteremia, *S.* Dublin, *S.* Choleraesuis, *S.* Heidelberg, *S.* Oranienburg, *S.* Panama, and *S.* Sandiego are associated with increased likelihood of bacteremia.

Salmonella bacteremia occurs with increased frequency in infants, the elderly, and patients with diseases associated with hemolysis (e.g., sickle cell diseases, malaria, bartonellosis), HIV, lymphoma, leukemia, disseminated histoplasmosis, and perhaps systemic lupus erythematosus. Localization to bone is common in patients with sickle cell diseases (Chapter 166).

Prolonged *Salmonella* bacteremia lasting for months may occur in patients with hepatosplenic schistosomiasis. In patients with HIV infection, recurrent, relapsing *Salmonella* bacteremia may develop, which may be difficult to cure with antimicrobial agents.

DIAGNOSIS

Although *Salmonella* enterocolitis is an invasive disease, the differential diagnosis includes all causes of acute diarrhea, including invasive bacteria such as *Campylobacter jejuni, Shigella* species, invasive *Escherichia coli, Yersinia enterocolitica,* and *Vibrio parahaemolyticus;* toxigenic bacteria such as *Vibrio cholerae,* enterotoxigenic *E. coli,* enterohemorrhagic *E. coli* (e.g., *E. coli* O157:H7), *Staphylococcus aureus, Bacillus cereus, Clostridium perfringens,* and *Clostridium difficile;* viruses; and protozoa such as *Entamoeba histolytica, Giardia intestinalis,* and *Cryptosporidium* species. Invasive bacterial causes of diarrhea, enterohemorrhagic *E. coli,* and *C. difficile* infection are also associated with polymorphonuclear leukocytes in stool, whereas bacterial toxigenic causes (other than *C. difficile* and enterohemorrhagic *E. coli*), viruses, and protozoa generally are not. The bacterial toxigenic causes of diarrhea other than *C. difficile* and enterohemorrhagic *E. coli* do not produce fever.

Stool culture is definitive for the diagnosis of *Salmonella* enterocolitis, but by the time the results of stool culture are available, most patients are recovering. A stained smear of the stool usually demonstrates polymorphonuclear leukocytes. Serologic studies are of little clinical value in *Salmonella* enterocolitis, but they may be of use in epidemiologic studies.

The differential diagnosis of *Salmonella* bacteremia includes all acute infectious and noninfectious causes of fever, including bacteremia caused by other organisms. The diagnosis is proved by isolation of the microorganism from blood or from another normally sterile site.

The differential diagnosis of enteric fever is very broad and depends in part on the area of the world where the infection was acquired. All causes of sustained fever are in the differential diagnosis, including infective endocarditis, disseminated tuberculosis, brucellosis, tularemia, *Mycoplasma pneumoniae* infection, rickettsial infections, Q fever, and viral infections such as infectious mononucleosis. Depending on the site of acquisition, diseases such as malaria, amebic abscesses of the liver, and visceral leishmaniasis enter into the differential diagnosis.

The diagnosis of enteric fever is best proved by isolation of the microorganism from blood, stool, or bone marrow. During the first week of illness, blood cultures are positive in about 90% of patients, but culture positivity decreases over the next 2 weeks to less than 50% during the third week of illness. Stool cultures are usually negative during the first week but are generally positive by the third week. Bone marrow cultures give the highest yield, with up to 95% being positive; they should be considered in suspected cases with negative blood cultures. Bone marrow cultures may be positive even after several days of antimicrobial treatment, when blood cultures have become negative. Urine cultures and cultures of punch biopsies of rose spots may also be positive. The string test to obtain samples of bile from the duodenum has also yielded positive cultures.

The peripheral leukocyte count is usually normal, but leukopenia, which occurs in about 20% of cases, may be suggestive of enteric fever. Fecal leukocytes are generally present.

The Widal and other serologic tests that detect serum antibodies against *S.* Typhi are limited by shortcomings of both sensitivity and specificity and rarely provide useful information to guide patient management. Polymerase chain reaction and other molecular techniques have not proved useful for diagnosis from blood and other specimens, but they have been used to determine the *Salmonella* serotype of bacterial isolates.

TREATMENT Rx

Enterocolitis

The primary approach to the treatment of *Salmonella* enterocolitis is fluid and electrolyte replacement. Drugs with antiperistaltic effects such as loperamide or diphenoxylate with atropine can relieve cramps, but they should be used sparingly because they can prolong the diarrhea.

Salmonella enterocolitis is self-limited, and antimicrobial therapy is usually not indicated, except perhaps in patient groups at high risk for invasive disease. Antimicrobial therapy reportedly has little effect on the clinical course, and in some studies, it has prolonged the duration of salmonellae excretion in stool. In addition, most patients are improving by the time salmonellae or other bacterial pathogens are isolated from stool.

The fluoroquinolones are active against virtually all bacterial pathogens that cause diarrhea (including salmonellae), except for *C. difficile* and many *Campylobacter* organisms. Thus, it is reasonable to use fluoroquinolones for patients with suspected or known *Salmonella* enterocolitis who are severely

ill and suspected of being bacteremic. The threshold for antimicrobial treatment is also decreased in those at increased risk for severe illness (e.g., infants, the elderly, patients with sickle cell disease, immunosuppressed individuals). As an example, in adults, ciprofloxacin, 500 mg every 12 hours orally or 400 mg every 12 hours intravenously for 3 to 5 days, or until defervescence, has been widely used. An extended-spectrum cephalosporin such as ceftriaxone is an alternative. In the presence of gross bloody diarrhea, antimicrobial therapy should be withheld until the possibility of *E. coli* O157:H7 infection has been eliminated because antimicrobial therapy may increase the frequency of hemolytic-uremic syndrome.

Other agents, such as amoxicillin and trimethoprim-sulfamethoxazole, have also been widely used in severely ill adults. However, many strains of *Salmonella* are now resistant to these agents.

Enteric Fever

Resistance to the traditional first-line antimicrobial agents (ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole) has emerged worldwide among the salmonellae causing enteric fever. Consequently, alternative antimicrobial agents are now preferred.

The fluoroquinolones have become the agents of choice for the treatment of enteric fever, for several reasons.[1] They can be administered orally and have high bioavailability, they concentrate in bile and the bowel, and they often retain activity against multidrug-resistant strains of *S.* Typhi and other causes of enteric fever. Most important, the fluoroquinolones have proved to be effective in the treatment of enteric fever, even with short courses (e.g., 3 to 7 days). Cure rates exceed 95%, and relapse and chronic fecal carriage after therapy are uncommon. Ciprofloxacin (500 mg orally twice a day) for 7 to 14 days has been the fluoroquinolone of choice for enteric fever. If a patient cannot tolerate oral therapy, the fluoroquinolones can be administered intravenously. Reduced susceptibility to fluoroquinolones, often associated with nalidixic acid resistance, is increasingly reported in *S.* Typhi strains both in the United States and elsewhere and is associated with treatment failure. Consequently, it is recommended that all isolates be tested in vitro against nalidixic acid; ideally, the minimal inhibitory concentration of the fluoroquinolone to be used should also be determined. If decreased fluoroquinolone susceptibility is suspected or demonstrated, an extended-spectrum cephalosporin (e.g., intravenous ceftriaxone) or azithromycin is indicated.

Extended-spectrum cephalosporins such as ceftriaxone are reliable agents for the treatment of enteric fever. Ceftriaxone dosed at 1 to 2 g every 12 to 24 hours for adults and 75 mg/kg/day for children, given intravenously or intramuscularly for 10 to 14 days, results in cure rates of 95%. Resistance to ceftriaxone has been described in clinical strains of *S.* Typhi, but this occurs rarely.

If the *Salmonella* isolate is shown to be susceptible by antimicrobial susceptibility testing, ampicillin, chloramphenicol, or trimethoprim-sulfamethoxazole may be considered. The ampicillin dose is 25 mg/kg intravenously every 6 hours. The use of chloramphenicol should be weighed against the risk of bone marrow toxicity. The chloramphenicol dose is 50 mg/kg/day orally, divided into four doses. Chloramphenicol can be given intravenously at the same dose if oral therapy is not possible. Trimethoprim-sulfamethoxazole (4/20 mg/kg intravenously or orally every 12 hours) is given for 10 to 14 days.

Azithromycin (10 mg/kg/day orally for 7 days) is effective in the treatment of patients with uncomplicated typhoid fever caused by multidrug-resistant strains.[2] The oral route of administration makes it a particularly attractive choice in settings where multidrug resistance is common and intravenous extended-spectrum cephalosporins are impractical, unavailable, or too expensive.

Patients often require supportive care with intravenous saline, correction of electrolyte and acid-base disturbances, and, in the setting of intestinal bleeding, blood transfusion. If perforation is suspected, abdominal imaging should be performed to evaluate for free air. If perforation seems likely, laparotomy should be performed as soon as possible to repair the perforation. In the setting of perforation, antimicrobial therapy should be broadened to cover bowel flora.

Steroid therapy is beneficial in some patients with severe enteric fever and coma, delirium, or shock. Dexamethasone is administered at doses of 3 mg/kg initially, followed by 1 mg/kg every 6 hours for 48 hours. Steroids can mask the signs and symptoms of abdominal perforation and should not be continued for more than 48 hours. Salicylates should be avoided.

Relapses of typhoid fever may be treated with the same antimicrobial regimen as the initial attack.

Bacteremia

The agents of choice to treat *Salmonella* bacteremia are the fluoroquinolones, such as ciprofloxacin, and the extended-spectrum cephalosporins, such as ceftriaxone. Typical doses are ciprofloxacin 400 mg every 12 hours intravenously and ceftriaxone 1 to 2 g every 12 to 24 hours intravenously. When the salmonellae are known to be susceptible, ampicillin 1 to 2 g intravenously every 4 to 6 hours or trimethoprim-sulfamethoxazole 8 mg/kg/day (of the trimethoprim component) intravenously can be used. Chloramphenicol is another option. Antimicrobial susceptibility testing is necessary because of the emergence of infections resistant to the fluoroquinolones or extended-spectrum cephalosporins.

In cases of sustained bacteremia, the possibility of endovascular infection should be investigated. For transient bacteremia or bacteremia without localization, therapy is continued for 7 to 14 days. With localization to bone, aneurysms, heart valves, and various other sites, antimicrobial therapy should be given for much longer periods (e.g., 6 weeks). Surgical drainage, removal of foreign bodies, or resection of an aneurysm is often necessary to cure localized infection. The possibility of schistosomiasis should be considered and treated, when present, in patients with sustained *Salmonella* bacteremia. Patients with HIV infection tend to experience repeated relapses after treatment courses for *Salmonella* bacteremia. In this group, initial treatment with ciprofloxacin for 2 weeks or longer is recommended. Long-term suppressive therapy has been suggested for those experiencing frequent relapses.

Carriers

Chronic carriers (i.e., >1 year) of salmonellae other than *S.* Typhi are rare. Stools of convalescent carriers spontaneously become negative over a period of weeks to months, and no therapy should be given. The rare chronic carrier of nontyphoidal serotypes (usually infected with *S.* Paratyphi *A, B,* or *C*) may be treated with a fluoroquinolone, amoxicillin, or trimethoprim-sulfamethoxazole in the doses listed later for 4 to 6 weeks. Patients who experience relapse usually have gallbladder disease (most often calculi) and will not be cured with antimicrobial therapy alone. Cholecystectomy plus antimicrobial therapy may cure these patients, but it is doubtful that the carrier state per se is a sufficient indication for cholecystectomy.

Chronic fecal carriers of *S.* Typhi can be treated with ciprofloxacin (500 to 750 mg twice daily) for 6 weeks or with amoxicillin at doses of 6 g/day in three to four divided doses plus probenecid 2 g/day in divided doses for 6 weeks. Trimethoprim-sulfamethoxazole (160/800 mg twice daily) plus rifampicin (300 mg twice daily) for 6 weeks may be considered as an alternative regimen. Patients with persistent urinary carriage and *S. haematobium* infection should be treated with praziquantel before eradication of *S.* Typhi is attempted. For patients with persistent carriage and anatomic abnormalities (e.g., gallstones), cholecystectomy combined with antimicrobial therapy is often necessary. For patients with persistent carriage despite adequate antimicrobial therapy and without an identifiable anatomic abnormality, chronic suppressive therapy may be considered. It should be noted that chronic carriers who do not prepare food and who practice adequate personal hygiene usually do not constitute a public health hazard. Therefore, after the institution of appropriate personal hygienic precautions, and in the absence of evidence of a chronic carrier infecting others, cholecystectomy is probably not indicated to eradicate the carrier state.

PREVENTION

Salmonella infection is best prevented by protecting the water supply, preventing fecal contamination during food production, cooking and refrigerating foods, pasteurizing milk and milk products, and handwashing before preparing foods. Travelers should judiciously avoid consuming untreated water, including ice, raw vegetables, and fruits. Food should be cooked or peeled, and drinks should be boiled, carbonated, or commercially bottled. The widespread presence of salmonellae in the animal kingdom means that reducing the risk for *Salmonella* infections requires a multifaceted approach.

There is no vaccine for *Salmonella* infection other than that for *S.* Typhi. Travelers should be vaccinated before going to areas that are endemic for typhoid fever. Two vaccines are available in the United States. One is the typhoid Vi capsular polysaccharide vaccine, which is administered as a single intramuscular injection, with booster doses given every 2 years if needed. This vaccine provides a degree of herd protection against typhoid fever when used at the population level. The other licensed typhoid fever vaccine is the oral live attenuated Ty21a vaccine. Revaccination is necessary every 5 years, if indicated. Ty21a vaccine should not be used in immunocompromised persons or those receiving antimicrobials. Both these vaccines confer greater than 75% protective efficacy. Efforts are under way to develop oral typhoid vaccines that are effective in young children.

Vaccines afford only partial immunity to typhoid fever. Persons who have been vaccinated should still restrict their diets to avoid potentially contaminated food and fluids. When cases of imported typhoid are identified in the United States, the local health department should be informed and will monitor stool cultures. Typhoid fever acquired in the United States is typically investigated by the public health department to identify potential sources and chronic carriers.

PROGNOSIS

Mortality in patients with *Salmonella* enterocolitis is rare; infants and the elderly are at greatest risk, with death occurring as a result of dehydration and

electrolyte imbalance. Mortality from *Salmonella* bacteremia is not uncommon and is most likely to occur in the very young, the very old, the malnourished, and the immunocompromised. *S.* Choleraesuis bacteremia has a very high case-fatality rate (20 to 30% if untreated) compared with other *Salmonella* serotypes.

Before the advent of antimicrobial therapy, typhoid fever had a case-fatality rate of 15 to 20%. This rate has been reduced to less than 1% in industrialized countries. However, the case-fatality rate remains high in some developing countries. In treated patients, the temperature usually returns to normal after 3 to 5 days of therapy, but this may take longer in patients treated with extended-spectrum cephalosporins than in those treated with fluoroquinolones and in those infected with isolates with decreased fluoroquinolone susceptibility who are treated with ciprofloxacin.

In the era before antimicrobial therapy, 5 to 10% of patients who recovered from typhoid fever had relapses. Relapses continued to occur in 10 to 15% of patients treated with chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole, but this seemed to be much less frequent (<5%) in those treated with ceftriaxone and fluoroquinolones. Intestinal bleeding or perforation occurs in about 5% of patients. With perforation, mortality rates of 10 to 30% have been reported. Up to 3% of patients recovering from *S.* Typhi infection become chronic fecal carriers.

SHIGELLOSIS

GERALD T. KEUSCH

DEFINITION

Shigellosis is an acute infection of the large bowel characterized by mucosal inflammation and fever. Clinical disease ranges from watery diarrhea to bloody diarrhea or dysentery and a triad of signs and symptoms: multiple small-volume bloody stools per day, abdominal cramping, and tenesmus, a painful straining with the urge to defecate.

The Pathogen

The etiologic agents of shigellosis are gram-negative bacilli of the family Enterobacteriaceae, tribe Escherichieae, and genus *Shigella*. The organism is so closely related to *Escherichia coli* (Chapter 312) that if it were discovered today, *Shigella* would be classified as distinct serotypes of *E. coli*.

EPIDEMIOLOGY

In the United States, approximately 10,000 to 15,000 confirmed cases of shigellosis are reported to the Centers for Disease Control and Prevention (CDC) each year. The incidence has been slowly diminishing for the past 3 decades, from 6.4 per 100,000 per year between 1968 and 1988 to 5.6 per 100,000 per year between 1989 and 2002; an all-time low of 3.5 per 100,000 was reported in 2006 (the most recent year for which statistics are available). About one third of cases occur in infants and children younger than 5 years, commonly associated with daycare centers, where hygiene is difficult to maintain. The majority of infections are due to *Shigella sonnei,* which is true in other developed countries but not in most developing countries. Because most cases are not diagnosed microbiologically, most infections go unreported. The CDC estimates that 450,000 cases of *Shigella* infection occur each year in the United States, primarily in the form of self-limited watery diarrhea. The small inoculum required to cause infection and disease, from 10 to 10,000 organisms, has been demonstrated in experimental human infections. This is why shigellosis is most often transmitted from person to person via organisms from stool carried on the hands and transmitted to another person or an object subsequently handled by a susceptible individual. It also explains why one case in a family is associated with transmission to 20 to 40% of household members, with children more likely to develop clinical illness than adults as a result of their more limited prior experience with the organism. Fecal contamination of food or water can also be involved, and in settings where there is open defecation and no sanitary disposal of feces, flies can transmit the organism to food or water, resulting in larger outbreaks. In the United States, food-borne shigellosis appears to be increasing in frequency, generally related to an infected food handler. Several recent multicountry outbreaks of *S. sonnei* due to contaminated fresh foods shipped from Africa or Southeast Asia demonstrate how globalization of the food supply can readily globalize infection with particular strains of *Shigella*. This has important implications for the importation of antibiotic-resistant strains from areas of the world where the prevalence is particularly high. In the United States, contamination of swimming pools or bathing areas, usually by young children harboring the organism who defecate in the water, can result in common source outbreaks. All these routes are involved in complex humanitarian emergencies such as floods, landslides, earthquakes, or the gathering of refugees of conflict into crowded camps with limited sanitary facilities.

Shigella dysenteriae and *Shigella flexneri* often cause more severe illness, resulting in bloody diarrhea or dysentery. The majority of shigellosis cases in developing countries are due to *S. flexneri* strains, with an important component due to *S. dysenteriae* type 1. *Shigella boydii* is found primarily in the Indian subcontinent and resembles *S. sonnei* more than *S. dysenteriae* type 1 or *S. flexneri* in terms of virulence. These four species cause disease of different severity, with *S. dysenteriae* type 1 being most severe, *S. flexneri* next, *S. boydii* distinctly less so, and *S. sonnei* the least severe, presenting primarily as watery diarrhea. Whenever there is severe underlying childhood malnutrition, however, even *S. sonnei* can cause lethal illness.

In the United States, the incidence peaks in summer and fall. There is no gender difference except among young adults, where females are infected more often, presumably because of closer contact with sick children. In young adults, shigellosis is also transmitted through anal-oral sex practices, most often among men who have sex with men, and it is more commonly due to *S. flexneri* than *S. sonnei*, the reverse ratio observed in the general population. In developing countries, seasonal peaks occur in the rainy season, when organisms from open defecation can be washed into the water used for drinking, or in the dry season, when water for personal hygiene is scarce. Asymptomatic carriage of organisms is limited to a few weeks. However, because an etiologic diagnosis of *S. sonnei* is rarely made, except in common source outbreaks investigated by local, state, or federal public health officials, convalescent carriers often return to their normal activities while still able to transmit infection. This may account for the predilection for outbreaks to occur in daycare centers.

PATHOBIOLOGY

When *Shigella* exit an infected host in feces, they are resistant to acid pH. This facilitates their ability to survive gastric acid and accounts in large part for the small inoculum required. Once past the stomach, the organisms turn off the genes governing acid resistance and turn on the genes that allow them to invade the host's colon. *Shigella* appear to first gain entry into M cells overlying the lymphoid Peyer's patches; they are then transcytosed to the lamina propria, where they are ingested by macrophages and induce inflammatory cytokines, leading to the migration of polymorphonuclear leukocytes, which force open the tight junctions between epithelial cells. This allows many more organisms to gain access to the basolateral membrane of the colonic epithelial cells, where they induce the host cells to ingest them by a mechanism

resembling phagocytosis. *Shigella* then lyse the phagocytic vesicle to enter the cytoplasm and multiply; although they are nonmotile, they use their capacity to cross-link actin to propel themselves to the host cell surface. There, by the induced phagocytosis-like mechanism, they pass laterally from one epithelial cell to another. The inflammation and death of contiguously invaded host epithelial cells lead to mucosal ulcerations and further exudation of blood and leukocytes into the colonic lumen. Mucosal inflammation and ulceration are the characteristic pathology caused by *Shigella*. The difference between infection by one species versus another is the severity of the process, which is proportional to the severity of the illness they cause.

The attributes of virulence are present in a large virulence plasmid present in all *Shigella* and in enteroinvasive *E. coli* serotypes capable of causing a similar clinical illness. The virulence plasmid encodes the proteins for a type 3 secretion system that is capable of transferring microbial effector proteins into the host cell; these proteins regulate the cytoskeleton of the host cell to ingest the organism. Once inside the epithelial cell, shigellae are sequestered from host immune responses. *S. dysenteriae* type 1 also produces a chromosomally encoded toxin, Shiga toxin, which inhibits protein synthesis and directly causes cell death. It is one important reason why infection due to this species is so severe. Structurally and antigenically similar toxins are produced by certain *E. coli*, notably serotype O157:H7, responsible for cases of hemorrhagic colitis (Chapter 312). All Shiga toxin–producing organisms are known causes of hemolytic-uremic syndrome (HUS; Chapter 175), a potentially lethal complication of infection due to the toxin's effects on vascular endothelium within the kidneys.

CLINICAL MANIFESTATIONS

Infections due to *S. sonnei* or *S. boydii* typically present after an incubation period of 1 to 3 days with fever and mild to moderate watery diarrhea (Table 317-1). They do not cause serious dehydration and resolve without treatment in 3 to 5 days. However, if the stool is examined under the microscope, many white and red blood cells are visible, indicative of the underlying inflammation of the mucosa. When the inflammation is more severe, as with *S. flexneri,* the watery diarrhea turns bloody and may progress to dysentery, with its characteristic small-volume bloody, mucoid stool passed many (10 to >40) times per day, abdominal cramps, and tenesmus. The most severe infections due to *S. dysenteriae* type 1 progress rapidly from watery to bloody diarrhea and frequently to frank dysentery. Bacteremia with the infecting strain or other enteric flora occurs in up to 10% of cases of severe dysentery due to *S. dysenteriae* type 1 and in some patients with *S. flexneri* infection. Intense mucosal inflammation can result in toxic megacolon, associated in many patients with leukemoid reactions and HUS. Colonic perforation and pancolitis are rare complications and may require surgical intervention. In resource-limited settings, where post-colectomy management may be difficult to ensure, conservative management with fluids and antibiotics or limited surgery to oversew a perforation is the prudent choice; however, mortality may still be as high as 50%. In young children, rectal prolapse may occur due to the intense proctitis, straining to pass stool, and less well developed mesenteric support for the rectosigmoid colon. A rapid rise in temperature can lead to a seizure, distinguished from typical febrile seizures by the older age of the child and the fact that more than one seizure is very uncommon. Patients may become obtunded or comatose, usually with *S. dysenteriae* type 1 or *S. flexneri* infections. This is often associated with hypoglycemia, due to poor food intake and inadequate gluconeogenesis, or hyponatremia, due to inappropriate secretion of antidiuretic hormone. Anorexia may be intense and prolonged. Combined with ongoing catabolism of host muscle protein associated with excessive pro-inflammatory cytokine production and protein-losing enteropathy due to colitis, this always results in some degree of protein-energy malnutrition (Chapter 222). Even with adequate protein-containing and energy-dense diets post infection, replacement of nutrient stores may take as long as four times the duration of the clinical illness. This is more problematic in developing countries where the diet is poor. Hence, full nutritional recovery may not occur before the next infection develops, causing further nutritional deterioration. Because of its prolonged metabolic effects, shigellosis is often the precipitating cause of severe protein-energy malnutrition or kwashiorkor. *Shigella* infection is also associated with reactive arthritis and other autoimmune inflammatory manifestations such as tendinitis, conjunctivitis, uveitis, urethritis, or erythema nodosum, a constellation of findings previously termed *Reiter's syndrome* (Chapter 273). This is most common in individuals positive for HLA-B27 antigen and may be a consequence of molecular mimicry. Routine laboratory studies document leukocytosis with many immature "band" forms, especially in patients with bloody diarrhea or dysentery, and this may progress to a leukemoid reaction with thrombocytopenia and microangiopathic hemolytic anemia. With the development of HUS (Chapter 175), the biochemical manifestations of renal failure are present.

DIAGNOSIS

Shigellosis presenting with fever and watery diarrhea is clinically indistinguishable from the many other causes of watery diarrhea unless the stool is examined microscopically to demonstrate the presence of red and white blood cells or *Shigella* infection is confirmed microbiologically. Bloody diarrhea or dysentery in patients in the developed world is most commonly due to *S. flexneri* or a Shiga toxin–producing *E. coli,* such as serotype O157:H7, and less commonly due to *Campylobacter jejuni,* nontyphoid *Salmonella* species, or, rarely, *Yersinia enterocolitica* or *Entamoeba histolytica.* In patients who have recently received antibiotics, bloody diarrhea is often the consequence of *Clostridium difficile* (Chapter 304). In developing countries, *S. flexneri* and *S. dysenteriae* type 1 are the most common causes of bloody diarrhea or frank dysentery. Although more sophisticated methods of diagnosis are available, including polymerase chain reaction or enzyme-linked immunoassay (ELISA) or other rapid immunoassays, the standard method remains microbiologic culture. For a genus capable of causing such severe illness, *Shigella* species are remarkably fragile outside the intestine. Culture is most often positive when stool is processed rapidly; this is best done at the bedside, and stool samples are better than rectal swabs. Using more than one selective culture medium (e.g., MacConkey and xylose-lysine-deoxycholate or *Salmonella-Shigella* agar) and obtaining multiple cultures can increase the yield. Initially, laboratory screening is based on the failure of *Shigella* species to ferment lactose. Subculture to differential media such as triple sugar iron confirms lactose negativity and the ability to ferment glucose anaerobically, while the lack of motility or production of H_2S distinguishes the putative isolate from *Salmonella* species. Specific diagnosis can then be made using standard serologic methods for *Shigella* O antigens. In the case of mild watery

TABLE 317-1 CLINICAL SYNDROMES AND COMPLICATIONS IN SHIGELLOSIS

STAGE	TIME OF APPEARANCE AFTER ONSET OF ILLNESS	SYMPTOMS AND SIGNS	PATHOLOGY AND PATHOGENESIS
Prodrome	Earliest findings	Fever, chills, myalgias, anorexia	None or early colitis
Watery diarrhea	0-3 days	Fever, abdominal cramps, loose stools	Colitis with fecal leukocytes and erythrocytes
Bloody diarrhea	1-3 days	Frequent stools containing blood and mucus, abdominal cramps and tenderness, fever, anorexia	Colitis with fecal leukocytes and erythrocytes
Dysentery	1-5 days	Frequent small-volume stools consisting of blood, mucus, and pus; severe abdominal cramps; tenesmus	More extensive colitis with crypt abscesses and mucosal ulcerations
Acute complications	3-7 days	Seizures, obtundation, bacteremia, colonic obstruction, mucosal perforation, peritonitis	Severe colitis, terminal ileitis
Additional acute complications due to infection with *Shigella dysenteriae* type 1	3-7 days	Toxic megacolon, leukemoid reaction, hemolytic-uremic syndrome	Severe colitis, expression of Stx toxin
Postinfectious syndromes	1-3 wk	Reactive arthritis, with or without urethritis and conjunctivitis	Autoimmune inflammatory response, most common in individuals expressing HLA-B27 antigen

diarrhea due to *S. sonnei,* the patient is often recovered by the time the laboratory results are available, so they are of little use in guiding treatment. Yields are maximized when patients with bloody diarrhea or dysentery are studied. These results are valuable for the patient, to select empirical treatment, and for epidemiologic purposes when antibiotic sensitivity is also determined, to track the emergence of antibiotic resistance.

TREATMENT

Because of the mild nature of *S. sonnei* infection in well-nourished children, cultures are not obtained, the specific diagnosis is typically unknown, and no treatment is required. Although it might be sensible from a public health perspective to eliminate convalescent carriers with antibiotic treatment to prevent subsequent transmission, such as in the setting of daycare centers, it cannot be justified because of *Shigella*'s predilection to acquire antibiotic resistance, resulting in the loss of valuable therapeutics to treat more severe illness. The CDC notes that because of the emergence of drug resistance, antibiotics should be reserved for more severe cases, even in outbreak settings. Some authorities have suggested that culture-positive patients—particularly food handlers, caretakers in daycare or clinical care settings, teachers or other school employees, and the immunocompromised—should be kept at home until three consecutive stool cultures are negative; however, this recommendation is unlikely to be followed in the vast majority of instances.

In the case of bloody diarrhea or dysentery, antibiotics are the mainstay of treatment. This is particularly problematic in developing countries, where many of the inexpensive, safe, and useful oral drugs, such as ampicillin and trimethoprim-sulfamethoxazole, have become ineffective because of drug resistance. Presently, a fluoroquinolone such as ciprofloxacin or azithromycin is reliable in most settings, but these drugs are expensive (particularly azithromycin). Parenteral ceftriaxone is very useful in severe illness. However, intravenous treatment requires hospitalization and monitoring and seriously increases the cost of treatment in both developed and developing countries.

In severe shigellosis, the prompt initiation of effective antibiotic treatment shortens the duration of illness and achieves a more rapid improvement in symptoms such as fever, cramps, and tenesmus. Evidence from Bangladesh in patients with *S. dysenteriae* type 1 infection also demonstrates that prompt treatment reduces the complication of HUS and presumably other complications due to colonic inflammation, such as megacolon, perforation, and rectal prolapse. In the United States and other developed countries, HUS is virtually exclusively associated with Shiga toxin–producing *E. coli.* The toxin genes in these *E. coli* are present on plasmids, in contrast to the chromosomal location of the *stx* gene in *S. dysenteriae* type 1, and are upregulated by commonly used antibiotics. Hence, most experts recommend withholding antibiotic treatment in patients with these *E. coli* infections.

Given the known epidemiology of antibiotic resistance among *Shigella* species, empirical therapy of adults with bloody diarrhea or dysentery can be initiated with ciprofloxacin 500 mg orally twice daily for 3 to 5 days. There is increasing evidence that shorter courses are sufficient, except perhaps for known or suspected *S. dysenteriae* type 1 infections, which should be treated with a full 5-day course. A reliable oral alternative is azithromycin, with an initial dose of 500 mg followed by 250 mg/day for 4 additional days. Depending on the epidemiology of resistance in specific geographic areas, ampicillin (500 mg orally four times daily for 3 days) or trimethoprim-sulfamethoxazole (160/800 mg combination twice daily for 3 days) may still be effective. Doses for young children are ciprofloxacin 10 mg/kg twice daily for 3 days; azithromycin 10 mg/kg on day 1, followed by 5 mg/kg for 4 more days; ampicillin 25 mg/kg four times daily for 5 days; and a pediatric syrup of trimethoprim-sulfamethoxazole containing 4/20 mg, respectively, twice daily for 5 days. Newer β-lactam antibiotics, such as amoxicillin or oral cephalosporins, are not recommended because initial studies have shown that they are less effective in vivo than predicted by in vitro drug sensitivity studies. This may be due to absorption and insufficient amounts in the intestinal lumen. Pivamdinocillin (mecillinam; marketed as Coactin) is effective but is not marketed in the United States. Nonabsorbable antimicrobial agents are contraindicated because effective treatment requires therapeutic levels of the drugs in both the lumen and the mucosal compartments.

In more severe infections, complications such as hypoglycemia or hyponatremia can be managed with appropriate glucose or saline given intravenously, but patients must be monitored by trained clinical staff. Colitis with toxic megacolon and intestinal perforation represent difficult problems, especially in the resource-poor settings where these complications are most likely to occur. Conservative medical or surgical management is best, even if not optimal. Renal failure due to HUS can generally be managed conservatively or with peritoneal dialysis, if available. Seizures are usually self-limited, and other neurologic complications respond to fluid and electrolyte management and correction of hypoglycemia and hyponatremia. Reactive arthritis is a greater problem, as it is an autoimmune response that occurs primarily in genetically susceptible individuals positive for HLA-B27 antigen. In addition to effective antibiotic treatment to eliminate the causative organism, chronic arthritis may require nonsteroidal anti-inflammatory agents, steroids, or inflammatory cytokine inhibitors. In the susceptible host, infection-induced reactive arthritis can result in troublesome destructive joint disease and requires ongoing medical management. Some evidence suggests that antimotility agents are contraindicated in shigellosis, particularly in cases of bloody diarrhea or dysentery in young children; these drugs may prolong contact between the organisms and the mucosa, thereby increasing microbial invasion and pathology, including toxic megacolon.

Because of the prolonged anorexia and catabolic responses in shigellosis, attention to nutrition is an important component of treatment.

PREVENTION

Personal hygiene, in particular handwashing after handling the diapers of infected children and before food preparation, the sanitary disposal of feces, and protection of food and water sources, is essential to limit the spread of shigellosis. Preventing fecal contamination of hands in daycare settings is particularly problematic because it is so difficult to stop young children from constantly exploring their world by bringing their fingers and potentially contaminated fomites to their mouths. In such settings, it is particularly important for the adult caretakers to observe good personal hygiene. Soap and water are sufficient for handwashing, but hand sanitizers work and may be more convenient. In places where soap is unavailable, even the use of water with sand or ash for scrubbing is useful. When the cause of an outbreak is known, keeping children away from daycare until their stool is negative, or separating infected children from the susceptible, is recommended but is not easy to ensure. Hygiene in the household of an index case, including handwashing and caution in the handling of soiled garments, caring for children with diarrhea, and food preparation, is essential to limit intrahousehold spread.

Vaccines, particularly for the more virulent species, would be useful. However, despite much effort, a safe and effective vaccine has not been developed or approved for general use. It is doubtful whether a vaccine for *S. sonnei* infection would be recommended for children in a developed country such as the United States, even if safe and effective, because the illness is so mild and self-limited and because other vaccines are more important to administer in the context of an increasingly antivaccine public. Such a vaccine might, however, be useful for travelers or those in the military who are deployed overseas. In contrast, effective and safe vaccines for *S. flexneri* or *S. dysenteriae* type 1 would be extremely useful in developing countries, where shigellosis accounts for a significant portion of the 1.5 million to 2.5 million deaths each year due to enteric infections. Our current understanding of immunity in shigellosis indicates that serotype-specific immunity is most important; however, whether this is best conveyed by antibody, whether immunoglobulin G or A, or by cell-mediated mechanisms remains uncertain. This has limited vaccine development efforts, which have focused on attenuated live oral vaccines; unfortunately, the vaccines most effective in inducing immunity have also been the most reactogenic, causing fever and often diarrhea in recipients. Current efforts are also directed toward killed whole cells, O antigen–protein conjugates, and subunit vaccines. Unless common protective antigens are identified, the most likely vaccine strategy will be based on a combination of serotype-specific antigens from the most common *S. flexneri* strains and *S. dysenterieae* type 1. We are a long way from having an approved vaccine for shigellosis.

PROGNOSIS

S. sonnei infection and most cases of *S. boydii* infection are mild and self limited, with no sequelae. Infection with *S. flexneri* or *S. dysenteriae* responds to proper treatment with antibiotics. When treatment is not effective, either a drug-resistant strain or another etiologic agent should be suspected. In some instances, severe shigellosis with pancolitis has been misdiagnosed as inflammatory bowel disease. This can be a disaster if the patient is treated with steroids. Early and effective treatment reduces the risk of complications such as HUS and probably megacolon and bowel perforation. Because of the autoimmune nature of reactive arthritis, early treatment might not prevent its occurrence but could mitigate its severity. Infection with one serotype of *Shigella* generally provides durable immunity to reinfection with the same strain, but it leaves the individual susceptible to other antigenically distinct strains and serotypes.

BRUCELLOSIS

ROBERT A. SALATA

DEFINITION

Bacteria of the genus *Brucella* cause disease with protean manifestations. Infection is transmitted to humans from animals as a consequence of occupational exposure or ingestion of contaminated milk products. Despite the attempt to institute effective control measures, brucellosis remains a significant health and economic burden in many countries.

The Pathogen

Brucellae are slow-growing, small, aerobic, nonmotile, nonencapsulated, non-spore-forming, gram-negative coccobacilli. *Brucella abortus, Brucella suis, Brucella melitensis,* and *Brucella canis* are best known to infect humans and are typed on the basis of biochemical, metabolic, and immunologic criteria. DNA hybridization analysis shows a high degree of homology among strains.

EPIDEMIOLOGY

Etiology

There are differences in virulence among the four major species. *B. abortus,* with a reservoir in cattle, is usually associated with mild to moderate sporadic disease; suppurative or disabling complications are rare. *B. suis* infection, resulting from swine contact, is often associated with destructive, suppurative lesions and may have a prolonged course. *B. melitensis,* with a reservoir in sheep, goats, and camels, may cause severe, acute disease and disabling complications. *B. canis,* spread to humans from infected dogs, causes disease with an insidious onset, frequent relapse, and a chronic course that is indistinguishable from that of infection related to *B. abortus.* Studies indicate that there are two new species, *Brucella pinnipediae and Brucella cetaceae,* related to seals and cetaceans, respectively. Two human cases of marine-associated *Brucella* infection have been reported. *Brucella microti,* with high pathogenicity, was recently isolated from the common vole, red fox, and soil. No instances of human infection have been reported. Brucellae are also potential agents for bioterrorism.

Incidence and Prevalence

More than 500,000 cases of brucellosis are reported yearly to the World Health Organization from 100 countries. *B. melitensis* infection accounts for the majority of cases, distributed primarily in the Mediterranean region (particularly Spain and Greece), Latin America, the Arabian Gulf, and the Indian subcontinent. *B. abortus* infection occurs worldwide but has been effectively eradicated in several European countries, Japan, and Israel. *B. suis* occurs mainly in the Midwestern United States, South America, and Southeast Asia, whereas *B. canis* infection is most common in North America, South America, Japan, and central Europe. Identification of the *Brucella* species recovered in humans can provide clues to the likely source of infection.

In animals, brucellosis is a chronic infection that persists for life. In association with effective control programs in animals, human brucellosis has decreased dramatically in the United States, from more than 6000 cases in 1947 to fewer than 200 cases each year since 1980. States reporting the greatest number of cases include Texas, California, Virginia, and Florida. In North America, brucellosis occurs mainly in the spring and summer and is more common in men, usually related to occupational exposure.

Brucella infection in the United States occurs mostly through direct contact with animals or their secretions in high-risk groups, including slaughterhouse workers, farmers and dairy workers, veterinarians, travelers to endemic areas, and laboratory workers handling the organisms. More than half the reported cases are associated with the meat-processing industry, particularly the kill areas, where infection is spread through abraded or lacerated skin; the conjunctiva, possibly by aerosolization; and, rarely, by ingestion of infected tissue. Many cases of *B. abortus* infection in veterinarians have resulted accidentally through exposure to the strain 19 vaccine used to immunize cattle. In the southern United States, 20% of feral swine are positive for *B. suis,* and human infections in hunters have been reported. *B. melitensis* infection, transmitted through the ingestion of goat's milk cheese, has been seen in U.S. travelers to and immigrants from Mexico. Brucellosis contracted abroad may not become symptomatic until the patient returns to the United States. Although persons with human immunodeficiency virus (HIV) infection are at risk for intracellular pathogens, the clinical manifestations of brucellosis in HIV-infected and noninfected individuals are similar in the few cases reported. There are increased reports of sexually transmitted brucellosis.

Brucellosis in pregnancy has been associated with spontaneous abortions, possible congenital abnormalities, and neonatal infections. Brucellosis in children accounts for only 3 to 10% of all reported cases worldwide; it is common in endemic areas (where it may account for 20 to 25% of cases) and is often a mild, self-limited process. Infection occurs most frequently in school-aged children and in familial outbreaks.

PATHOBIOLOGY

Pathogenesis

After penetrating the epithelial cells of human skin, conjunctiva, pharynx, or lung, *Brucella* organisms initially induce an exuberant polymorphonuclear neutrophil response in the submucosa. After ingestion of organisms by neutrophils and tissue macrophages, spread to regional lymph nodes occurs. If host defenses within the lymph nodes are overwhelmed, bacteremia follows. The usual incubation period between infection and bacteremia is 1.5 to 3 weeks. Bacteremia is accompanied by phagocytosis of free *Brucella* organisms by neutrophils and localization of bacteria primarily to the spleen, liver, and bone marrow, with the formation of granulomas.

If the inoculum is large and the patient receives no treatment, large granulomas may form, suppurate, and serve as a source of persistent bacteremia, with the potential for multiorgan spread. The primary virulence factor of *Brucella* appears to be cell wall lipopolysaccharide.

Both virulent and attenuated strains of *Brucella* are readily phagocytized by neutrophils after opsonization with normal human serum. Whole bacteria and extracts of *Brucella* species may inhibit neutrophil oxidative burst activity and degranulation. Intracellular killing of ingested bacteria has been demonstrated with *B. abortus* but not *B. melitensis;* this may explain differences in pathogenicity between these species. The major cell wall antigen and virulence factor of *Brucella* is the smooth lipopolysaccharide containing A and M antigens, which also dominates antibody production.

Immunity

Humoral factors may be important in the host defense against *Brucella.* Even in the absence of specific agglutinating antibody, normal human serum is bactericidal for *Brucella* organisms; *B. abortus* is more susceptible to serum lysis than is *B. melitensis.* The intracellular location within macrophages of the organism may provide a means for the bacteria to escape the lethal effects of serum. Specific serum agglutinating antibody has opsonic activity but does not correlate with the development of protective immunity.

A role for mononuclear phagocytes and cell-mediated immunity in brucellosis has been demonstrated. Protection against *Brucella* infection in animals is associated with preceding infection with *Listeria monocytogenes* or *Mycobacterium tuberculosis,* both of which stimulate cell-mediated immune mechanisms. Skin testing with *Brucella* proteins elicits a typical delayed hypersensitivity response in infected individuals. Macrophages, activated

TABLE 318-1 CLINICAL CLASSIFICATION OF HUMAN BRUCELLOSIS

CLASSIFICATION	DURATION OF SYMPTOMS BEFORE DIAGNOSIS	MAJOR SYMPTOMS AND SIGNS	DIAGNOSIS	COMMENTS
Subclinical	—	Asymptomatic	Positive (low titer) serology, negative cultures	Occurs in abattoir workers, farmers, and veterinarians
Acute and subacute	Up to 2-3 mo and 3 mo–1 yr	Malaise, chills, sweats, fatigue, headache, anorexia, arthralgias, fever, splenomegaly, lymphadenopathy, hepatomegaly	Positive serology, positive blood or bone marrow cultures	Presentation can be mild, self-limited *(B. abortus)* or fulminant with severe complications *(B. melitensis)*
Localized	Occurs with acute or chronic untreated disease	Related to involved organs	Positive serology, positive cultures in specific tissues	Bone or joint, genitourinary, hepatosplenic involvement most common
Relapsing	2-3 mo after initial episode	Same as acute illness but may have higher fever and more fatigue, weakness, chills, and sweats	Positive serology, positive cultures	May be extremely difficult to distinguish relapse from reinfection
Chronic	>1 yr	Nonspecific presentation but neuropsychiatric symptoms and low-grade fever most common	Low titer or negative serology, negative cultures	Most controversial classification; localized disease may be associated

with T helper 1 (T_H1)–type cytokines (e.g., interferon-γ, tumor necrosis factor-α, interleukin-1, interleukin-12), kill *Brucella.* Recent studies have shown that, despite high levels of T_H1 cytokine production, including interferon-γ, deficient effector phagocytic activity persists.

CLINICAL MANIFESTATIONS

Clinically, human brucellosis can be conveniently but arbitrarily divided into subclinical illness, acute or subacute disease, localized disease and complications, relapsing infection, and chronic disease (Table 318-1).

Subclinical Illness

Detected only by serologic testing, asymptomatic or clinically unrecognized human brucellosis often occurs in high-risk groups, including slaughterhouse workers, farmers, and veterinarians. More than 50% of abattoir workers and up to 33% of veterinarians have high anti-*Brucella* antibody titers but no history of recognized clinical infection. Children in endemic areas frequently have subclinical illness.

Acute and Subacute Disease

After an incubation period of several weeks or months, acute brucellosis may occur as a mild, transient illness (*B. abortus* or *B. canis*) or as an explosive, toxic illness with the potential for multiple complications (*B. melitensis*). Approximately 50% of patients have an abrupt onset over days, whereas the remainder have an insidious onset over weeks. Symptoms in brucellosis are protean and nonspecific. More than 90% of patients experience malaise, chills, sweats, fatigue, and weakness. More than 50% of patients have myalgias, anorexia, and weight loss. Fewer patients complain of arthralgias, cough, testicular pain, dysuria, ocular pain, or visual blurring. Likewise, few localizing physical signs are apparent. Fever, with temperatures often greater than 39.4° C (103° F), occurs in 95% of patients. An undulating or intermittent fever pattern is unusual. A pulse-temperature deficit (i.e., relative bradycardia) may occur. Splenomegaly is present in 10 to 15% of cases, and lymphadenopathy occurs in up to 14% (axillary, cervical, and supraclavicular locations are most frequent, related to hand wound or oropharyngeal routes of infection); hepatomegaly is less frequent. Other laboratory findings in acute or subacute disease may include mild anemia, lymphopenia or neutropenia (especially with bacteremia), lymphocytosis, thrombocytopenia, or (rarely) pancytopenia. The majority of infected individuals recover completely without sequelae if the appropriate diagnosis is made and prompt therapy is initiated.

Localized Disease and Complications

Brucella organisms can localize in almost any organ, but they most commonly localize in bone, joint, central nervous system, heart, lung, spleen, testis, liver, gallbladder, kidney, prostate, pancreas, and skin. Localized disease may occur simultaneously at multiple sites. Localized complications most often appear in association with a more chronic course of illness, although complications may occur with acute disease caused by *B. melitensis* or *B. suis.* In the United States, localized disease is most frequently related to *B. suis.* Osteoarticular complications are most frequent and are reported in 10 to 80% of series. The most common site is sacroiliitis in younger persons and spondylitis in older persons. Vertebral osteomyelitis (most often in the lumbar area) is also well recognized and can be associated with paravertebral, epidural, and psoas abscesses.

Relapsing Infection

Up to 10% of patients with brucellosis experience relapses after antimicrobial therapy. Relapses usually occur 3 to 6 months after completion of therapy but may be seen up to 2 years after treatment. Relapses are often associated with antimicrobial resistance and the intracellular location of organisms, which protects the bacteria from certain antibiotics and host defense mechanisms. Relapsing infection is difficult to distinguish from reinfection in high-risk groups with continued exposure. Studies have shown that relapses are associated with inappropriate or insufficient antimicrobial therapy, positive blood cultures on initial presentation, and an acute onset of disease.

Chronic Disease

Disease with a duration of more than 1 year has been called *chronic brucellosis.* A majority of patients classified as having chronic brucellosis really have persistent disease caused by inadequate treatment of the initial episode, or they have focal disease in bone, liver, or spleen. About 20% of patients diagnosed with chronic brucellosis complain of persistent fatigue, malaise, and depression; in many respects, this condition resembles chronic fatigue syndrome. These symptoms are frequently not associated with clinical, microbiologic, or serologic evidence of active infection and may represent a preexisting psychoneurosis.

DIAGNOSIS

Culture

Many more common illnesses mimic the clinical presentation of brucellosis, and a thorough history is needed, including occupation, travel to endemic areas, avocations, and ingestion of at-risk food and beverages. The most conclusive means of establishing the diagnosis of brucellosis is positive culture from normally sterile body fluid or tissue. Rates of positive cultures have ranged from 15 to 90%, depending on the methods employed and the specimen type. The culture of *Brucella* organisms is potentially hazardous to laboratory personnel.

In acute brucellosis, positive blood cultures are obtained in 10 to 30% of cases (as high as 85% with *B. melitensis*). Blood culture positivity decreases with increasing duration of illness. With *B. melitensis* infection, bone marrow cultures are of higher yield than blood cultures. Blood processed in radiometric detection or isolator systems may yield positive cultures in less than 10 days. With localized brucellosis (e.g., lymph nodes, spleen, liver, skeletal system), cultures of purulent material or tissues usually yield *Brucella* organisms. Culture of cerebrospinal fluid is positive in 45% of patients with meningitis. Antibody against *Brucella* may be demonstrated in cerebrospinal fluid by enzyme-linked immunosorbent assay (ELISA).

Standard Tube Agglutination

In the absence of microbiologic confirmation, a presumptive diagnosis can be made by history and serology. The most frequently used test is the standard tube agglutination (STA) test, measuring antibody to *B. abortus* antigen.

TABLE 318-2 TREATMENT FOR BRUCELLOSIS

	TREATMENT	COMMENTS
Acute, with no endocarditis or central nervous system involvement	Doxycycline (200 mg/day) plus rifampin (600-900 mg/day) for 6 wk	Treatment of choice by World Health Organization; widely used; low rate of relapse; intramuscular administration of streptomycin may be difficult
	or	
	Tetracycline (2 g/day) for 6 wk plus streptomycin (1 g/day) or gentamicin for 1 wk	Combination therapy still preferred; fluoroquinolones plus rifampin is an alternative
	Alternative agents: chloramphenicol, fluoroquinolones, trimethoprim-sulfamethoxazole, imipenem	
In children	Trimethoprim-sulfamethoxazole plus rifampin	
Central nervous system	Doxycycline plus rifampin and trimethoprim-sulfamethoxazole	Third-generation cephalosporin can be substituted if susceptible in vitro
Localized	Surgically drain abscesses plus antimicrobial therapy for ≥6 wk	
Brucella endocarditis	Bactericidal drugs; early valve replacement may be necessary	Possible aortic valve destruction and/or major arterial emboli

A four-fold or greater rise in titer to 1 : 160 or higher is considered significant. A presumptive case is one in which the agglutination titer is positive (1 : 160) in single or serial specimens, with symptoms consistent with brucellosis. By 3 weeks of illness, more than 97% of patients demonstrate serologic evidence of infection. This test detects antibodies to *B. abortus, B. suis,* and *B. melitensis* but not to *B. canis.* Serologic confirmation of *B. canis* infection requires *B. canis* or *Brucella ovis* antigen. Despite adequate antibiotic treatment, significant STA titers can persist for up to 2 years in 5 to 7% of cases. Because the STA titer may remain elevated, it is not useful in differentiating relapsing infection from other febrile illnesses in patients with past *Brucella* infections. Individuals with subclinical infection may demonstrate significant STA titers. In chronic localized brucellosis, STA titers may appear absent or low owing to a prozone phenomenon. This prozone effect appears to be related to the presence of immunoglobulin G or immunoglobulin A blocking antibodies; it can be eliminated if dilutions are carried out to at least 1 : 1280. False-positive STA titers related to immunologic cross-reactivity have been associated with *Brucella* skin testing, cholera vaccination, or infection with *Vibrio cholerae, Francisella tularensis,* or *Yersinia enterocolitica.*

Other Tests

Certain newer antibody tests, including ELISA, are more sensitive and specific than STA and are being used more widely. Preliminary studies of the diagnosis of brucellosis using polymerase chain reaction with random or selected primers of blood and other fluids or tissues have been promising, but additional evaluation is necessary, and access to this diagnostic technology is still limited.

TREATMENT

Rx

Effective treatment of *Brucella* infection requires antibiotics that can penetrate intracellularly, are available for prolonged therapy to prevent relapse, and are bactericidal in order to treat central nervous system infection and endocarditis. There is still considerable debate over which antibiotic regimen is superior, but the combination of oral doxycycline for 45 days or 8 weeks plus intramuscular gentamicin for 5 to 7 days is equally effective as traditional therapy using doxycycline for 45 days plus streptomycin for 14 days.■ The World Health Organization recommends doxycycline plus rifampin orally for 6 weeks. This regimen is less effective for cases of spondylitis. Monotherapy with fluoroquinolones has been disappointing, and if these agents are used, they should always be combined with another active agent. Recent in vitro studies have demonstrated significant activity and synergy of tigecycline with gentamicin and rifampin; these observations must be supported in clinical trials. Recommendations are given in Table 318-2.

PREVENTION

The control of human brucellosis is directly related to prevention programs in domestic animals and the avoidance of unpasteurized milk and milk products. In slaughterhouses, important means of prevention include careful wound dressing, the wearing of protective glasses and clothing, the prohibition of raw meat ingestion, and the use of previously infected (immune) individuals in high-risk areas. Work is ongoing to find an effective vaccine for humans. There is controversy about the effectiveness of postexposure antimicrobial prophylaxis.

PROGNOSIS

Brucellosis that is treated appropriately within the first month of symptom onset is curable. Acute brucellosis often produces severe weakness and fatigue, and patients are frequently unable to work for up to 2 months. Immunity to reinfection follows initial *Brucella* infection in the majority of individuals. With early antimicrobial therapy, cases of chronic brucellosis or localized disease and complications are rare. Of the patients who die of brucellosis, 84% have endocarditis involving a previously abnormal aortic valve, often associated with severe congestive heart failure.

TULAREMIA AND OTHER *FRANCISELLA* INFECTIONS

WILLIAM SCHAFFNER

DEFINITION

Tularemia is an infectious zoonosis caused by *Francisella tularensis,* a small aerobic, pleomorphic, gram-negative bacillus. Many animal species harbor the organism, most prominently rabbits, squirrels, and muskrats. Humans acquire the infection through various means: direct contact with infected animal tissues, ingestion of contaminated water or meat, the bite of an

infected tick or deer fly, or breathing an aerosol of bacteria. Although *F. tularensis* is highly infectious and is a well-recognized risk to laboratory personnel manipulating culture plates of the organism, it is a paradox that the illness is not communicable from person to person. Edward Francis established that deer flies can transmit the infection from animals to humans and provided detailed descriptions of its clinical manifestations. Colloquially, the disease is often referred to as *rabbit fever* or *deer fly fever.*

The Pathogen

The organism occurs in two major subspecies (biovars). *F. tularensis* biovar *tularensis* (type A) is more virulent in animals and humans, has distinctive biochemical reactions (it produces acid from glycerol and has citrulline ureidase activity), and is the common North American biovar. In contrast, *F. tularensis* biovar *holarctica* (type B) is less virulent and occurs commonly in Europe and Asia. Type B is most frequently isolated from rodent species, including muskrats *(Ondatra zibethicus),* mice *(Mus musculus),* beavers *(Castor canadensis),* voles (*Microtus* species), and water voles *(Arvicola terrestris),* and has been associated with an outbreak of infection in wild-caught prairie dogs. Specific virulence factors for *F. tularensis* have not been identified.

EPIDEMIOLOGY

Tularemia has been reported in the United States, Canada, Mexico, Japan, and Europe, particularly Scandinavia. It has not been reported in the United Kingdom or the Southern Hemisphere. In the United States, reported cases diminished during the second half of the 20th century from a high of 2291 cases in 1939 to the approximately 125 cases reported annually at present. Tularemia has occurred in all the continental states, but four states account for 56% of reported cases: Arkansas, Missouri, Oklahoma, and South Dakota. The island of Martha's Vineyard off the coast of Massachusetts is also a focus of tularemia.

In the United States, tularemia is usually acquired from tick bites or from contact with infected animals, especially rabbits. Tick-associated cases now constitute the majority and occur during the summer. The most common vectors in the United States are the wood tick *(Dermacentor andersoni),* the dog tick *(Dermacentor variabilis),* and the Lone Star tick *(Amblyomma americanum).* A smaller peak of autumn-winter cases is a consequence of rabbit hunters skinning and eviscerating their game. Public health education materials aimed at decreasing the hazards of handling wild animals have contributed to the reduction of tularemia in hunters. Mosquitoes are the common vectors in northern Europe. Occasional individuals acquire infection from the bite of an infected animal or, more likely, from the bite of an animal whose mouth was contaminated from recently eating a diseased animal. The latter probably explains most instances of cat-bite tularemia.

Males experience a higher incidence of disease than females in all age groups, probably as a consequence of their greater exposure to the outdoors and animal-related activities and less use of protective measures against tick bites. Persons in all age groups are affected, with children 5 to 14 years of age and older adults most prominently represented. In the United States, American Indians/Alaska natives experience the highest annual incidence (0.5 per 100,000); whites have a lower risk (0.04 per 100,000), and African Americans and Asians/Pacific Islanders have the lowest occurrence of tularemia (≤0.01 per 100,000).

Although tularemia is usually a sporadic infection, outbreaks of disease have been traced to laboratory exposure, contaminated groundwater, muskrat handling, lawn mowing, and brush cutting. In the latter two cases, primary pneumonic tularemia apparently occurred when the affected individuals created an environmental aerosol by mowing grass and cutting brush that had been contaminated with *F. tularensis* excreted in the urine and feces of infected rodents. The organism can survive in water, mud, and straw for weeks to months.

Recently, interest in tularemia has been enhanced because of its potential use as a bioterrorism agent. Its high infectivity (as few as 10 organisms have induced pneumonic disease), its ease of dissemination, and the difficulty of rapidly diagnosing acute illness are characteristics that merit its inclusion among threat agents. Thus, tularemia must be reported immediately to local public health authorities. Unusual patterns of disease will be investigated for both conventional and bioterrorist sources.

PATHOBIOLOGY

F. tularensis can infect humans through several portals of entry, including the skin, mucous membranes, and gastrointestinal and respiratory tracts. It requires intracellular residence and can multiply within macrophages and other cells. After inoculation into the skin and subcutaneous tissue, local bacterial multiplication occurs and evokes a suppurative necrotic reaction characterized by an initial polymorphonuclear response, followed by an influx of macrophages and lymphocytes. These suppurative lesions evolve into granulomas. Bacteremia can occur both early and late during this process. The infection can disseminate to the lymph nodes, liver, spleen, lungs, and pleura. Viable *F. tularensis* can persist in tissues for long periods, contributing to the tendency to relapse after treatment.

CLINICAL MANIFESTATIONS

Classically, the clinical manifestations of tularemia have been separated into six categories: ulceroglandular, glandular, oculoglandular, typhoidal, oropharyngeal, and pneumonic. Although this classification has historic roots, it should not be used rigidly because many patients have features of several types. The course of illness is determined by the portal of entry, the degree of systemic involvement, and the dose and virulence of the infecting strain of *F. tularensis.*

The general features of tularemia are similar, regardless of the portal of entry. After exposure, the usual incubation period is 3 to 5 days (range, 1 to 21 days). The disease begins abruptly with the onset of fever (≥101° F), chills, malaise, and headache. Myalgia, vomiting, sore throat, and abdominal pain can also occur. Almost half the patients have a pulse rate that is substantially slower than would be anticipated based on the degree of fever (pulse-temperature dissociation). The fever may abate somewhat after 1 to 3 days, only to recur and continue along with other symptoms for 2 to 3 weeks. Untreated, weight loss, easy fatigue, and lymphadenopathy may persist for weeks longer.

Ulceroglandular Disease

Ulceroglandular disease is the form of infection most readily recognized by physicians. Along with fever and other constitutional symptoms, the patient calls attention to tender, swollen lymph nodes that drain an inoculation site. The nodes are usually axillary or inguinal, and a local lesion appears concurrently or 1 or 2 days before or after the lymphadenopathy. The lesions at the site of inoculation begin as small, red, tender, or painful papules that progress to pustules and then undergo necrosis to produce an ulcer with sharp, somewhat elevated edges and a flat base that becomes black. Untreated, the ulcers heal over a period of weeks and leave scars. Tick-induced infections produce lesions on the trunk, about the waist, and in the perineum, along with the expected local adenopathy. Children typically have occipital and cervical adenopathy from tick bites on the neck and in the hair. Animal exposure often produces lesions on the hands and forearms. Lesions may be multiple. Because the organisms evoke a localized granulomatous response, frank lymphangitis does not occur in uncomplicated tularemia, but an occasional patient manifests a chain of nodules in "sporotrichoid" fashion along the lymphatic drainage.

Patients with such apparently "localized" disease often have symptoms and findings indicating a more widespread infection. Sore throat with or without an erythematous pharynx occurs, as well as chest radiographic findings of patchy infiltrates in the lower lobes, pleural effusions, and hilar adenopathy.

Glandular and Typhoidal Disease

Glandular disease is essentially the same clinical syndrome as ulceroglandular disease, but without the local lesion. Thus, the patient has fever, constitutional symptoms, and lymphadenopathy. The local lesion may have been on a part of the body where it was not seen, or it may have been small and already healed by the time the patient sought medical care. Glandular disease accounts for only 3 to 20% of cases. Typhoidal disease does not show evidence of lymphadenopathy and is essentially characterized by fever of unknown cause. These illnesses evade diagnosis unless the physician specifically considers the possibility of tularemia and inquires about tick or animal exposure. Occasionally, the diagnosis is made fortuitously when a positive blood culture is reported.

Oculoglandular Disease

Oculoglandular disease is rare (<5% of cases) and occurs when the conjunctival sac is the portal of entry via an aerosol, splash, or contaminated fingers. It is almost always unilateral and can have a dramatic manifestation with inflamed, swollen eyelids, chemosis, and painful conjunctivitis. The palpebral conjunctiva often shows small yellow nodules and ulcers, counterparts to the skin lesions of ulceroglandular disease. The affected regional lymph nodes are those of the head and neck.

Oropharyngeal Disease

Oropharyngeal disease is also uncommon in the United States and occurs when the mucous membranes of the mouth and pharynx are the portal of entry. Contaminated water or food (inadequately cooked game meat) is the source. Painful exudative pharyngitis and tonsillitis, pharyngeal ulcers, and swollen retropharyngeal and cervical lymph nodes are seen.

Pneumonic Disease

Although pneumonia may be one aspect of the other tularemic syndromes, *pneumonic tularemia* refers to an illness that manifests as a distinctive pneumonia. It accounts for about 10% of reported cases and occurs from inhalational exposure. This is the form of the disease that would result from bioterrorism. In addition to fever and malaise, patients may have a dry cough, substernal discomfort, pleural pain, dyspnea, and sore throat. These pulmonary symptoms may not be very prominent in the context of the systemic illness. Hemoptysis is unlikely. The results of physical examination reflect the extent and distribution of the pneumonic process, which may range from barely evident to frank consolidation with pleural effusion. Radiographic findings range from modest peribronchial infiltrates early in the illness to distinctive bronchopneumonia with effusion. Hilar adenopathy is present in more than a third of cases. Sputum examination is not helpful. Pleural effusions generally contain more than 1000 lymphocytes/mm^3. Gram stains are negative, and pleural biopsies occasionally contain granuloma, thus inviting confusion with tuberculosis. Without a suggestive history of tick or animal exposure, patients with tularemic pneumonia may be thought to have poorly responding community-acquired pneumonia. Fluoroquinolone antibiotics are commonly used as empirical therapy in this circumstance to treat some patients with undiagnosed tularemia pneumonia.

DIAGNOSIS

The diagnosis of tularemia usually involves serologic testing with tube agglutination or microagglutination techniques. Antibody concentrations do not reach diagnostic levels until after the 11th day of illness. A single acute titer of 1 : 160 is considered presumptive; a confirmed diagnosis requires a fourfold rise in titer between acute and convalescent specimens. Titers of both immunoglobulin M and immunoglobulin G antibodies may remain elevated for many years after the illness.

Differential Diagnosis

The differential diagnosis of patients with tularemia is substantial. The local lesions can be confused with cat-scratch disease, brown recluse spider bites, *Mycobacterium marinum* infection, herpes simplex infection (Chapter 382), and even syphilis (Chapter 327) and chancroid (Chapter 309) when the lesions are in the perineum or on the penis. Pneumonic tularemia resembles common community-acquired pneumonia (Chapter 97), as well as less common infections such as psittacosis, legionellosis, and Q fever. The glandular and typhoidal forms can resemble typhoid fever (Chapter 316), brucellosis (Chapter 318), ehrlichiosis, and other illnesses accompanied by nonspecific fevers.

Routine laboratory studies do not provide specific results. Leukocyte counts may be within normal limits or elevated; thrombocytopenia, elevated liver enzymes, and sterile pyuria occur with some frequency. *F. tularensis* may be isolated from blood cultures and tissue specimens when media containing cysteine are used. Laboratory personnel should be notified when tularemia is suspected so that appropriate media can be used and to ensure that safeguards are in place to protect against the production of hazardous aerosols.

TREATMENT Rx

Because tularemia is a relatively uncommon disease, therapeutic recommendations are based on a combination of in vitro studies and accumulated clinical experience. The preferred antimicrobials are streptomycin and gentamicin; either one is given for 10 days. Streptomycin is given at a dose of 1 g intramuscularly twice daily. Gentamicin may be more readily available and is administered at a dose of 5 mg/kg intramuscularly or intravenously once daily. Both chloramphenicol and the tetracyclines have been used in the past to treat tularemia; however, use of both these bacteriostatic agents has resulted in higher rates of relapse than treatment with streptomycin or gentamicin. Because chloramphenicol may produce bone marrow toxicity, it is rarely used today. Doxycycline is administered at a dose of 100 mg intravenously twice daily for 14 days. In recent years, ciprofloxacin has been used successfully in a growing number of patients; the dosage is 400 mg intravenously twice daily for 10 days. Both these drugs can be switched to oral administration of the same doses as soon as tolerated by the patient.

PREVENTION

Prevention of tularemia entails minimizing exposure to ticks and avoiding direct exposure to wild animals. Tick protection includes clothing that extends to the wrists and ankles, regular inspection for attached ticks, and the use of insect repellents containing diethyltoluamide (DEET). Gloves should be worn when skinning and dressing game animals, especially rabbits, and all wild rabbit and other game meats should be cooked thoroughly.

A live, attenuated vaccine has been used in the past to provide some protection to researchers working with *F. tularensis.* The vaccine is not available commercially.

PROGNOSIS

Before treatment became available, acute tularemia often lasted as long as a month, followed by several months of debility. Mortality approached 10%. When appropriately diagnosed and treated, the mortality from tularemia is now 1% or less.

PLAGUE AND OTHER *YERSINIA* INFECTIONS

KENNETH L. GAGE

The genus *Yersinia* currently contains more than 15 species, only 3 of which are known to be significant human pathogens (*Yersinia pestis, Yersinia enterocolitica,* and *Yersinia pseudotuberculosis*). The remaining species are normally considered nonpathogenic and are most frequently isolated from environmental specimens, including fish, water, and fecal samples. Although these minor yersiniae have been identified primarily from environmental samples, they are occasionally recovered from patient samples, suggesting a possible role as human pathogens.

YERSINIA PESTIS

DEFINITION

Plague is a highly fatal flea-borne disease that is best known as the cause of the Black Death of the Middle Ages. Its etiologic agent, *Y. pestis,* is a gram-negative coccobacillus belonging to the family Enterobacteriaceae.

The Pathogen

Y. pestis is microaerophilic, nonmotile, and nonsporulating; it can exist as a facultative intracellular pathogen and exhibits bipolar staining with Wayson, Giemsa, and Wright stains (Fig. 320-1). It is fragile outside its hosts or vectors but can be grown within 24 to 48 hours on a variety of bacteriologic media at temperatures ranging from 4 to 40° C. *Y. pestis* lacks a true capsule but has a carbohydrate-protein envelope referred to as the *capsular* or *fraction 1 antigen.* Production of this antigen occurs only at temperatures above 33° C. Wild-type strains typically bear three plasmids with sizes of approximately 100 to 110 kilobases (kb), 70 to 75 kb, and 9.5 kb (19 kb if present as a

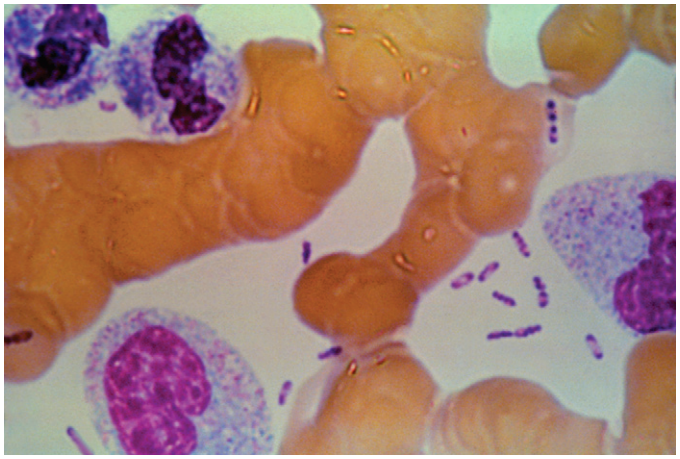

FIGURE 320-1. Wayson-stained blood smear from a fatal case of human septicemic plague. (Courtesy Centers for Disease Control and Prevention archives.)

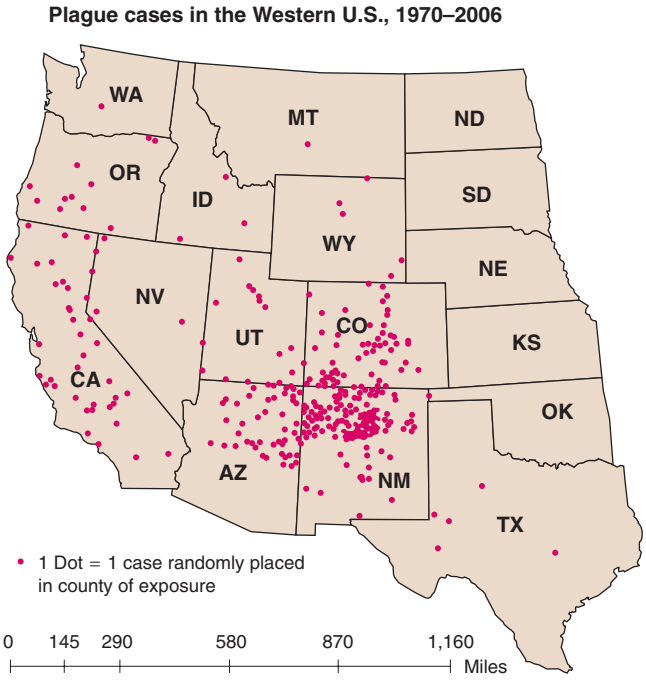

FIGURE 320-2. Distribution of human plague cases in the United States. Case points were randomly placed within counties where exposures occurred to indicate the general distribution and clustering of cases by region. (Courtesy John Montenieri, Centers for Disease Control and Prevention.)

dimer). Although only one serotype is thought to exist, strains can be classified into biotypes. The three classic biotypes (antiqua, mediaevalis, and orientalis) differ in their ability to ferment glycerol and reduce nitrates. All three biotypes occur in Asia, which is generally accepted as the site where plague originated. Two biotypes exist in Africa (antiqua and orientalis), but only the orientalis biotype occurs in the Americas. Although these three biotypes have historical and biogeographic significance, all are highly virulent and appear to cause virtually identical signs and symptoms in humans. Recently, a fourth biotype (microtus), which is purportedly nonpathogenic for humans, was reported from east-central Asia. More modern typing methods, including ribotyping, multiple-locus variable-number tandem repeat assays, and single-nucleotide polymorphism analysis, are useful for molecular epidemiology studies, identification of probable environmental sources of human infection, and phylogenetic analysis.

EPIDEMIOLOGY

Y. pestis is maintained in nature through transmission cycles involving certain rodent species and their fleas, which act as vectors. Although other mammals often become infected with *Y. pestis* and occasionally succumb to plague, the only non-rodent species thought to be important hosts for infecting vector fleas are some species of rabbits and hares, the steppe pika of central Asia, and the house shrew of southeastern Asia and Madagascar. Rodent-consuming carnivores and raptors might play indirect roles in spreading plague by transporting infected rodent fleas from one area to another.

Foci of *Y. pestis* infection occur in rodent populations in many regions of Africa, Asia, and the Americas, although only about 2000 to 5000 human cases were reported each year to the World Health Organization (WHO) in the period 1987 to 2009. In the 1960s and 1970s, the majority of human cases occurred in Southeast Asia, which was the site of civil wars and political unrest. However, beginning in the 1980s, this situation began to change, and most cases now occur in Africa and nearby Madagascar. According to the most recently released WHO statistics for 2004 to 2009, 96.6% of the world's cases occurred in the Democratic Republic of Congo, Madagascar, Uganda, and other countries in Africa. Asian countries reported only 1.6% of the total cases, and another 1.8% were reported from countries in the Americas, including the United States. Since 1970, evidence of *Y. pestis* infection has been identified in animals or their fleas in 17 western states, and human cases have been identified in 13 of these states (Fig. 320-2).

Humans most frequently acquire plague as a result of being bitten by infectious fleas. On a worldwide basis, the risk of flea bite exposure is highest in poverty-stricken areas that are situated near natural plague foci and have large infestations of commensal rats (*Rattus* sp) heavily infested with fleas, particularly the oriental rat flea (*Xenopsylla cheopis*). *X. cheopis* readily feeds on humans and is an efficient vector of *Y. pestis* to people as well as to rats. Persons are most likely to be bitten by infectious *X. cheopis* when plague epizootics cause massive mortality among susceptible rats, forcing these fleas to seek new hosts. Currently, certain regions of central and southern Africa (including Madagascar), southeastern Asia and India, and a few areas in South America remain at high risk for rat-associated plague outbreaks. The spread of rat-associated plague from one region to another, perhaps by the natural movement of rats or their transport along with trade goods, poses a threat of major epidemics in large rat-infested cities. The appearance of bubonic cases acquired via flea bite in large cities also greatly increases the possibility that pneumonic plague will develop in untreated bubonic cases and that the infection will spread to others through coughing and the expulsion of infectious respiratory droplets (primary pneumonic plague). Though rare in the United States, primary pneumonic plague still poses a threat in developing countries, with outbreaks occurring in the past 20 years in India, Ecuador, Madagascar, the Democratic Republic of Congo, and Uganda.

At present, rat-associated plague poses little risk to persons in the United States, with the last cases being reported in 1925. Since that time, most cases have occurred as a result of being bitten by infectious wild rodent fleas (79% in one case series), although a significant number (19%) were exposed while handling *Y. pestis*–infected animals, including rabbits, domestic cats, wild rodents, and wild carnivores. These direct-contact exposures occurred primarily in persons who had been bitten or scratched by infected cats or had skinned infectious rabbits or rodents for meat or certain wild carnivores for their fur. The risk of exposure to infectious wild rodent fleas or animals is typically greatest when epizootics cause high mortality in certain rodent species in the western United States, particularly ground squirrels, prairie dogs, wood rats, and chipmunks. Epizootics appear to progress most rapidly during late spring to early fall, when human cases also peak, probably because this is the period of greatest flea vector activity. The few human cases reported during the winter months are typically acquired through direct contact with infected animals, and affected individuals have a history of hunting or trapping wild animals or handling domestic cats. The exposure sites for most U.S. cases are peridomestic environments, with smaller numbers of exposures occurring during recreational activities such as hunting or camping. Occupational exposure has also rarely occurred among veterinary staff, biologists, and trappers. Rarely, primary pneumonic plague has been acquired in the United States through the inhalation of infectious materials (2% of cases) by means of close face-to-face contact with *Y. pestis*–infected cats that had oral lesions or signs of plague pneumonia, including cough.

Recently, concern has been raised that plague could be used as an agent of bioterrorism (Chapter 20). In most projected scenarios, bioterrorists would spread plague in an aerosol form, potentially resulting in numerous primary pneumonic cases, high mortality, and widespread panic, especially if the *Y. pestis* strains released had been engineered to be resistant to antimicrobial agents commonly used to treat plague.

PATHOBIOLOGY

Few bacteria rival the pathogenicity of *Y. pestis* for humans. *Y. pestis* usually enters the body at the site of a flea bite or perhaps as a result of contact between abraded or cut skin and blood or other body fluids from a *Y. pestis*–infected animal. On entering the body, plague bacteria come under attack by host phagocytes and other host defenses. The ability to escape from these defenses and disseminate to regional lymph nodes depends in part on a protease (Pla) that helps degrade fibrin clots and promote the production of excess plasmin, which can affect inflammatory exudates, break down extracellular proteins and basement membranes, and reduce levels of chemoattractants, possibly because of the inhibition of interleukin-8 production at the site of initial infection. Another virulence factor, YopM, is one of many *Yersinia* outer proteins (Yops), encoded by genes on the mid-sized (70 to 75 kb) plasmid of *Y. pestis.* Although most other Yops are degraded by the Pla protease, YopM is resistant to its activity and probably aids in the dissemination of *Y. pestis* by competing with platelets for thrombin, a factor that not only reduces clotting but also inhibits the activation of platelets, thereby lowering local inflammatory responses and promoting the dissemination of *Y. pestis* to regional lymph nodes. Initial invasion and dispersal to regional lymph nodes also depend on the ability of *Y. pestis* to survive for at least brief periods in host phagocytes. Survival in such environments is promoted by other Yops that work in concert with a type III secretory apparatus to deliver into host phagocytes those Yops that act as intracellular effectors. These effector Yops disturb the cytoskeletal dynamics of phagocytic cells and block their production of pro-inflammatory cytokines. Affected phagocytes are rendered incapable of killing the invading *Y. pestis,* thereby allowing this bacterium to survive extracellularly in lymphoid tissues. Survival of *Y. pestis* in mammalian hosts also depends on its ability to acquire sufficient quantities of iron for growth. The most important means of iron uptake in *Y. pestis* is a siderophore (yersiniabactin) system that can effectively compete with host iron-binding molecules for this essential nutrient. Although the ability of *Y. pestis* to resist host phagocytic killing and survive intracellularly in phagocytes is thought to be particularly important during the early stages of infection, plague bacteria also express a glycoprotein capsular antigen (caf1 or fraction 1 antigen) that confers resistance to phagocytosis. Expression of caf1 is temperature dependent, being repressed at the cooler temperatures found in the flea vector and upregulated at mammalian host body temperatures.

Infected lymph nodes, termed *buboes,* can appear edematous and congested early in the course of illness but exhibit little evidence of inflammatory infiltrates or vascular injury. These buboes represent the most obvious manifestation of the lymphatic system's efforts to arrest the spread of *Y. pestis,* and within a few days after infection, they contain massive numbers of *Y. pestis* and heavy neutrophil infiltrates, which causes them to swell to the size of a hen's egg and become surrounded by serous fluid. As the illness progresses, hemorrhagic necrosis and vascular damage in the node become apparent; some nodes spontaneously rupture, and abscesses appear. Although *Y. pestis* can be present in small quantities in blood samples taken relatively early in the course of infection, large quantities of plague bacteria usually appear in the blood of patients with bubonic plague only after the lymph node defenses are overwhelmed.

As the bacteria escape from the node and proliferate in blood, patients with bubonic plague begin to exhibit evidence of plague septicemia (secondary septicemic plague). Patients with inadequately treated septicemic plague can experience widespread and overwhelming destruction of tissues as *Y. pestis* spreads to various organs, eventually resulting in their failure. Patients who die of plague often experience diffuse interstitial myocarditis, cardiac dilation, diffuse hemorrhagic splenic necrosis, renal glomeruli containing fibrin thrombi, and multifocal necrosis in the liver. Disseminated intravascular coagulation can lead to thrombosis within capillaries, vascular necrosis, ecchymoses, acral gangrene, and cutaneous, mucosal, and serosal petechiae. In a small proportion of cases, septicemia occurs in the absence of buboes or other signs of localized infection, a condition referred to as *primary septicemic plague.* Septicemic plague can also occur secondary to primary pneumonic plague.

Rarely, plague can be acquired through the inhalation of infectious respiratory droplets or other materials. Patients with primary pneumonic plague typically experience a rapidly progressing lung infection that is initially lobular, then lobar, and finally multilobar, with large numbers of *Y. pestis* being present in the alveoli and pulmonary secretions of affected sites. Pneumonic plague can also occur secondary to bubonic or primary septicemic plague. In these instances, *Y. pestis* invades the lungs in a diffuse manner, with most bacilli appearing in interstitial spaces. The most common pathologic findings are edema, diffuse pulmonary congestion, limited neutrophilic infiltration, and hemorrhagic necrosis. Cavitation and liquefaction necrosis can also occur and result in scarring of the lungs, particularly at sites of consolidation.

FIGURE 320-3. Young Malagasy boy with a bubo. (Courtesy Brook Yockey, Centers for Disease Control and Prevention.)

CLINICAL MANIFESTATIONS

The three most commonly observed forms of plague (in order of decreasing occurrence) are bubonic, septicemic, and pneumonic. Unusual manifestations of plague include meningitis and pharyngitis. In rare instances, *Y. pestis* has been inoculated through the conjunctiva, resulting in oculoglandular plague. The incubation period is 2 to 6 days for bubonic plague and 1 to 3 days for primary pneumonic plague.

The characteristic swollen and tender lymph nodes (buboes) of bubonic plague usually appear in the node or nodes located closest to the site of initial infection (Fig. 320-3). Most cases of bubonic plague in the United States are thought to be acquired from flea bites on the legs, as indicated by the appearance of inguinal or femoral lymph node involvement on the side where the flea bite occurred. Axillary buboes are also common, often indicating the handling of an infected animal or other flea-infested object. Cervical buboes are much less common in the United States than in many developing countries, perhaps because persons in the latter are more likely to sleep on dirt floors in flea-infested huts, thus increasing their chances of being bitten about the head and neck by infectious fleas. Rarely, a skin lesion appears at the site of an infectious flea bite or other source of inoculation.

Symptoms of bubonic plague include fever, chills, myalgia, arthralgia, headache, malaise, and prostration. Untreated patients with bubonic plague become increasingly toxic, remain febrile, and experience tachycardia, agitation, confusion, delirium, and convulsions.

Septicemic plague manifests as a rapidly progressive, overwhelming endotoxemia. Patients often complain of gastrointestinal symptoms, including nausea, vomiting, diarrhea, and abdominal plain. Disseminated intravascular coagulation can also occur with the appearance of petechiae, ecchymoses, bleeding, and ischemia in the tips of the extremities. Later-stage septicemic patients are likely to experience refractory hypotension, renal shutdown, obtundation, and other signs of shock. Patients with late-stage septicemic plague can also exhibit acute respiratory distress syndrome (Chapter 104), which has occasionally been confused with hantaviral pulmonary syndrome (Chapter 389) in the American Southwest. Because septicemic plague is likely to be fulminant and fatal, favorable outcomes depend on rapid diagnosis and prompt treatment with appropriate antimicrobials.

Pneumonic plague can be accompanied by fever, cough, chest discomfort that becomes increasingly painful, tachycardia, dyspnea, bacteria-laden sputum, chills, headache, achiness, weakness, and dizziness. As the illness progresses, patients may experience increasing respiratory distress, hemoptysis, cardiopulmonary insufficiency, and circulatory collapse. In the early stages of illness, patients with primary pneumonic plague may have signs of localized pulmonary involvement, beginning in a single lung and rapidly

progressing to segmental consolidation and later bronchopneumonia, with death ensuing within 24 hours of the onset of symptoms. Localized infection is unlikely to be observed in the lungs of patients with secondary pneumonic plague because the lung tissues are infected initially through circulatory spread, which results in a diffuse interstitial pneumonitis. The appearance of sputum also differs in primary versus secondary pneumonic plague, being watery or mucoid, frothy, and perhaps tinged with blood in primary pneumonic cases but scanter, thicker, and more tenacious in secondary pneumonic cases.

DIAGNOSIS

Plague fatalities are typically related to delay in seeking treatment or misdiagnosis. The differential diagnosis of plague in its various clinical forms includes staphylococcal (Chapter 296) or streptococcal adenitis (Chapter 298) or pneumonia (Chapter 97); cat-scratch disease (Chapter 323); tularemia (Chapter 319); chancroid (Chapter 309); acute filarial lymphadenitis (Chapter 366); mycobacterial infection (Chapter 333); septicemia caused by other bacteria; meningococcemia; bacterial endocarditis; mycoplasmal pneumonia and other community-acquired pneumonias; legionnaires' disease (Chapter 322); Q fever; influenza pneumonitis (Chapter 372); hantaviral pulmonary syndrome (Chapter 389); viral pneumonia caused by respiratory syncytial virus (Chapter 370), cytomegalovirus (Chapter 384), or other viruses; and strangulated inguinal hernia.

Laboratory confirmation relies on bacterial culture accompanied by specific bacteriophage lysis tests or detection of a four-fold rise in antibody titer to the *Y. pestis* F1 capsular antigen over a period of 2 to 4 weeks. Although the procedures for confirming the laboratory diagnosis of *Y. pestis* infection are relatively simple, delays can occur because the relevant expertise and reagents are often limited to a few public health or reference laboratories. Because cases of plague can rapidly progress to a life-threatening illness, and because culture of *Y. pestis* on bacteriologic media may require 48 hours or longer before colonies become visible, it is essential that patients suspected of having plague receive appropriate antimicrobial therapy immediately after samples have been taken. Direct fluorescent antibody assays can be used to identify *Y. pestis* bacteria in bubo aspirates, sputum samples, and tracheal washes; this procedure requires about 1 hour and provides strong presumptive evidence of infection. A presumptive diagnosis can also be obtained rapidly by detecting *Y. pestis* DNA in polymerase chain reaction (PCR) assays or *Y. pestis*–specific antigens in immunologic assays, but these tests are not widely available. Recently, rapid immunochromatographic tests have been developed that can detect plague antigen or antibodies. The potential advantages of these tests are that they require few laboratory resources, can be done in field settings, and yield results in less than an hour. One such test designed to detect *Y. pestis* antigens in patient samples has been used in some developing countries to diagnose plague, but these assays are still being evaluated and are not widely available. Preferred laboratory samples include blood, serum, bubo aspirates, tracheal washes, and swabs of skin lesions or pharyngeal mucosa. Cerebrospinal fluid can also be collected from patients in whom plague meningitis is suspected.

PREVENTION

No commercially available plague vaccine exists in the United States. Newer recombinant vaccines designed to stimulate immune responses to the F1 and V antigens of *Y. pestis* are undergoing clinical trials and have yielded promising results, but they are unlikely to be available in the near future.

Human plague risk can be reduced through the implementation of effective surveillance programs to rapidly identify human cases and threatening epizootics. When appropriate, affected areas can be treated with insecticides to reduce the risk for flea bite exposure. Appropriate steps should be taken to reduce the amount of food and shelter available to rodents. In rare instances, rodenticides can be used to reduce host numbers, but their use is not recommended before the implementation of effective flea control measures. Persons living in or visiting areas endemic for plague should avoid sick or dead animals and use insect repellents to reduce the risk for infectious flea bites. Dogs and cats should be prevented from roaming freely in rodent-infested areas, and these animals should be treated with flea control agents that safely and effectively kill fleas. Although most dogs appear to be somewhat resistant to plague, cats are highly susceptible, often experience severe illness, and can serve as sources of infection for their owners or veterinary staff. Cats that roam outside in endemic areas and suddenly become seriously ill should be taken to a veterinarian for evaluation.

Persons with pneumonic plague should be held in respiratory isolation for at least 48 hours after the initiation of appropriate antimicrobial therapy, and persons caring for such patients should follow respiratory droplet precautions (mask, gloves, gown, eye protection). Although human-to-human transmission has not been reported in the United States for many decades, rare cases of primary pneumonic plague have occurred after face-to-face contact with infected cats that had oral lesions or symptoms of pneumonic plague. Veterinary staff from plague-enzootic areas should take appropriate precautions (mask, gloves, gown, eye protection) when handling sick cats with illnesses suggestive of plague.

Prophylactic antimicrobial therapy is generally recommended for persons with possible plague exposure only in relatively high-risk situations, such as after close contact with pneumonic plague patients, handling of *Y. pestis*–infected animals, or being bitten by rodent fleas in an area with a recent history of epizootic activity. The most recently recommended prophylactic antimicrobials are doxycycline and ciprofloxacin (Table 320-1).

TREATMENT

Rx

The most commonly recommended agent for treating plague is streptomycin (see Table 320-1), but a randomized trial in Tanzania concluded that gentamicin and doxycycline are effective for treating plague in adults and children and cause few adverse responses.■ A review of human cases treated in New Mexico also strongly suggests that gentamicin is effective and can be substituted for streptomycin. Tetracyclines are effective for treating uncomplicated cases of bubonic plague, and chloramphenicol is believed to be effective, particularly for plague meningitis. Although antimicrobial resistance is not believed to be a problem in the United States, strains resistant to tetracyclines and other agents have been described occasionally, and resistance to streptomycin and chloramphenicol may also occur. The occasional persistence of *Y. pestis* in necrotic or partially necrotic tissues emphasizes the importance of adequately excising these tissues.

PROGNOSIS

Patients with uncomplicated bubonic plague respond quickly to appropriate antimicrobial therapy and typically defervesce, with relief from most other systemic manifestations within 2 to 5 days. Large buboes can remain swollen, however, for more than a week after the *Y. pestis* infection has been eliminated, and some patients require many weeks of convalescence before feeling fully recovered. In rare instances, ischemic necrosis in septicemic cases has resulted in the amputation of digits.

ENTEROPATHOGENIC YERSINIAE

DEFINITION

Y. enterocolitica and *Y. pseudotuberculosis* differ significantly from *Y. pestis,* in that they are enteropathogenic, rarely cause death, and are spread via the fecal-oral route. Like *Y. pestis,* both of these bacteria are gram-negative members of the family Enterobacteriaceae.

The Pathogens

Y. enterocolitica is genetically quite distinct from *Y. pseudotuberculosis* and *Y. pestis;* the plague bacterium is thought to have arisen as a recent clone of *Y. pseudotuberculosis,* and the chromosomal DNA of these two species is extremely similar. All three species share an approximately 70-kb plasmid that encodes for various proteins (Yops) that are key virulence factors. Unlike *Y. pestis,* the enteropathogenic yersiniae are urease positive and motile at temperatures lower than 30° C. *Y. pseudotuberculosis* is rhamnose positive, thereby distinguishing it from the closely related *Y. pestis* and the more distantly related *Y. enterocolitica.* The enteropathogenic yersiniae are genetically more diverse than the more recently evolved plague bacterium. *Y. enterocolitica* contains 6 biogroups and more than 50 serogroups, whereas *Y. pseudotuberculosis* has been classified into 6 distinct serogroups (O groups 1 to 6).

EPIDEMIOLOGY

Enteropathogenic yersiniae are transmitted via the fecal-oral route, and successful infection of the host requires large doses of bacteria (median infective dose of 10^8 to 10^9 bacteria). Typical sources of infection include the consumption of contaminated foods such as dairy products, inadequately cooked meat, and certain vegetables. Both *Y. enterocolitica* and *Y. pseudotuberculosis*

TABLE 320-1 RECOMMENDATIONS FOR THE TREATMENT OF PATIENTS WITH PNEUMONIC PLAGUE IN CONTAINED AND MASS CASUALTY SETTINGS AND FOR POSTEXPOSURE PROPHYLAXIS*

PATIENT CATEGORY	RECOMMENDED THERAPY
CONTAINED CASUALTY SETTING	
Adults	Preferred choices: Streptomycin 1 g IM twice daily Gentamicin 5 mg/kg IM or IV once daily or 2 mg/kg loading dose followed by 1.7 mg/kg IM or IV 3 times daily Alternative choices: Doxycycline 100 mg IV twice daily or 200 mg IV once daily Ciprofloxacin 400 mg IV twice daily† Chloramphenicol 25 mg/kg IV 4 times daily‡
Children§	Preferred choices: Streptomycin 15 mg/kg IM twice daily (maximum daily dose, 2 g) Gentamicin 2.5 mg/kg IM or IV 3 times daily¶ Alternative choices: Doxycycline: if ≥45 kg, give adult dosage; if <45 kg, give 2.2 mg/kg IV twice daily (maximum, 200 mg/day) Ciprofloxacin 15 mg/kg IV twice daily† Chloramphenicol 25 mg/kg IV 4 times daily‡
Pregnant women¶	Preferred choice: Gentamicin 5 mg/kg IM or IV once daily or 2 mg/kg loading dose followed by 1.7 mg/kg IM or IV 3 times daily¶ Alternative choices: Doxycycline 100 mg IV twice daily or 200 mg IV once daily Ciprofloxacin 400 mg IV twice daily†
MASS CASUALTY SETTING AND POSTEXPOSURE PROPHYLAXIS**	
Adults	Preferred choices: Doxycycline 100 mg PO twice daily†† Ciprofloxacin 500 mg PO twice daily† Alternative choice: Chloramphenicol 25 mg/kg PO 4 times daily‡‡
Children§	Preferred choices: Doxycycline††: if ≥45 kg, give adult dosage; if <45 kg, give 2.2 mg/kg PO twice daily Ciprofloxacin 20 mg/kg PO twice daily Alternative choice: Chloramphenicol 25 mg/kg PO 4 times daily‡‡
Pregnant women¶	Preferred choices: Doxycycline 100 mg PO twice daily†† Ciprofloxacin 500 mg PO twice daily Alternative choice: Chloramphenicol 25 mg/kg PO 4 times daily‡‡

*These are consensus recommendations of the Working Group on Civilian Biodefense and are not necessarily approved by the Food and Drug Administration. One antimicrobial agent should be selected, and therapy should be continued for 10 days. Oral therapy should be substituted when the patient's condition improves.
†Other fluoroquinolones can be substituted at doses appropriate for age. The ciprofloxacin dosage should not exceed 1 g/day in children.
‡The concentration should be maintained between 5 and 20 μg/mL. Concentrations >25 μg/mL can cause reversible bone marrow suppression.
§In children, the ciprofloxacin dose should not exceed 1 g/day, and the chloramphenicol dose should not exceed 4 g/day. Children younger than 2 years should not receive chloramphenicol.
¶Aminoglycoside dosages must be adjusted based on renal function. Evidence suggests that gentamicin 5 mg/kg IM or IV once daily would be efficacious in children, although this is not yet widely accepted in clinical practice. Neonates up to 1 week of age and premature infants should receive gentamicin 2.5 mg/kg IV twice daily.
¶In neonates, a gentamicin loading dose of 4 mg/kg should be given initially.
**The duration of treatment of plague in a mass casualty setting is 10 days. The duration of postexposure prophylaxis to prevent plague infection is 7 days.
††Tetracycline can be substituted for doxycycline.
‡‡Children younger than 2 years should not receive chloramphenicol. An oral formulation is available only outside the United States.
Adapted from Inglesby TV, Dennis DT, Henderson DA, et al. Plague as a biological weapon: medical and public health management. Working Group on Civilian Biodefense. *JAMA*. 2000; 283:2281-2290.

can survive and proliferate slowly at refrigerator temperatures. Though far less common, person-to-person transmission has been reported, as has transmission via blood transfusion. Pigs, rodents, rabbits, sheep, goats, cattle, horses, dogs, cats, and sometimes birds serve as reservoirs for these yersiniae. Most hosts act as asymptomatic carriers, but a few human cases have been associated with handling sick animals. Symptomatic patients shed large amounts of yersiniae for as long as 2 to 3 weeks. Untreated, infected persons can become carriers and shed for 2 to 3 months.

Yersiniosis is a reportable disease in many countries. Most cases result from *Y. enterocolitica* infection, and this agent reportedly accounts for 1 to 3% of all cases of acute enteritis in some areas. The overall annual incidence is about 0.9 cases per 100,000 persons in the United States, but the incidence rates vary among ethnic groups, being highest in African Americans (3.2 cases per 100,000) and lower in Asian Americans (1.5 cases per 100,000), Hispanics (0.6 cases per 100,000), and whites (0.4 cases per 100,000). The highest incidence occurs in African American infants (141.9 cases per 100,000). Regardless of ethnicity, the incidence decreases with age. High rates among African American populations have been associated with the home preparation of chitterlings made from contaminated pork intestines.

Y. enterocolitica serotypes O:3, O:8, O:9, and O:5,27 have been associated with human disease. Serotype O:3 predominates in most countries and is found most commonly in swine. Serotype O:9 has been isolated from sheep, cows, and goats. Although serotype O:8 infections appear to be decreasing in incidence in the United States, they are becoming increasingly important in Japan, Italy, and France. In Europe, most cases involve serotype O:3 infections, although a few are associated with serotypes O:9 and O:5,27. Biotype 1A appears to be nonpathogenic, and biotype 5 has been isolated only from hares. Strains pathogenic in humans are esculin, salicin, and pyrazinamidase negative.

Y. pseudotuberculosis has been isolated from rodents, cattle, sheep, cats, dogs, and birds. It occurs worldwide but is most common in northern Europe and in Asia, including Japan. O group 1, 2, and 3 strains are associated with human disease, with most cases being attributed to O:1 or O:2 strains. Infected animals serve as chronic carriers and sources for the infection of water and foods such as meat, dairy products, and stored vegetables. Some cases have been associated with the handling of kittens and puppies. Recent outbreaks of *Y. pseudotuberculosis* in Finland were traced to eating iceberg lettuce and carrots (serotypes O:3 and O:1, respectively). A large Canadian outbreak was associated with milk that had been pasteurized but nevertheless became contaminated. Outbreaks in the former Soviet Union have been associated with the consumption of root vegetables that were stored underground for winter consumption and presumably became contaminated with rodent excreta containing *Y. pseudotuberculosis.*

PATHOBIOLOGY

On reaching the ileum, *Y. enterocolitica* adheres to the mucosa, where intracellular infections in Peyer's patches, mucosal cells, and macrophages can occur. Invasion of the ileal mucosa is favored by the presence of invasin, an outer membrane protein, and a 17-kD surface factor (Ail). An inflammatory response causes abdominal pain and diarrhea, as well as ulcerative ileitis, mesenteric adenitis, and necrosis within Peyer's patches. If the regional defenses are breached, the bacteria can disseminate and cause sepsis and hepatic and splenic abscesses. Polyarthritis can also occur later in the course of illness, particularly in human leukocyte antigen (HLA)-B27–positive individuals.

Like *Y. pestis,* the enteropathogenic yersiniae attack host lymphoid tissues. Invasion of these tissues and resistance against host defenses depend on the possession of an approximately 70-kb plasmid that bears genes encoding for various Yops and the so-called V antigen. The products of this plasmid work in concert to inhibit phagocytosis and reduce inflammation, thereby suppressing the host immune response and favoring persistence of these microbes.

Once *Y. enterocolitica* and *Y. pseudotuberculosis* become established in the lymph nodes, they can resist phagocytosis, which allows them to replicate extracellularly and form aggregates in the nodes. The ability to acquire host iron can be a significant factor contributing to the virulence of *Y. enterocolitica* strains. O:8 serotypes, which are virulent for mice, have the *irp2* (iron repressible 2) gene that encodes for a pair of high-molecular-weight outer membrane proteins, whereas the mouse avirulent O:3 and O:9 serotypes lack *irp2.* O:3 and O:9 serotypes typically remain confined to the guts of their hosts, except when iron overload is present or patients are being treated with an iron chelator.

Patients with reactive arthritis (Chapter 273) are more likely to have fewer gastrointestinal symptoms, lower T-cell proliferative responses to *Yersinia* antigens, lower initial immunoglobulin (Ig) M responses, higher and more persistent IgG and IgA responses, and increased levels of IgA with a secretory component. *Yersinia*-specific antibody responses are also more likely to persist in patients with reactive arthritis than in those with uncomplicated gastrointestinal disease. *Yersinia* antigens thought to contribute to reactive arthritis include Yops and released proteins, which stimulate host CD4 cells, and heat shock protein 60, which has been hypothesized to work in conjunction with other antigens to modulate the host immune response. Evidence exists that hosts can maintain chronic *Y. enterocolitica* infections for years after the initial infection, a factor that may induce the inflammation associated with reactive arthritis (Chapter 273).

CLINICAL MANIFESTATIONS

After an incubation period of about 3 to 7 days, a gastroenteritis typically develops that can be difficult to distinguish from *Salmonella* (Chapter 316) or *Campylobacter* (Chapter 311) gastroenteritis. The most common clinical syndromes associated with *Y. enterocolitica* infection are acute enteritis with fever, diarrhea, vomiting, right lower quadrant pain suggestive of appendicitis (Chapter 144), erythema nodosum, and reactive arthritis. Other common symptoms include associated pharyngitis, rash, joint pain, and headache. Stool examination reveals leukocytes or erythrocytes, and one fourth of patients experience bloody diarrhea.

Y. pseudotuberculosis infections most commonly manifest as acute mesenteric adenitis with diarrhea, fever, vomiting, and bloody stools.

Enterocolitis is most likely to occur in young children, whereas older children more frequently experience acute terminal ileitis, mesenteric adenitis, and systemic disease. Pseudoappendicitis has been reported in patients with mesenteric lymphadenitis. Sepsis is uncommon and is most likely to occur in persons with underlying conditions such as diabetes mellitus, cirrhosis, immunosuppression, older age, and hemochromatosis. Splenic abscesses, meningitis, or endocarditis can develop in septic patients, and mortality can approach 50%. Erythema nodosum is identified in about a third of all patients and in 10% of adults.

DIAGNOSIS

Yersiniosis should be suspected in patients with abdominal pain and fever, especially if they live in endemic areas. Diagnosis is best accomplished by isolation of the bacterium from stool, blood, or other appropriate samples. Recovery of *Y. enterocolitica* and *Y. pseudotuberculosis* from clinical and environmental samples can be greatly complicated by the presence of other bacteria that are likely to predominate. The preferred selective agar for isolation from stool specimens is CIN (cefsulodin-irgasan-novobiocin) agar prepared with relatively low cefsulodin concentrations. Isolation of yersiniae is also helped by culture at 25 to 30°C, which results in better growth than when cultures are kept at 35°C and favors growth of the more cold-tolerant yersiniae over other bacteria that require higher temperatures. Once obtained, isolates can be confirmed as enteropathogenic *Yersinia* by biochemical tests. Biotyping and serotyping, which are often available only in research or reference laboratories, can provide useful epidemiologic information. Isolation difficulties and the reported low sensitivity (about 10^3 to 10^6 colony-forming units per gram of sample) of current isolation techniques have led some to suggest that PCR or other DNA-based methods are likely to result in the more rapid and sensitive detection of these bacteria.

Tube or microagglutination tests can identify antibodies to the pathogenic *Y. enterocolitica* serogroups O:3, O:9, O:5,27, and O:8, but cross-reactivity can be a problem, particularly between *Y. enterocolitica* O:9 and *Brucella* species. PCR for O genotyping of *Y. pseudotuberculosis* could eventually replace traditional serotyping methods. Immunologically mediated *Yersinia* illnesses, including reactive arthritis, are associated with the production of IgA antibodies that can be detected by enzyme-linked immunosorbent assay (ELISA) or immunoblotting. IgG antibodies can persist for many years, but persistence of IgA antibodies for more than a few months could indicate a chronic *Yersinia* infection.

PREVENTION

Prevention depends on measures intended to protect persons from contact with contaminated environments, foods, and wastes. These include using proper sewage disposal methods, protecting water supplies from contamination with human or animal wastes, following appropriate procedures for animal husbandry and slaughtering, thoroughly cooking meats (especially pork), avoiding long-term storage of meats at temperatures higher than 39° F, and consuming only pasteurized milk. Individuals should thoroughly wash their hands after handling potentially contaminated pork or other foods. Diarrheic persons should not work in food-handling areas, care for young children, or work with patients, and hospital staff should follow enteric precautions. Vaccines are not available.

TREATMENT Rx

Antibiotics do not improve the course of uncomplicated enterocolitis or mesenteric adenitis, and the use of antimicrobial therapy is not recommended for intestinal forms of the disease. Such therapy is, however, recommended for immunocompromised patients, patients with septicemia, and those with systemic disease or extraintestinal foci of infection. It should be noted that in vitro susceptibility does not necessarily indicate efficacy in vivo.

Broad-spectrum cephalosporins, sometimes accompanied by aminoglycosides, have resulted in successful outcomes in patients with extraintestinal forms of yersiniosis, including septicemia. Ciprofloxacin, cefotaxime, and ceftriaxone are considered the most effective agents for treating *Y. enterocolitica* serogroup O:3 infection. In addition, *Y. enterocolitica* serogroup O:3 and O:9 isolates possess chromosomally determined β-lactamases that can confer resistance to ampicillin, carbenicillin, and cephalothin. Although serogroup O:8 strains, which produce type A β-lactamase, show resistance to the latter two agents, they are susceptible to ampicillin. It has yet to be determined whether antimicrobial therapy is useful for treating immunologically mediated forms of yersinial illness, including reactive arthritis.

PROGNOSIS

Cases of *Y. enterocolitica* enteritis are generally mild and self-limited after a 2- to 3-week course of illness. Sequelae most commonly include reactive arthritis and erythema nodosum. Glomerulonephritis and myocarditis have also been reported, particularly with serogroup O:3, biotype 4, phage type 8 infections. Other sequelae can include endocarditis, pericarditis, and osteitis. *Y. enterocolitica*–induced reactive arthritis, which can appear 1 to 3 weeks after infection, is oligoarticular, asymmetrical, and peripheral; it occurs most frequently in the lower limbs and eventually resolves over a period of a few weeks to months. HLA-B27–positive patients are more likely to experience severe and prolonged arthritis.

Y. pseudotuberculosis infections are also generally mild and self-limited. Reported complications include erythema nodosum, iritis, reactive arthritis, and nephritis.

WHOOPING COUGH AND OTHER *BORDETELLA* INFECTIONS

ERIK L. HEWLETT

DEFINITION

Pertussis (whooping cough), an acute respiratory illness with a potentially protracted clinical course, is caused by infection with *Bordetella pertussis* or related members of the genus, especially *Bordetella parapertussis*. The

infection is highly contagious and can have both endemic and epidemic features in a population, but there are no chronic carriers of the organism. Pertussis is not solely a pediatric illness, and the greatest increases in incidence in recent years have been in adolescents and adults. Although death is rare except in infants, in whom mortality approaches 1% in the United States, almost 300,000 people are believed to die of pertussis worldwide each year.

The Pathogen

There are now eight species in the genus *Bordetella,* but *B. pertussis, B. parapertussis,* and *B. bronchiseptica* (primarily a veterinary pathogen) are most likely to cause respiratory infections in humans. Recently identified species such as *B. holmesii* and *B. trematum* have been associated with bacteremia and wound infections. The organisms are fastidious, gram-negative, coccobacillary in shape, and particularly small relative to other gram-negative organisms. *B. pertussis* was first isolated by Bordet and Gengou in 1906, and the medium used for culture (Bordet-Gengou agar) still bears their names.

EPIDEMIOLOGY

In the pre-vaccine era (before the mid-1950s), pertussis was primarily a childhood illness; as a result, the disease has received little attention in adult medicine. The extensive use of pertussis vaccines in the United States and other parts of the world resulted in a marked reduction of pertussis in the population and a change in the age-specific incidence of disease, with the majority of cases now occurring in infants too young to be vaccinated and in adolescents and adults who become susceptible because of waning immunity after childhood vaccination. In recent years, this shift has been particularly notable, with 25,827 cases of pertussis reported in the United States in 2004, the highest number since 1959. Approximately 60% of those cases occurred in adolescents and adults. The annual incidence of reported cases in the United States has remained above 10,000 since that time. In fact, seroepidemiologic data suggest that 25% of adolescents and adults with a cough lasting more than 1 week have pertussis. The disease is endemic in the United States, but epidemics occur every 3 to 4 years.

B. pertussis is highly contagious and is believed to be spread primarily by large droplets. Although there is no classic "carrier" state such as that recognized for many other infectious organisms, the organism can be cultured for a brief time from exposed individuals who remain asymptomatic. Although these subjects could, in theory, spread the organism, they are unlikely to do so because they are not coughing. Dissemination in a community is often due to symptomatic adolescents, who spread the organism during school attendance and social events. Health care personnel are also important sources of transmission, and health care–associated outbreaks can affect both vulnerable patients and their care providers.

PATHOBIOLOGY

Although *B. pertussis* and related organisms produce a number of interesting toxins, and pertussis has been described as a "toxin-mediated" disease, there is no clear pathophysiologic link between the known virulence factors and clinical manifestations of disease. The infection is localized to the respiratory tract, where organisms adhere to the ciliated surface of epithelial cells, many of which are damaged and lost from the mucosa. Mucous secretion is prominent, especially during later stages of the illness. Intracellular *B. pertussis* organisms have been demonstrated both in vitro and in samples collected from patients, but this is not an obligate intracellular organism, and the significance of these observations remains unknown.

The toxins and adhesins are important both for their potential role in the pathogenesis of disease and for their use as antigens in acellular pertussis vaccines. Filamentous hemagglutinin (FHA), pertactin, and fimbriae are adhesins that are components of some acellular vaccines, and all currently available vaccines include pertussis toxin (PT). In addition to being an adhesin, FHA has been shown to modulate the functions of cells in the host immune system. PT is a member of the family of adenosine diphosphate–ribosylating toxins that includes cholera toxin and diphtheria toxin, and its intracellular target consists of several guanosine triphosphate–binding proteins such as $G_{i\alpha}$. Although PT causes lymphocytosis and enhances insulin secretion, its target cell or cells and its contribution to the clinical manifestations of pertussis are still a mystery. Bordetellae also possess an adenylate cyclase (AC) toxin, which is a bacterial AC that enters host cells to produce supraphysiologic levels of cyclic adenosine monophosphate (cAMP). AC toxin acts against phagocytic cells, such as polymorphonuclear leukocytes and alveolar macrophages, whose antibacterial functions are inhibited by the increased cAMP. Additional "toxins," including the tracheal cytotoxin BrkA, tracheal colonization factor, and heat-labile or dermonecrotic toxin, have been identified by virtue of their activities in vitro or in animals. The relationship of these toxins to disease also remains ill defined.

CLINICAL MANIFESTATIONS

Although the classic paroxysmal cough of pertussis is striking and unforgettable, not all patients experience the typical cough. Infants may have apnea as an early manifestation, and only sometimes does the characteristic cough develop subsequently.

Incubation Period

After exposure to a patient with active pertussis (typically by way of aerosol from an infected patient who is coughing), an infected individual does not experience the onset of symptoms until 1 to almost 3 weeks later. This relatively long incubation period makes it difficult to track transmission and increases the time necessary for intervention and the institution of control measures.

Catarrhal Phase

Importantly, the symptoms that initiate the catarrhal phase (rhinorrhea, increased lacrimation, conjunctival injection, and sometimes low-grade fever) are nonspecific and do not suggest pertussis, except in the setting of an ongoing hospital or community outbreak. This phase, which can last from a few days to as long as a week, is often associated with the onset of nonproductive cough.

Paroxysmal Phase

A patient's transition to the paroxysmal phase and initiation of the typical cough can suggest the diagnosis of pertussis. This striking cough consists of a series of uncontrollable expirations, followed by gasping inhalation, which, depending on the airway anatomy, can be responsible for the "whooping" sound. Whoop is more frequent in children than in adults. It is not uncommon for each episode of coughing to be associated with cyanosis and end with gagging and vomiting, which in an infant can result in dehydration and malnutrition. The paroxysmal stage can last up to 4 weeks, and the development of fever or worsening pulmonary function during this time should suggest the possibility of secondary pneumonia. Eighty percent or more of adolescents and adults with pertussis have paroxysmal cough, but the frequency of whoop and post-tussive vomiting in this population is quite variable. In addition, during the paroxysmal stage, adults experience symptoms not described in children, such as a scratchy throat, other pharyngeal symptoms, and episodes of sweating.

Convalescent Phase

A reduction in the frequency and severity of coughing attacks marks the transition to the convalescent phase, which can last weeks to months. It is often during this time that adults present to the health care system with "chronic cough" and may be evaluated for conditions such as asthma, tuberculosis, other chronic lung diseases, malignancies, and gastroesophageal reflux. After the coughing spells have ended, patients may experience a return of the paroxysmal cough in conjunction with an unrelated upper respiratory illness; this is often incorrectly interpreted as a recurrence of pertussis. Eighty percent of adults with pertussis have an illness of at least 3 weeks' duration, and 27% are still coughing after 90 days.

Complications

In infants and children younger than 5 years, hospitalization is common; 5 to 10% have pneumonia, nearly 1% of infants experience seizures, and encephalopathy is seen in 0.1%. Pertussis pneumonia in infants and small children can be complicated by pulmonary hypertension. Adolescents and adults have these same complications with a lower frequency, but adults can experience other problems associated with underlying medical conditions. For example, there are anecdotal reports of cough syncope, herniated intervertebral disc, sudden-onset hearing loss, angina episodes, and carotid artery dissection.

DIAGNOSIS

Several methods can be used to detect *B. pertussis,* its products, and the host response to them, but each has its limitations. Culture of a nasopharyngeal swab or aspirate (Fig. 321-1) is the "gold standard" (specificity approaching 100% in symptomatic patients), but even with the use of specialized transport

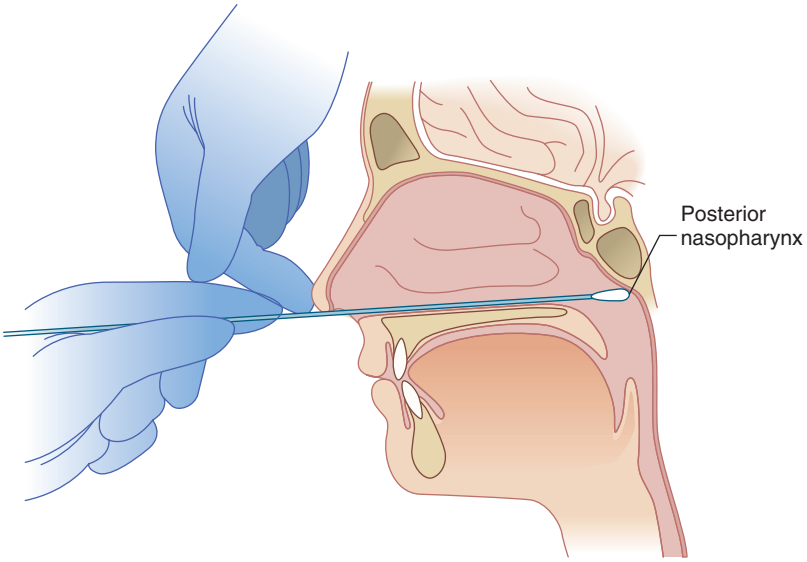

FIGURE 321-1. Technique for obtaining a nasopharyngeal specimen for the isolation of *Bordetella pertussis*. Dacron or calcium alginate swabs are recommended to obtain culture specimens. Dacron swabs are appropriate if polymerse chain reaction testing will be performed. (Redrawn from Cornia PB, Lipsky BA, Saint S, Gonzales R. Clinical problem solving: nothing to cough at. *N Engl J Med.* 2007;357:1432-1437.)

medium and processing in a careful, interested laboratory, recovery rates are often less than 50% and are completely dependent on the duration of illness and whether antimicrobial treatment was initiated before specimen collection. Polymerase chain reaction (PCR)–based diagnostic tests of nasopharyngeal swabs or aspirates are much more sensitive than culture and can remain positive for several days after the initiation of antimicrobial treatment. In addition, appropriately designed PCR assays can identify and distinguish among *B. pertussis, B. parapertussis,* and *B. bronchiseptica.* However, several apparent "outbreaks" of pertussis were later found to represent false-positive PCR results. Detection of serum antibodies to products of *B. pertussis* can be used to identify patients during infection, but care must be taken to distinguish an acute response from residual antibodies from prior immunization.

In view of the limited resources and equipment available for the diagnosis of pertussis, the World Health Organization has established a clinical case definition: 21 or more days of paroxysmal coughing with laboratory confirmation or epidemiologic linkage. Although this definition is often used for clinical trials, it is now clear that its application can result in cases of lesser severity or shorter duration being missed.

TREATMENT

Rx

Supportive Therapy

Because infants and young children have the highest risk for complications and death, supportive therapy is often the most important component of their medical care. Close observation (preferably in the hospital) is essential to ensure adequate feeding, oxygenation, and hydration to minimize complications in this age group. None of the pharmacologic interventions tested for the amelioration of cough and other symptoms is effective in pertussis.■

Antimicrobial Agents

There are two reasons to use antimicrobials in a patient with pertussis: first, to eliminate the causative organism and reduce transmission, and second, to limit the course of illness in the treated patient by eliminating the infection. Because individuals can remain culture positive and can potentially transmit *B. pertussis* for several weeks after the onset of symptoms, it is appropriate to treat patients who are seen within that time frame. Whether antimicrobials provide symptomatic relief is controversial, but they can do so only when treatment is started within the first week of symptoms.

The recommendation of the Centers for Disease Control and Prevention for the treatment of pertussis in adults is azithromycin (500 mg on day 1, followed by 250 mg/day on days 2 to 5), clarithromycin (1 g/day in two divided doses for 7 days), erythromycin (2 g/day in four divided doses for 14 days), or trimethoprim-sulfamethoxazole (trimethoprim 320 mg/day, sulfamethoxazole 1600 mg/day, in two divided doses for 14 days). It has now been shown that treatment with erythromycin for 7 days is as effective as treatment for 14 days. The newer macrolides (azithromycin and clarithromycin) are better tolerated but more expensive.■

PREVENTION

Chemoprophylaxis

Chemoprophylaxis with the aforementioned antimicrobial agents is an important mechanism for controlling outbreaks in hospitals or in the community.■ This approach is effective when initiated before the onset of symptoms and is recommended for individuals exposed within the preceding 3 weeks; high-risk persons with underlying health problems, particularly infants; or those who might have occupational or other contact with susceptible hosts.

Immunization

A killed, whole cell vaccine was introduced in the late 1940s. Use of that product had a dramatic effect on the incidence of pertussis, with the number of reported cases in the United States falling from more than 200,000 annually to less than 2000 in 1980. In the 1970s and 1980s, recognition of the adverse events associated with the whole cell product and public concern led to the development of the purified acellular pertussis vaccines that are in use today.

Current acellular pertussis vaccines, which contain one or more purified protein antigens (all contain PT and other combinations of FHA, pertactin, and fimbriae types 2 and 3), are administered to infants and children up to the age of 6 years. They are safe and efficacious and cause significantly fewer adverse reactions compared with the whole cell vaccines. In recognition of the significant incidence of pertussis in adolescents and adults and their role in transmitting the disease to infants and small children, several vaccines are now licensed for administration to these age groups. Use of these vaccines is now routinely recommended to boost immunity in adolescents 11 to 18 years old who completed the recommended childhood vaccination series. An important group for whom adult booster immunization is not yet available is pregnant women, who can acquire *B. pertussis* and transmit it to their neonates.

Future work will be directed at improving and standardizing diagnostic methods and increasing vaccine coverage to include pregnant women and other adults.

PROGNOSIS

Most patients will eventually clear *B. pertussis,* even without antimicrobial treatment, but in most cases the illness lasts weeks to months. Antimicrobials are of limited effectiveness in altering the course of the illness unless they are started before the paroxysmal phase. The introduction of booster doses of vaccines for adolescents and adults has the potential to control pertussis in well-immunized populations.

LEGIONELLA INFECTIONS

THOMAS J. MARRIE

DEFINITION

Legionellosis is the term for infection due to bacteria in the *Legionella* genus, of which there are two main manifestations—pneumonia (legionnaires' disease) and Pontiac fever (named after Pontiac, Michigan, where it was first recognized). The latter is usually a mild febrile illness presumed to be a reaction to lipopolysaccharide of *Legionella* species.

The 58th annual convention of the American Legion was held at a hotel in Philadelphia from July 21 to 24, 1976. Subsequently, 182 of the delegates became ill (hence the name legionnaires' disease), and 146 were hospitalized at 87 institutions across the United States. Most had radiographic evidence of pneumonia, and 29 (16%) died. Within about 6 months of the outbreak, a new microorganism, *Legionella pneumophila,* was isolated from the pulmonary tissue of some of those who had died in the Philadelphia outbreak. In retrospect, the organism had first been isolated in 1943.

The Pathogen

Legionellae are small, gram-negative, aerobic, non-spore-forming bacilli that measure 0.3 to 0.9 µm wide by 2 to 20 µm long (Fig. 322-1A to D). These organisms require special media for growth, and many laboratories are unable to isolate legionellae; thus, when laboratory expertise is uncertain, a negative culture is meaningless. They usually do not stain with Gram stain, and in tissue specimens, Dieterle or Warthin-Starry stain is used to visualize these organisms. *Legionella micdadei* retains the modified acid-fast stain and can appear as acid-fast bacilli in clinical specimens. Legionellae are aquatic organisms that thrive in both natural and man-made waterways and distribution systems, especially hot water pipes, water heaters (electrical more so than gas heaters), cooling towers, and water fountains. In these systems, they are found in biofilms that help confer resistance to biocides and chlorine. They are also found in moist soil and mud. They can survive in these environments for long periods and can tolerate temperatures of 0 to 68° C and a pH range of 5 to 8.5. In their natural environments, they are intracellular parasites of protozoa such as the freshwater ameba *Acanthamoeba* and *Hartmanella* species (Fig. 322-1E). Humans are accidental hosts who become infected by inhaling *Legionella* bacteria or ameba laden with these bacteria. Genomes of four different strains of *L. pneumophila* have been sequenced, and they range in size from 3.3 to 3.5 Mb. Legionellae have many eukaryotic-like proteins, which may help the intracellular growth of these organisms in human macrophages by mimicking host proteins. *Legionella* species have type I, II, IV, and V secretion systems, which allow the efficient and rapid delivery of molecules into the phagocytic host cell.

The number of new *Legionella* species continues to grow; there are now at least 56 *Legionella* species and 73 or more serogroups, including 15 serogroups of *L. pneumophila*. A variety of typing systems can be used to further refine the isolates so that individual strains can be identified, a factor that is important for determining the source of an outbreak or understanding the difference between environmental and clinical isolates. It is noteworthy that *L. pneumophila* and all its serotypes cause disease in humans, whereas only about 50% of the remaining species of *Legionella* cause such disease.

EPIDEMIOLOGY

The incubation period for Legionnaires' disease (LD) is most commonly cited as 2 to 10 days, with extremes of 1 to 28 days. Person-to-person transmission does not occur. Legionellosis is found worldwide, predominantly in developed countries owing to the frequent use of cooling towers and complex plumbing systems. Underdiagnosis may be a feature in developing countries owing to the laboratory facilities required. From 1990 to 2005, 23,076 cases of LD were reported in the United States. Only 1.7% of these cases occurred in children, whereas 63% occurred in those aged 45 to 64 years. The number of cases has increased over time. Males account for 61% of cases, and rates are highest in the eastern United States, where most cases occur in the summer or fall. There is an association between increased rainfall and cases of LD. The connection may be aerosolization of *Legionella* from rain puddles on roads. Eastern Canada also has higher rates of LD than the rest of that country. In a U.S. study, 20 to 25% of cases were travel related, whereas in Europe, 390 of 656 (59%) outbreaks reported from 1995 to 2005 were travel related. Travel to Italy, France, Spain, and Turkey accounted for more than 50% of the cases.

The most common risk factors for the acquisition of LD are listed in Table 322-1. *Legionella* species account for 1 to 5% of community-acquired pneumonia requiring admission to a hospital. In some areas, *Legionella* accounts for about the same percentage of pneumonia treated on an ambulatory basis. Nosocomial LD is usually due to contamination of the hospital's water supply. Colonization of 30% or more of the distal water outlets by *Legionella* is almost always associated with cases of LD. Most patients who are infected with non-*pneumophila Legionella* infections are immunocompromised. Nosocomial legionellosis has occurred with *L. pneumophila, L. micdadei, L. bozemanii, L. dumoffi, and L. sainthelensis.*

Legionella infections can be sporadic or occur in outbreaks. Outbreaks have been associated with exposure to a variety of aerosol-producing devices, including showers, a grocery store mist machine, cooling towers, whirlpool spas, decorative fountains, and evaporative condensers. LD can be acquired

TABLE 322-1 RISK FACTORS FOR LEGIONNAIRES' DISEASE

RISK FACTOR	APPROXIMATE INCREASED RISK (-FOLD) OVER PERSONS WITHOUT THIS RISK FACTOR
HOST FACTORS	
Renal failure requiring dialysis	20
Corticosteroid therapy	5-10
Hairy cell leukemia	20
Lung or hematologic cancer	7-20
Cytotoxic chemotherapy	5

Age older than 50 yr	2
Diabetes mellitus	2
Solid organ transplantation (immunosuppression)	2
Anti–tumor necrosis factor treatment	16-21
Chronic heart or lung disease	>1
Splenectomy (non-*pneumophila* strains only)	—
ENVIRONMENTAL FACTORS	
Travel	2
Recent plumbing work in home or at work	2
Hospitalization	—
Exposure to contaminated water sources—cooling towers, hot tubs, decorative fountains	—
Exposure to potting soil (Australia)—*Legionella longbeachae*	—

up to 10 km away from contaminated cooling towers. Aspiration of contaminated potable water by immunosuppressed patients is another mechanism by which *Legionella* is acquired.

Pontiac fever occurs predominantly in outbreaks with very high attack rates. *L. pneumophila, L. micdadei,* and *L. anisa* have been implicated in outbreaks of Pontiac fever. Among residents of nursing homes, Pontiac fever has been associated with *L. pneumophila* concentrations greater than 10^4 colony-forming units/L in shower water. Those receiving corticosteroid therapy have a six-fold higher risk of developing Pontiac fever.

PATHOBIOLOGY

After being inhaled, legionellae are phagocytized in the lungs by alveolar macrophages. Legionellae abrogate phagosome-lysosome fusion and replicate in an endosome surrounded by the endoplasmic reticulum. Once it is intracellular, the bacteria-laden endosome recruits small vesicles, mitochondria, and ribosomes, and within 4 to 6 hours it becomes enveloped by the endoplasmic reticulum, thereby establishing the replicative endosome. Bacterial growth then begins and continues in the macrophages for approximately 24 hours, at which time the macrophage disintegrates by apoptosis and the bacteria are released. The released bacteria are often phagocytized by other macrophages, dendritic cells, and epithelial cells, perpetuating the infection. Cell-mediated immunity is necessary for recovery from *Legionella* infection. Production of type 1 interferons has a protective effect by promoting the activation of macrophages. Activated macrophages limit the intracellular replication of legionellae by decreasing the expression of transferrin receptors and limiting the availability of iron to the bacteria. Toll-like receptor (TLR) 2, TLR4, TLR5, and TLR9 are activated during infection with *L. pneumophila*. Interleukin (IL)-1α, IL-1β, IL-4, IL-6, IL-12, and IL-18 are detected during *Legionella* infection. Vaccination of guinea pigs with the purified major outer membrane protein OmpS protects against an LD100 lethal challenge, whereas immunization with purified Hsp60 provides little protection. Polymorphonuclear leukocytes are present in abundance in the infected lung, but their role in clearing the infection is unclear. Bacteria can spread beyond the lung and cause metastatic infection. However, many extrapulmonary effects of LD, such as cerebellar ataxia and confusion, are not due to metastatic infection; they are presumably due to as yet unidentified toxins. The infected lung is consolidated, and there is usually no parenchymal damage once recovery occurs. Abscess formation and bronchiolitis obliterans or fibrosing alveolitis are occasionally seen.

The pathogenesis of Pontiac fever is unclear. The onset of illness occurs within 12 to 36 hours after the inhalation of, presumably, endotoxin. This period is too short for bacterial multiplication to cause the symptoms.

CLINICAL MANIFESTATIONS

Most of our knowledge of the clinical features of LD comes from studying patients who have been hospitalized with this illness—that is, those with the most severe manifestations. Fever (often quite high), malaise, and cough are present in most patients. Chills occur in about 75%, and dyspnea in just over half the patients. Other features include myalgias, headache, chest pain, and diarrhea. The cough is nonproductive in 50% of patients; others have scant sputum production that is usually mucoid, rarely purulent, and very rarely bloody. There are no clinical features that distinguish individual patients with LD from those with pneumonia caused by other pathogens. However, when patients with LD are compared with those with community-acquired pneumonia due to other agents, the patients with LD are more likely to have myalgias, headache, diarrhea, and a higher mean oral temperature at the time of presentation. They also present to the hospital sooner after the onset of symptoms—4.7 days versus 7.7 days. When patients with LD were compared with patients with bacteremic pneumococcal pneumonia, the following features were associated with *Legionella* pneumonia: male sex (odds ratio [OR] 4.6), heavy drinking (OR 4.8), previous β-lactam therapy (OR 19.9), axillary temperature greater than 39° C (OR 10.3), myalgias (OR 8.5), and gastrointestinal symptoms (OR 3.5). Pleuritic chest pain and purulent sputum were less likely to be present. In a young, otherwise healthy person with rapidly progressive pneumonia (especially if the progression occurs in the setting of β-lactam therapy), LD should be strongly suspected. Mental confusion is common, and on occasion, the presentation is dominated by extrapulmonary manifestations such as cerebellar ataxia, seizures, or encephalitis. Rarely, extrapulmonary infection such as prosthetic valve endocarditis, sinusitis, dialysis shunt infection, or abscess formation occurs.

Physical findings include fever, tachypnea, relative bradycardia, and initially only a few crackles on chest examination. Later the findings of pulmonary consolidation are not uncommon. Abdominal examination is usually unremarkable. Rash as a manifestation of LD is very rare. Progression of the illness is not uncommon, even following the institution of antibiotic therapy. This is more likely in immunocompromsied patients, who may require up to a week to respond to therapy. About half the patients with LD who require hospitalization have a complicated course.

Pontiac fever has an incubation period of about 36 hours. Fever, severe myalgia, headache, and extreme fatigue are the dominant manifestations. The illness is of short duration, lasting, on average, 3 days.

DIAGNOSIS

It is most important to have a high index of clinical suspicion that a patient might have LD. Routine laboratory tests are nonspecifically abnormal. Leukocytosis is common; leukopenia, thrombocytopenia, and disseminated intravascular coagulation also occur. Other laboratory abnormalities can include hyponatremia (in about half the patients, sometimes severe), hypophosphatemia (also common, occurring early and resolving within a few days of the initiation of treatment), mild liver function test abnormalities (except for alkaline phosphatase, which is occasionally very elevated), elevated creatine kinase (occasionally with rhabdomyolysis), microscopic hematuria, and mild proteinuria. High procalcitonin levels exceeding 1.5 are associated with a higher rate of admission to intensive care units and death.

There are a number of specific tests for the diagnosis of LD. Tests to detect *L. pneumophila* SG 1 antigen in urine are available commercially. These are easy to use, but there is a false-negative rate of up to 26%. LD is now usually diagnosed with a urinary antigen test, and it is often diagnosed earlier in the course of the illness than previously. This may be a factor in the lower mortality rates from LD compared with historic rates. Sputum culture has a low sensitivity but is 100% specific. It should be performed on all patients suspected of having LD. Serologic tests are not clinically useful because of the long time (6 to 12 weeks) required to seroconvert; however, they do have a role in the work-up of outbreaks of LD. Polymerase chain reaction (PCR) can be used to amplify *Legionella* DNA in sputum, bronchoalveolar lavage fluid, pleural fluid, pulmonary tissue, or serum. However, PCR tests are not sufficiently developed to be used in most diagnostic laboratories.

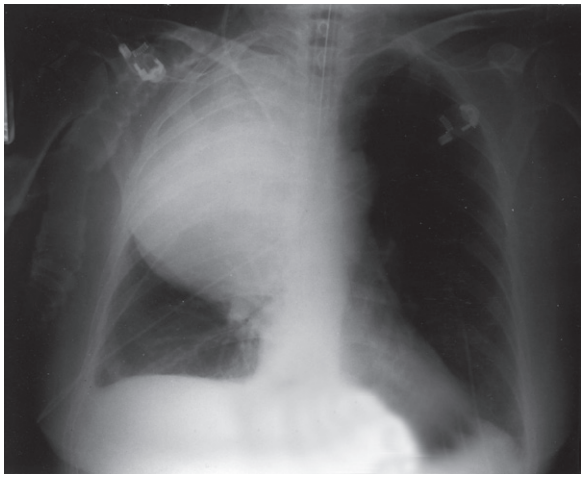

FIGURE 322-2. Posteroanterior chest radiograph of a patient with community-acquired pneumonia due to *Legionella pneumophila*. Note the dense consolidation of the right upper lobe, with bulging of the fissure. Such dense consolidation is a common radiographic appearance of legionnaires' disease.

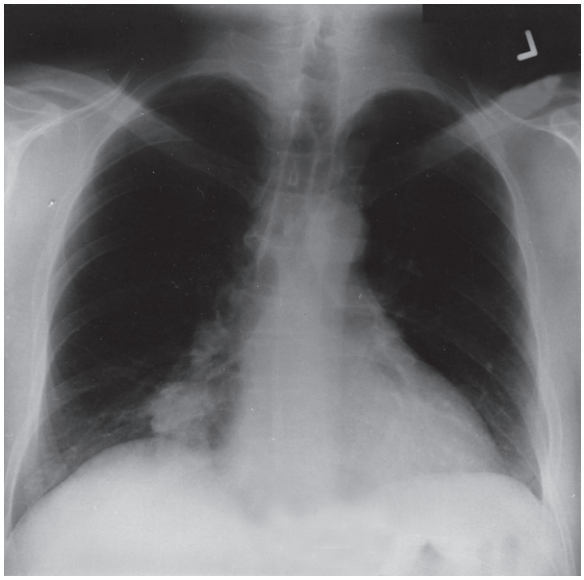

FIGURE 322-3. Posteroanterior chest radiograph of a patient with community-acquired legionnaires' disease (*L. pneumophila*) manifesting as a right lower lobe nodular opacity.

A chest radiograph is necessary to establish a diagnosis of pneumonia. About half the patients with LD have unilateral pulmonary involvement. The lower lobes are involved most commonly. About one third of patients have a pleural effusion. Dense opacification is common, but interstitial and nodular opacities also occur. Cavitation is uncommon. Figures 322-2 through 322-5 illustrate some of the radiographic findings in LD.

The diagnosis of Pontiac fever is based on demonstration of *Legionella* in water to which the patient was exposed, seroconversion to *Legionella,* and a compatible clinical course.

Differential Diagnosis

LD should be considered in any patient with pneumonia who is admitted to the hospital, especially those who require treatment in an intensive care unit. If *Legionella* is present in a hospital's water supply, LD should be considered in all patients with nosocomial pneumonia.

TREATMENT

Rx

If the diagnosis of LD is known, levofloxacin and moxifloxacin are first-choice agents (Table 322-2). Unfortunately, no randomized controlled trials have studied the therapy of LD. Data from a prospective, nonrandomized study indicate that levofloxacin is superior to macrolides for the treatment of severe LD.■ In this study carried out in Murcia, Spain, 3.4% of the patients receiving levofloxacin had complications, compared with 27.2% of those receiving macrolides; the levofloxacin patients had a shorter length of stay—5.5 versus 11.3 days. The addition of rifampin to levofloxacin produced no additional benefit. In one clinical trial, 20 of 21 patients with LD were cured when treated with azithromycin. In another study, the authors selected 139 cases of *L. pneumophila* pneumonia in a prospective series of 1934 consecutive cases of community-acquired pneumonia. The overall mortality rate was 5%. Eighty patients received initial therapy with a macrolide, and 40 received levofloxacin. Those who received levofloxacin had a faster time to defervescence (2 vs. 4.5 days) and to clinical stability (3 vs. 5 days) and a shorter median length of stay (8 vs. 10 days); there were no significant differences in complications or mortality. In a review of data from six clinical trials, 75 patients with *Legionella* infection were treated with levofloxacin, and 90% of these infections had resolved clinically at the post-therapy visit 2 to 14 days after the termination of treatment. The authors concluded that treatment with levofloxacin 500 mg/

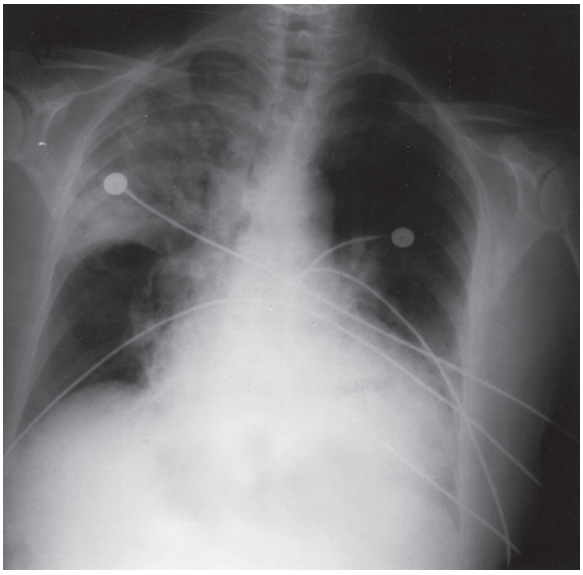

FIGURE 322-4. Posteroanterior chest radiograph of a patient with community-acquired *Legionella feeleii* pneumonia. There is patchy consolidation of the right upper lobe.

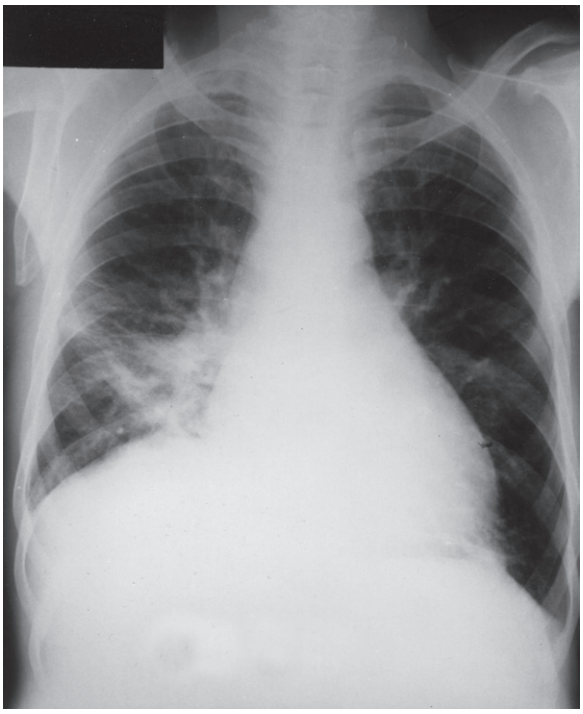

FIGURE 322-5. Posteroanterior chest radiograph of a patient with community-acquired pneumonia due to *Legionella pneumophila*. There is patchy consolidation at the right base, with subsegmental atelectasis and elevation of the right hemidiaphragm.

TABLE 322-2 TREATMENT FOR LEGIONNAIRES' DISEASE

SEVERITY OF *LEGIONELLA* PNEUMONIA	DRUG	DOSAGE
Mild pneumonia in a non-immunocompromised person treated at home	Azithromycin	500 mg once daily for 5 days
	Clarithromycin	500 mg bid for 10 days
	Doxycycline	200 mg loading dose, then 100 mg bid for 10 days
	Levofloxacin	500 mg once daily for 10 days
	Moxifloxacin	400 mg once daily PO for 10 days
Pneumonia requiring hospitalization and/or pneumonia in an immunocompromised person	Levofloxacin	750 mg once daily (IV initially) for 10-14 days*
	Azithromycin	500 mg once daily for 10 days*
	Moxifloxacin	400 mg once daily for 10 days*
	Ciprofloxacin	400 mg q8h IV for 14 days*
	Erythromycin	1000 mg IV qid for 3 days; then 500 mg qid for a total of 21 days
	plus	
	Rifampin	600 mg PO bid for 5 days

*Increase duration of treatment to 21 days for immunocompromised persons.

day for 7 to 14 days or 750 mg/day for 5 days was effective. In a study of 33 patients admitted to an intensive care unit with LD, fluoroquinolone administration within 8 hours of arrival was associated with decreased mortality. There are no good data on the duration of treatment of LD. The consensus is that 7 to 10 days of treatment with azithromcyin or a quinolone is sufficient. However, longer treatment is required if there is lung abscess, empyema, or endocarditis. In immunosuppressed patients, therapy should last for 21 days.

A meta-analysis of 24 trials involving 5015 patients with pneumonia showed that for patients with LD, there was a significant benefit when empirical therapy for pneumonia included agents active against *Legionella*. ■ All patients who are severely ill with pneumonia should receive empirical therapy that treats *Legionella* as well as other pathogens. This is in line with the pneumonia guidelines issued by the American Thoracic Society and the Infectious Diseases Society of America.

PROGNOSIS

The case-fatality rate from LD has been decreasing. In one study from Spain, the case-fatality rate fell from 35% in 1993 to 5.6% in 2004. In general, the fatality rate is higher in sporadic cases than in outbreak cases, and it is higher in nosocomial cases compared with community-acquired cases. The highest fatality rate is seen in nosocomial LD, where it is still about 30%. Earlier diagnosis using the urinary antigen test and more effective antibiotic therapy account for much of the reduction in mortality. Factors associated with mortality are older age, immunosuppression, and severity of pneumonia.

Cases of LD should be reported to local health officials. An investigation is often required to determine the source of the *Legionella*.

323 *BARTONELLA* INFECTIONS

JEAN-MARC ROLAIN AND DIDIER RAOULT

DEFINITION

Bartonella species belong to the alpha 2 subgroup of *Proteobacteria* and are closely related to the genera *Brucella*, *Agrobacterium*, and *Rhizobium*. Since 1993 the genus *Bartonella* has been reorganized by adding the genera *Rochalimaea* and *Grahamella* to the family Bartonellaceae. More than 30 known *Bartonella* species and 3 subspecies have been isolated from both animals and humans. These bacteria are considered emerging pathogens that are associated with zoonosis and/or human infections. Among them, 13 validated species have been implicated in human diseases: *B. henselae, B. quintana, B. bacilliformis, B. elizabethae, B. clarridgeiae, B. vinsonii* subsp. *arupensis, B. vinsonii* subsp. *berkhoffii, B. alsatica, B. tamiae, B. grahamii, B. washoensis, B. rochalimae,* and *B. koehlerae* (Table 323-1). The other *Bartonella* species have been isolated only from the blood of animals, including rodents, felids, canids, dolphins, and ruminants. The route of transmission of *Bartonella* species in mammals and humans is via fleas, ticks, mites, and lice (see Table 323-1).

Bartonella infections are emerging infectious diseases that lead to a wide spectrum of either acute or chronic diseases. The status of the host immune response plays an important role in the development of the different manifestations. Four different clinical syndromes may occur with *Bartonella* infections: infection of red blood cells and erythrophagocytosis, granulomatous disease controlled by the immune response, blood culture–negative endocarditis and bacteremia, and vasculoproliferative diseases. A single *Bartonella* species can cause either acute or chronic infections and either vasculoproliferative or suppurative manifestations, but with different pathogenetic mechanisms that mainly depend on the patient's immune status. For example, *B. quintana* is responsible for trench fever as well as endocarditis, bacteremia in the homeless population, and vasculoproliferative diseases, whereas B. *bacilliformis* is the agent of Carrion's disease, which corresponds to either an acute intra-erythrocytic bacteremic disease (Oroya fever) or a chronic vasculoproliferative disease (verruga peruana). Infection of red blood cells has been well established for *B. bacilliformis* (Oroya fever) and *B. quintana* (trench fever and bacteremia in the homeless), whereas *B. henselae* and *B. koehlerae* have been seen in erythrocytes of infected cats. *B. henselae* can cause granulomatous disease—that is, cat-scratch disease (CSD)—which affects lymph nodes but can also be responsible for other clinical manifestations and/or complications such as endocarditis. Vasculoproliferative diseases include bacillary angiomatosis caused by *B. henselae* and *B. quintana*, peliosis hepatis caused by *B. henselae*, and verruga peruana caused by *B. bacilliformis*. The immune status of the host plays a critical role in the development of these different forms of the disease. *B. henselae* usually causes CSD (a self-limited disease) in immunocompetent hosts, whereas it is responsible for bacillary angiomatosis in immunocompromised patients. In patients with a previous valvulopathy, any *Bartonella* infection may lead to endocarditis.

The Pathogen

Bartonella species are small, gram-negative, fastidious, pleomorphic coccobacilli or slightly curved rods (0.5 by 1 to 2 μm). Because of the slow growth of these bacteria and the lack of reproducible biochemical methods for their

TABLE 323-1 *BARTONELLA* SPECIES CAUSING HUMAN DISEASE

BARTONELLA SPECIES	First Cultivation		YEAR OF DESCRIPTION	RESERVOIR HOST/VECTOR	HUMAN DISEASE

B. washoensis			2000	Ground squirrel	Myocarditis

identification, they are usually identified using molecular methods. Recently, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry has emerged as a new technique for species identification and is an accurate and reproducible method for the rapid and inexpensive identification of *Bartonella* species. The bacteria can grow on enriched blood-containing media with a 5% carbon dioxide atmosphere after 5 to 15 days to up to 45 days on primary culture. The optimal growth temperature ranges from 28° C for *B. bacilliformis* to 35 to 37° C for the other species. *Bartonella* species can also be cocultured with endothelial cells. *Bartonella* species are either flagellated or nonflagellated cells. *B. bacilliformis* uses flagella for binding and deforming into the surface of erythrocytes. Bacteria can either persist in the blood stream of the host as intra-erythrocytic parasites or colonize human endothelial cells.

EPIDEMIOLOGY

Almost all *Bartonella* species are vector-borne bacteria (see Table 323-1). Some are limited geographically, such as *B. bacilliformis*, which is only found in the Andes Mountains in South America at high altitudes, where its principal vector *Lutzomia verrucarum* is distributed; others have a worldwide distribution, such as *B. henselae* and *B. quintana*. Each *Bartonella* species is highly adapted to its mammalian reservoir, in which bacteria usually cause a long-lasting intra-erythrocytic bacteremia that may be asymptomatic. Humans are the hosts and reservoirs for *B. bacilliformis* and *B. quintana. B. quintana* is transmitted via the human body louse by inoculation of arthropod feces through broken skin (Chapter 367). Cats represent the main reservoir hosts for *B. henselae* infection; this pathogen is the agent of CSD in humans, caused by cat bites or scratches. *B. henselae* infection is transmitted from cat to cat by the cat flea. Cat fleas may also be infected by *B. quintana.* The role of dogs as reservoir hosts has been documented for several species, including *B. vinsonii* subsp. *arupensis, B. vinsonii* subsp. *berkhoffii,* and *B. henselae.* Wild rabbits are the reservoir hosts for *B. alsatica,* which was recently reported to be an agent of endocarditis and lymphadenopathy in humans in close contact with rabbits. For other *Bartonella* species known to cause diseases in humans (see Table 323-1), their pathogenic role and mode of transmission are not fully understood.

INFECTION OF RED BLOOD CELLS: OROYA FEVER AND TRENCH FEVER

PATHOBIOLOGY

In Oroya fever, *B. bacilliformis* invades up to 80% of erythrocytes and produces their massive lysis, which results in severe hemolytic anemia, the major symptom of the disease. Similarly, trench fever is characterized by an intracellular erythrocyte parasitism by *B. quintana,* with the percentage of infected red blood cells ranging from 0.001 to 0.005% (Fig. 323-1). Bacteria can also be seen extracellularly and in erythroblasts. This intracellular erythrocyte parasitism can presumably preserve the pathogens for efficient transmission by body lice, protect *B. quintana* from the host immune response, and contribute to decreased antimicrobial efficacy. During bacteremia in the homeless, *B. quintana* can also be seen in red blood cells.

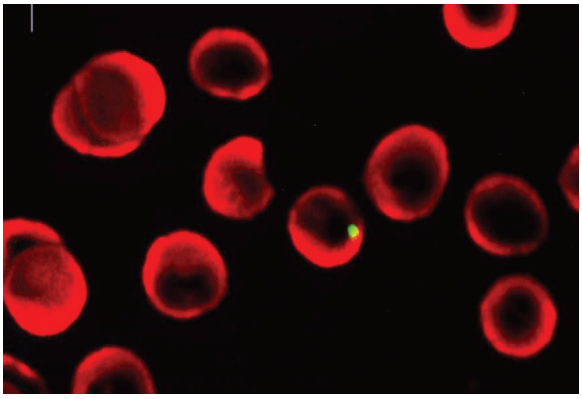

FIGURE 323-1. Section of human red blood cell infected with *Bartonella quintana* as viewed by confocal microscopy.

CLINICAL MANIFESTATIONS

The main clinical manifestations of infection by *Bartonella* species are summarized in Table 323-2.

Oroya fever is the acute or hemolytic phase of Carrion's disease, caused by *B. bacilliformis*; it usually develops 3 to 12 weeks after inoculation. Oroya fever results from the massive invasion of erythrocytes by *B. bacilliformis*, and without antibiotic treatment, it causes death in up to 85% of infected humans by hemolysis or when complicated by opportunistic infections such as salmonellosis. The onset is usually abrupt, with high fever, chills, headache, and anorexia. Patients have intense myalgias and arthralgias, abdominal pain, and jaundice. Complications are frequent, including meningoencephalitis, dyspnea, delirium, and superinfection leading to death. Asymptomatic persistent bacteremia may serve as the reservoir of the organism.

Trench fever is transmitted by lice (Chapter 367) and is the clinical manifestation of *B. quintana.* Trench fever affected more than 1 million people

during World War I; more recently, *B. quintana* has been recognized in immunocompromised hosts, homeless people, and chronic alcoholics. Clinical manifestations of trench fever may range from asymptomatic infection to severe, life-threatening illness. After an incubation period of 2 to 3 weeks, there is a sudden onset of fever that lasts 1 to 3 days associated with headache, shin pain, and dizziness. Although fatal cases have not been reported, the disease may persist for 4 to 6 weeks and result in prolonged disability. Relapses may occur years later, and in some cases there may be bacteremia with no clinical signs.

CAT-SCRATCH DISEASE

PATHOBIOLOGY

Little is known about the pathogenesis of the long-lasting lymphadenopathy in CSD. Immunopathogenesis is assumed to play an important role in CSD because bacteria have only rarely been isolated from affected lymph nodes. Thus, the disease is usually controlled by the host immune response, and there are few or no viable bacteria when lymph node biopsy specimens are analyzed; they are necrotic by pathology.

CLINICAL MANIFESTATIONS

Typical CSD is the most common manifestation of infection with *B. henselae* and usually presents as a self-limited regional lymphadenitis. Transmission from cat to human occurs directly by a cat scratch or cat bite or possibly by a cat flea or tick bite. A typical papule or pustule may be seen 3 to 10 days after the scratch or bite at the site of inoculation and may last for 1 to 3 weeks. The subsequent lymphadenopathy is localized mainly to the axillary, cervical, or submaxillary nodes that drain the area where the cat scratch occurred. The enlarged lymph node is often painful and tender. Lymphadenopathy sometimes lasts for months, and in a few cases it can persist for as long as 1 to 2 years. In some cases the lymph node may suppurate if it is not drained. Most patients are not febrile during the course of typical CSD. Systemic or severe disease may occur in about 5 to 14% of patients, with most of them suffering severe systemic symptoms due to disseminated infection. *B. alsatica* was recently reported as a cause of lymphadenitis in a woman scratched on the finger while butchering a wild rabbit. Interestingly, it has recently been demonstrated that following exposure to *B. henselae*, patients may develop bacteremia with or without clinical signs of typical CSD, and in patients with valvular lesions, this may result in infective endocarditis. Thus, CSD represents the primary infection of *B. henselae,* and endocarditis may follow in patients with heart valve lesions.

Approximately 10% of patients with CSD have atypical clinical manifestations, including prolonged fever (>2 weeks), malaise, neuroretinitis, encephalitis, erythema nodosum, hepatitis, fatigue, weight loss, and splenomegaly. A recent clinical study showed that musculoskeletal manifestations (myalgia, arthritis, arthralgia, tendinitis, osteomyelitis, neuralgia) were present in more than 10% of patients with CSD, demonstrating that these clinical manifestations are not as rare as might be expected from the cases reported in the past. In this series of 913 patients, myalgia and arthropathy were the most common manifestations, with an incidence of 5.8% and 5.5%, respectively. Moreover, these manifestations occurred primarily in adults whose ages ranged from 20 to 59 years. Myalgia had a mean duration of 4 weeks and was often severe. Arthropathy had a mean duration of 5.5 weeks, was more common in female patients older than 20 years, affected large and medium joints (half of those involved being weight-bearing joints), and was associated with symmetrical erythema nodosum early in the course of CSD. These musculoskeletal manifestations are often severe and may evolve into chronic forms that persist for more than a year. Tendinitis, neuralgia, and osteomyelitis are less common, with incidences lower than 1%.

Ocular and Neurologic Manifestations

Parinaud's oculoglandular syndrome is a self-limited conjunctivitis associated with preauricular lymphadenopathy. Other atypical manifestations include neurologic syndromes (meningoencephalitis, meningitis, neuroretinitis). Encephalopathy may occur in 2 to 4% of CSD patients, mainly adolescents and adults. Patients usually have persistent headaches with or without fever and may develop seizures. Acute neurologic disorders range from self-limited nuchal rigidity to pupillary dilatation or aphasia and hemiplegia; they may last for several weeks to months. Neuroretinitis has been associated with CSD in patients experiencing a sudden unilateral loss of visual acuity. The most common picture remains papilledema associated with macular exudates causing stellar retinitis. A few reports have now established that *B. henselae* can be responsible for uveitis, along with *B. grahamii* and *B. quintana.* Patients present with either nongranulomatous or granulomatous uveitis.

Finally, tick-borne *B. henselae* infection has been described, including scalp eschar and neck lymphadenopathy after tick bites in three patients during the colder months in France. *B. henselae* was detected using molecular tools both in skin biopsy (cervical and occipital) and in a *Dermacentor marginatus* tick removed from the scalp of one patient. All three patients had asthenia, but none had alopecia.

ENDOCARDITIS

PATHOBIOLOGY

B. quintana, B. henselae, B. alsatica, B. vinsonii subsp. *berkhoffii, B. elizabethae,* and "*Candidatus Bartonella mayotimonensis*" have been associated with blood culture–negative endocarditis, whereas *B. vinsonii* subsp. *arupensis* has been detected in a patient with fever and bacteremia; *B. washoensis* has been identified in one patient with myocarditis; *B. rochalimae* was recently reported in a patient with fever, bacteremia, and splenomegaly; and *B. tamiae* has been isolated in a patient with a febrile illness. Patients with endocarditis usually have preexisting heart valve disease that promotes the development of infective endocarditis and, in some cases, a definite risk factor for infection specifically with *Bartonella.* Endocarditis caused by *Bartonella* species exhibits slight inflammation, with a few inflammatory mononuclear cells and small vegetations; the bacteria are seen extracellularly in dense immunopositive clusters that are mainly included in vegetations and in neutrophil and macrophage cytoplasm.

CLINICAL MANIFESTATIONS

The most commonly identified agents of *Bartonella* endocarditis are *B. quintana,* followed by *B. henselae* and other *Bartonella* species. Patients appear to

have chronic, blood culture–negative endocarditis, usually with fever (90%). Echocardiography reveals vegetations (in 90%) that should be removed by surgery in the majority of patients. Infections with *B. henselae* are epidemiologically linked to close contact with cats or cat fleas and previous valvular heart disease, whereas *B. quintana* endocarditis is frequently described in homeless and alcoholic patients with body lice infection and can be observed in patients without previous valve lesions. The onset is usually subacute, with some patients being afebrile at the time of admission. About half the patients have embolic phenomena. Interestingly, there is a north (Europe) to south (North Africa) gradient for the proportion of *Bartonella* endocarditis in humans; thus *Bartonella* is apparently a very common cause of endocarditis in North Africa. Sporadic cases of endocarditis have been also associated with *B. koehlerae*, *B. vinsonii* subsp. *berkhoffii*, *B. vinsonii* subsp. *arupensis*, *B. elizabethae*, *B. alsatica*, and "*Candidatus Bartonella mayotimonensis*."

VASCULOPROLIFERATIVE DISEASE: VERRUGA PERUANA, BACILLARY ANGIOMATOSIS, AND PELIOSIS HEPATIS

PATHOBIOLOGY

Bartonella species have the ability to cause vasculoproliferative lesions through a process of pathologic angiogenesis resulting in the formation of new capillaries from preexisting ones. These typical vasoproliferations can be expressed as skin lesions called bacillary angiomatosis, which are caused by *B. quintana* and *B. henselae;* there is also a cystic form in the liver and spleen called peliosis hepatis, which is caused only by *B. henselae*. Skin lesions are very similar to those reported for verruga peruana, the chronic form of Carrion's disease. Bacillary angiomatosis is a neovascular proliferation that has been reported most commonly in AIDS patients and involves the skin (Fig. 323-2) and lymph nodes; it occurs less frequently in patients with other causes of immunosuppression and exceptionally in immunocompetent patients. In bacillary angiomatosis, lesions comprise proliferating endothelial cells, bacteria, and mixed infiltrates of macrophages/monocytes and polymorphonuclear neutrophils, leading to chronic inflammation. Bacteria are clustered as aggregates both surrounding and within endothelial cells, indicating that the vascular endothelium represents a target tissue for intra- and extracellular colonization in vivo. Histologically, bacillary angiomatosis is a lobular proliferation of small blood vessels containing endothelial cells and bacteria, usually seen in clusters when stained with Warthin-Starry. As in bacillary angiomatosis, lesions of verruga peruana are characterized by lobular proliferations and atypical endothelial cells forming both relatively solid sheets and small, well-formed vessels with patent lumens. Lesions are typically infiltrated, indicating a chronic inflammatory process.

FIGURE 323-2. Skin lesion of bacillary angiomatosis.

CLINICAL MANIFESTATIONS

As already noted, bacillary angiomatosis is seen most often in AIDS patients. Cutaneous lesions often arise in crops and can be subcutaneous or dermal nodules with red or purple papules millimeters to centimeters in diameter. When cutaneous lesions are absent, the diagnosis is often difficult and delayed because signs of visceral involvement are usually nonspecific. The potentially systemic nature of bacillary angiomatosis is reflected by the involvement of brain, bone, lymph node, bone marrow, skeletal muscle, conjunctiva, and mucosal surfaces of the gastrointestinal and respiratory tracts. Peliosis hepatis affects solid internal organs, primarily the liver, with reticuloendothelial elements; in the liver it is defined as a vascular proliferation of sinusoidal hepatic capillaries resulting in blood-filled spaces. The spleen, abdominal lymph nodes, and bone marrow may also be involved.

Following acute Oroya fever, patients usually develop angioproliferative cutaneous tumors called verruga peruana after a latent period ranging from weeks to months. The infection is characterized by benign cutaneous vascular lesions that typically consist of round papules that are frequently pruritic and bleeding. The infection is accompanied by malaise and arthralgias. Skin lesions may change over time from miliary to nodular subcutaneous lesions to large mulaire lesions. These large lesions are often engorged with blood and prone to ulceration and bleeding. This eruptive phase clinically resembles Kaposi's sarcoma or bacillary angiomatosis. However, it has a low morbidity, and there are no reports of mortality.

DIAGNOSIS OF *BARTONELLA* INFECTION

Methods used for the diagnosis of *Bartonella* infection include serology, microscopy, culture, molecular amplification of *Bartonella* species genes, direct immunofluorescence, and immunohistochemistry. The usefulness of these techniques may vary according to the disease involved (Table 323-3).

Serologic Tests

Serology remains the most widely used method for the diagnosis of CSD and *Bartonella* endocarditis because culture and isolation are difficult and time-consuming, and molecular methods are not available in all laboratories. There are currently two classic serologic methods for the diagnosis of *Bartonella* infections: enzyme-linked immunosorbent assay (ELISA) and immunofluorescence assay (IFA). By IFA, an immunoglobulin G titer of 1:64 or greater should be considered positive for CSD, whereas patients with endocarditis

IF = immunofluorescence; SENLAT = scalp eschar and neck lymphadenopathy.

usually have higher antibody titers (≥1:800). In homeless patients, bacteremia has been associated with serologic tests that were positive for *B. quintana*. However, reported sensitivities of IFA vary considerably, from nearly 100% to less than 30%, depending on the nature of the antigens used and the selected patients. Moreover, owing to cross-reactive antibodies between *Bartonella* species, the diagnosis of *Bartonella* infection at the species level is usually not possible. More sophisticated methods should be used, especially Western blot with cross-adsorption analysis. Western blot is also useful for the differential diagnosis of endocarditis because the profile obtained for endocarditis is specific compared with that for CSD or chronic bacteremia.

Microscopy, Immunofluorescence, and Immunohistochemistry

The diagnosis of Oroya fever is based on examination of a peripheral blood smear stained by Giemsa; the percentage of infected red blood cells is sufficiently high so that bacteria are visible. Similarly, *B. quintana* can be seen within red blood cells using specific monoclonal antibody by immunofluorescence and confocal microscopy (see Fig. 323-1). Microscopic examination after Warthin-Starry silver staining or immunohistochemistry of cardiac valve or skin biopsy is also useful for the detection of *Bartonella* organisms in patients with endocarditis and bacillary angiomatosis.

Culture

Bartonella species can be recovered from the blood of bacteremic patients as well as from cardiac valves, skin and liver biopsies, and, rarely, lymph nodes. Bacteria can be isolated directly from these specimens after plating onto blood agar solid media, blood culture in broth, and cocultivation in endothelial cells. Cultures are usually positive after 2 weeks of incubation, but up to 45 days may be necessary for primary isolation.

Molecular Detection Methods

Direct detection and final identification of *Bartonella* species from blood and tissue specimens, including lymph node, cardiac valve, skin, and liver, can be achieved using polymerase chain reaction (PCR) amplification and sequencing of various housekeeping genes. Real-time PCR with Taqman probes has been added to the panel of molecular techniques for the specific detection of *Bartonella* at the species level from lymph nodes in CSD, directly from cardiac valves in patients with endocarditis, and in patients with bacillary angiomatosis or peliosis hepatis.

Differential Diagnosis

The differential diagnosis of bacillary angiomatosis is Kaposi's sarcoma, but visualization of bacteria in the tissue specimen can help distinguish between these two entities. Trench fever may be confused mainly with typhus group rickettsiosis, relapsing fever, and malaria. CSD may be confused with tularaemia, pyogenic lymphadenitis, mycobacterial infection, and neoplasia.

TREATMENT

Trench Fever

Before the advent of antibiotics, acetylsalicylic acid was the most effective drug for the pain caused by trench fever. However, a randomized clinical trial in homeless persons with episodes of bacteremia demonstrated that the combination of gentamicin and doxycycline is more effective in stopping bacteremia compared with no treatment or the use of β-lactams or doxycycline alone. Because the intra-erythrocytic presence of *B. quintana* decreases antimicrobial efficacy, the duration of treatment is critical in trench fever. Patients with *B. quintana* bacteremia should be treated with gentamicin (3 mg/kg body weight/day IV for 14 days), in combination with doxycycline (200 mg/day PO) for 28 days.

Oroya Fever and Verruga Peruana

In Oroya fever, treatment with penicillin, streptomycin, fluoroquinolones, tetracycline, or erythromycin produces rapid defervescence and disappearance of the organisms from the blood, usually within 24 hours. As an alternative treatment, chloramphenicol can be used alone or in combination with a β-lactam. Treatment with chloramphenicol may also have the advantage of covering commonly associated *Salmonella* species. Patients with Oroya fever should be treated with chloramphenicol (500 mg PO four times a day) for 14 days in combination with another antibiotic (especially a β-lactam compound). Streptomycin (15 to 20 mg/kg/day for 10 days) was the traditional treatment for verruga peruana. However, its use is problematic, especially in children, and rifampin has become the drug of choice for the treatment of eruptive-phase bartonellosis. Failures of rifampin treatment have been reported in verruga peruana. Finally, ciprofloxacin (500 mg PO twice daily for 7 to 10 days) has been used successfully for the treatment of multiple eruptive-phase lesions in adults and has been proposed as an appropriate alternative. Doxycycline in association with gentamicin may be used to treat the eruptive phase of Carrion's disease.

Cat-Scratch Disease

Typical CSD is a self-limited illness that resolves within 2 to 6 months and usually does not respond to therapy because the bacteria within necrotic lymph nodes are not alive. In cases of long-lasting lymphadenopathy, patients should be reassured that it is benign and will probably subside spontaneously within 2 to 4 months. Management consists of analgesics for pain and prudent follow-up. However, azithromycin (500 mg PO on day 1 and 250 mg PO on days 2 to 5 as single daily doses) is an alternative for patients with large, bulky lymphadenopathy. If lymphadenopathy does not resolve, lymph nodes can surgically be removed. For atypical presentations of CSD, there are no data regarding the benefit of specific antimicrobial therapy for immunocompetent patients. For neuroretinitis, the combination of doxycycline (100 mg PO or IV twice daily) with rifampin (300 mg PO twice daily) seems to promote disease resolution, improve visual acuity, reduce optic disc edema, and decrease disease duration.

Endocarditis

Patients with *Bartonella* endocarditis have a higher death rate and undergo valvular surgery more frequently than patients with endocarditis caused by other pathogens. Patients with suspected (but culture-negative) *Bartonella* endocarditis or proved *B. quintana* endocarditis should be treated with oral doxycycline 100 mg twice a day for 6 weeks in combination with gentamicin 3 mg/kg/day in one intravenous daily dose for 14 days. The American Heart Association consensus on treating infective endocarditis is ceftriaxone plus gentamicin, with or without doxycycline, when *Bartonella* is suspected, and doxycycline plus gentamicin when *Bartonella* endocarditis is confirmed. However, there is direct evidence that patients receiving an aminoglycoside are more likely to fully recover, and those treated with aminoglycosides for at least 14 days are more likely to survive than those receiving a shorter duration of therapy. In the absence of any prospective study for the treatment of *Bartonella* endocarditis, the same regimen as in *B. henselae* and *B. quintana* should be used for endocarditis when another *Bartonella* species has been identified as the causative agent.

Bacillary Angiomatosis and Peliosis Hepatis

Without appropriate therapy, infection spreads systemically and can involve virtually any organ, and the outcome is sometimes fatal. Thus, antibiotic treatment is warranted in all cases of *Bartonella*-associated vasculoproliferative disease. Based on empirical clinical reports, erythromycin remains the treatment of choice and has been used successfully to treat many patients with bacillary angiomatosis. The response to treatment in bacillary angiomatosis can be dramatic in immunocompromised patients, with resolution of palpable subcutaneous lesions within hours. Erythromycin also has an antiangiogenic effect on microvascular endothelial cells that could explain this quick disappearance of lesions. Erythromycin (500 mg four times daily) for 3 months is first-line therapy. Doxycycline (100 mg PO or IV twice daily) is currently proposed as an appropriate alternative. In patients with serious infections, erythromycin or doxycycline can be used in combination with rifampin (300 mg PO twice daily). The duration of therapy is critical. We recommend that treatment be given for at least 3 months for bacillary angiomatosis and 4 months for peliosis hepatis. Peliosis hepatis responds slowly, and hepatic lesions continue to improve after several months of treatment, whereas cutaneous bacillary angiomatosis demonstrates improvement after 4 to 7 days of treatment and resolves after about 1 month of treatment. Relapses of peliosis hepatis and bacillary angiomatosis lesions after antibiotic treatment have been reported frequently, especially in immunocompromised patients with a shorter duration of therapy. Patients who relapse after the recommended treatment should probably be retreated for 4 to 6 months with erythromycin (500 mg PO four times daily) or doxycycline (100 mg PO twice daily), and those with repeated relapses should receive antibiotic therapy as long as they are immunocompromised.

PREVENTION

Because arthropods play an important role in the transmission of feline *Bartonella* species to humans, rigorous arthropod control (Chapter 367) should be recommended by health care workers, particularly when advising immunocompromised individuals on the risks related to pet ownership. Cat fleas live on both cats and dogs and are best controlled by fumigating areas where these animals live.

PROGNOSIS

Mortality in those with Oroya fever was as high as 50% before the antibiotic era but is now limited by the use of antibiotics. Trench fever should be treated

with antibiotics to avoid more severe disease, especially in patients with valvulopathy who are at risk of developing endocarditis. CSD usually resolves spontaneously without any treatment in immunocompetent patients. In the case of complications or in immunocompromised patients, antibiotic therapy should be given, and patients usually respond well to treatment. Finally, for vasculoproliferative diseases, antibiotics are usually effective if given for a long time, but cutaneous lesions in verruga peruana may benefit from surgery.

324

GRANULOMA INGUINALE (DONOVANOSIS)

EDWARD W. HOOK III

DEFINITION

Granuloma inguinale, also known as donovanosis, is a slowly progressive ulcerative disease that involves principally the skin and subcutaneous tissues of the genital, inguinal, and anal regions.

The Pathogen

The causative organism is *Klebsiella granulomatis* (formerly *Calymmatobacterium granulomatis*), a facultative intracellular parasite. The organism is challenging to cultivate but can be grown in yolk sacs, and successful cell culture has been reported from South Africa and Australia. Successful culture, in turn, has permitted the development of polymerase chain reaction (PCR) assays for research purposes.

EPIDEMIOLOGY

The organism is primarily transmitted sexually, but it can probably be transmitted by nonsexual contact as well. Transmission efficiency is relatively low, and multiple sexual contacts with an infected partner seem to be necessary for the transmission of infection. The disease is uncommon in the United States, with fewer than 50 recorded cases annually. Historically, however, it is more common in other areas of the world, including India, Papua New Guinea, southern Africa, and parts of Australia. Even in these endemic areas, the limited data available suggest that the disease may be becoming less common.

CLINICAL MANIFESTATIONS

The initial lesion usually appears as a subcutaneous nodule that erodes through the surface and develops into a beefy, elevated granulomatous lesion (Fig. 324-1). The lesion is painless and unassociated with systemic symptoms. Lesion exudate is often described as foul smelling. Secondary bacterial infection may cause a necrotic, painful, ulcerative lesion that may be rapidly destructive. A cicatricial form may also occur, with a depigmented elevated area of keloid-like scar containing scattered islands of granulomatous tissue. Genital lesions are commonly associated with pseudobuboes in the inguinal region; these swellings are usually not due to involvement of the inguinal lymph nodes but rather to granulomatous involvement of subcutaneous tissue. Metastatic infection of bones or viscera is occasionally seen. Clinical experience suggests that secondary carcinomas may be a rare complication of granuloma inguinale.

DIAGNOSIS

The diagnosis is made by demonstrating intracellular Donovan's bodies in histiocytes or other mononuclear cells from lesion scrapings or biopsy samples. Wright stain and Giemsa stain of fresh impression smears or unfixed biopsy specimens usually demonstrate the bacilli relatively easily, although multiple biopsies may be necessary in chronic cases. Histologic examination of biopsy specimens shows mononuclear cells with some infiltration by polymorphonuclear leukocytes but no giant cells. In infected lesions, *K. granulomatis* is found primarily in histiocytes or other mononuclear cells. Cell culture and PCR methods are primarily research tools. No serologic test is clinically available.

Differential Diagnosis

The differential diagnosis includes squamous cell carcinoma, chancroid (Chapter 309), lymphogranuloma venereum (Chapter 326), syphilis (Chapter 327), and other ulcerative granulomatous diseases. In the absence of therapy, patients may not present until lesions have been present for months, long after the lesions of syphilis and other ulcerative sexually transmitted diseases have resolved. Chancroid is usually differentiated by its irregular undermined borders, which are not seen in typical cases of granuloma inguinale. Dark-field examination and serologic tests should help distinguish syphilis. Biopsy of lesions may be necessary to distinguish granuloma inguinale from certain tumors.

TREATMENT

Rx

There are no recent clinical trials of therapy for granuloma inguinale. Recommended treatment consists of doxycycline 100 mg twice daily. Azithromycin 1.0 g weekly, ciprofloxacin 750 mg twice daily, or erythromycin base 500 mg four times daily, and one double-strength trimethoprim-sulfamethoxazole tablet twice daily, are all recommended as alternative therapies. An aminoglycoside (e.g., gentamicin 1 mg/kg intravenously every 8 hours) may be added if these regimens do not result in clinical improvement within a few days. Treatment should be administered for at least 3 weeks and until lesions are completely healed. Patients should be monitored for at least several weeks after treatment is discontinued because of the possibility of relapse. Although the risk of communicability appears to be low, sexual contacts should also be examined; at present, treatment of contacts is not indicated in the absence of clinically evident disease.

325 *MYCOPLASMA* INFECTIONS

STEPHEN G. BAUM

DEFINITION

Mycoplasma organisms of the class Mollicutes are ubiquitous as pathogens and colonizing agents in the plant, animal, and insect kingdoms. They represent the smallest known free-living forms, but because they have fastidious growth requirements, they are difficult to culture. However, the presence of several species of *Mycoplasma* as commensals in animals and on human oral and genital mucosa frequently resulted in contamination of cell cultures. Such contamination led to the false implication of mycoplasmas as causative agents in many human diseases, both trivial and life-threatening. Of the human diseases proved to be due to mycoplasmas, pneumonia caused by *Mycoplasma pneumoniae* is by far the most clinically important. This infection constitutes a significant proportion of cases previously classified as "atypical pneumonia," a nonspecific term for patchy pneumonias that generally do not respond to β-lactam antibiotics and have etiologic agents that are not easily cultured or visible on Gram stain. The term *atypical pneumonia* persists despite our increasing ability to identify specific etiologic agents such as viruses, *Legionella,* and *Chlamydophila.* Other proven *Mycoplasma* infections include those in the urogenital tract caused by *Ureaplasma* species, *Mycoplasma hominis,* and *Mycoplasma genitalium;* wound infections caused by *M. hominis;* and overwhelming systemic infection in immunocompromised patients caused by *Mycoplasma fermentans* (*incognitus* strain).

The Pathogen

Mycoplasmas are short rods (10 × 200 nm) that have no cell wall and are bounded by a sterol-containing membrane; thus, they are unaffected by cell wall–inhibiting antimicrobials such as β-lactams. In tissue culture, mycoplasmas are intracellular, but in vivo, infection is primarily extracellular and affects epithelial cells and their organelles, such as cilia. Attachment to respiratory epithelium is by way of terminal adhesin proteins. Mycoplasmas are active in stimulating several components of the immune system. They can act as polyclonal T-cell and B-cell activators and can cause capping of lymphocytes.

EPIDEMIOLOGY

M. pneumoniae infection is spread person to person by respiratory droplets produced by coughing. Relatively close association with the index case appears to be required. The disease is usually introduced into families by a young child; in some studies, most of the infected adults were the parents of young children. As opposed to most viral respiratory infections, which manifest 1 to 3 days after infection, *Mycoplasma* has an incubation period of 2 to 3 weeks. Therefore, a careful history showing several weeks between cases within a family may be an important clue to the mycoplasmal etiology. Organisms can be cultured from the sputum of infected individuals for weeks to months after clinically efficacious treatment, and it is unclear how the treatment of an index case affects subsequent transmission to family members.

Most cases of *Mycoplasma* respiratory infection occur singly or as family outbreaks. However, in closed populations, such as military recruit camps and boarding schools, *Mycoplasma* can cause mini-epidemics and may be responsible for 25 to 75% of cases of pneumonia in such settings. Serologically based epidemiologic studies have documented the high incidence of *Mycoplasma* respiratory infection throughout the world. In the United States, it is estimated that each year at least one case of *Mycoplasma* pneumonia occurs for every 1000 persons, or more than 2 million cases annually. The incidence of *Mycoplasma* nonpneumonic respiratory infection may be 10 to 20 times greater. The highest attack rates are in individuals 5 to 20 years old, but *M. pneumoniae* infection can occur at any age and may cause particularly severe disease in neonates.

As opposed to viral respiratory infections that peak in winter in temperate climates, a few studies have reported a peak incidence of *M. pneumoniae* outbreaks in the fall. Most surveys, however, show little or no seasonal predominance in sporadic cases. There is an age-related relationship of upper versus lower respiratory tract infection caused by *M. pneumoniae.* In children younger than 3 years, primarily upper respiratory tract infection develops, whereas in those 5 to 20 years old, bronchitis and pneumonia tend to occur. In older adults, pneumonia predominates.

The prevalence and incidence of clinical urogenital disease caused by *Ureaplasma urealyticum, Ureaplasma parvum, M. hominis,* and *M. genitalium* are much less well documented (Table 325-1). These organisms are rarely cultured outside the realm of clinical studies, and they exist as clinically inapparent commensals of the genitourinary tract. Diseases attributed to *Ureaplasma* species include urinary tract infection with and without calculus formation. The organism has been implicated as a cause of low birthweight in neonates. *M. hominis* is a common genitourinary and oral commensal as well and has been documented as a cause of endometritis and postpartum fever.

M. hominis has also caused sternal wound infection after cardiothoracic surgery and has been implicated in arthritis in immunocompromised patients. *Mycoplasma salivarium* may be involved in periodontal disease, and *M. genitalium* is implicated in some cases of nongonococcal urethritis and vaginitis. *M. fermentans, incognitus* strain, was identified about 3 decades ago as an infectious agent in immunocompromised patients, in whom it causes overwhelming multisystem involvement.

PATHOBIOLOGY

Because of the low fatality of most *Mycoplasma* infections, there is little human pathologic material. Inoculation onto animal tracheal organ cultures is followed by ciliary damage and desquamation of surface epithelium. This latter effect is probably responsible for the hacking cough in *Mycoplasma* respiratory infection.

Several characteristics of *M. pneumoniae* probably play a direct role in the respiratory pathogenicity of this organism. The first is the affinity of *M. pneumoniae* for respiratory epithelial cells. Attachment appears to be between a terminal organelle at one end of the filamentous organism and a sialated glycoprotein (I-FI) on the surface of both respiratory epithelium and erythrocytes that acts as a receptor. The mycoplasmal terminal adhesin

TABLE 325-1 SITES AND INFECTIONS RELATED TO HUMAN MYCOPLASMAS

SUBGROUP	SITES OF ISOLATION	DISEASES	OCCURRENCE
M. hominis	GU tract (F > M)	Cervicitis, vaginitis, ?prostatitis	Common
	Conjunctivae (neonate)	Conjunctivitis	
	Blood (peripartum)	Peripartum sepsis	
	Surgical wounds, joints	Sternotomy infection, arthritis	
M. orale	Oropharynx	?	Common
M. pneumoniae	Respiratory tract	URI, pneumonia	Common
M. salivarium	Oropharynx, gingiva	?Periodontal disease	Common
M. fermentans	GU tract, blood, tissues	Multisystem disease in AIDS	Uncommon
M. genitalium	GU tract	Urethritis, cervicitis, PID	Uncommon
Ureaplasma spp	GU tract	Urethritis, upper GU infection	Common

AIDS = acquired immunodeficiency syndrome; F = female; GU = genitourinary; M = male; PID=pelvic inflammatory disease; URI = upper respiratory tract infection.

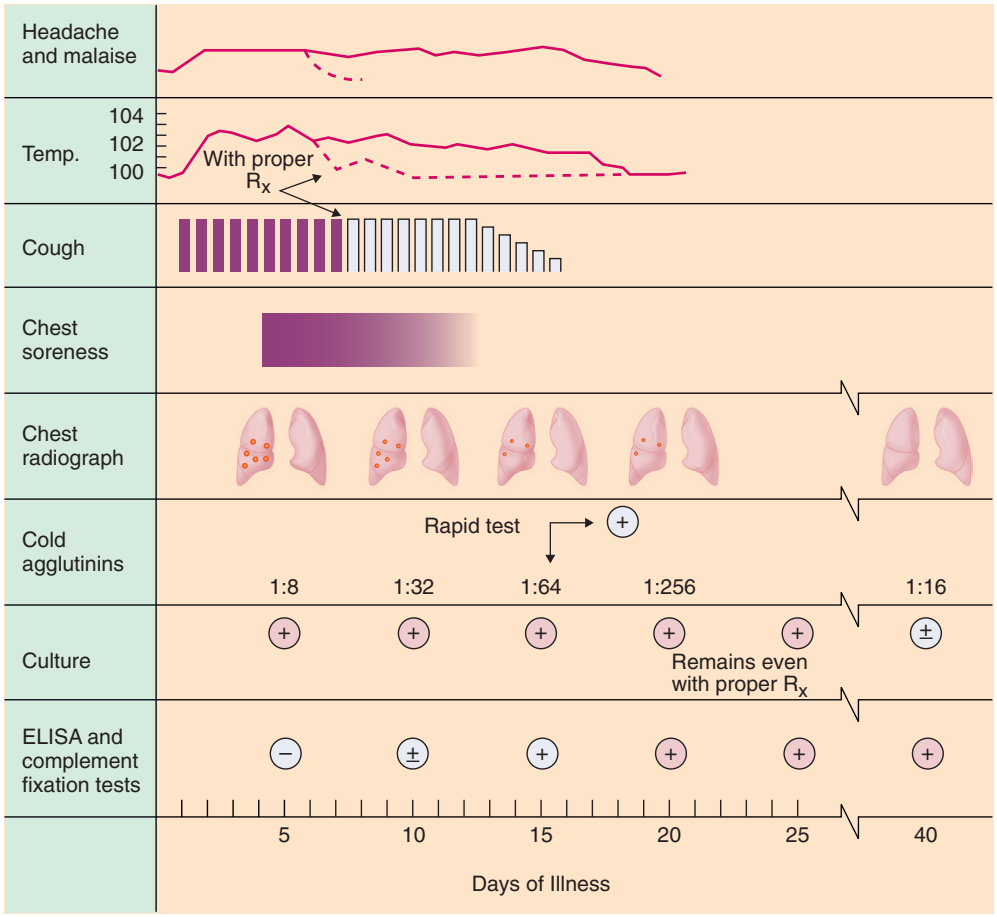

FIGURE 325-1. Major clinical and laboratory manifestations of mycoplasmal pneumonia. ELISA = enzyme-linked immunosorbent assay. (Adapted from Baum SG. Mycoplasmal infections. In: Wyngaarden JB, Smith LH Jr, eds. *Cecil Textbook of Medicine,* 17th ed. Philadelphia: Saunders; 1985:1506.)

proteins (P1, P30, P116, and HMW1-3) have been purified, and adherence-deficient mutants are avirulent. *M. pneumoniae* attaches to ciliated epithelial cells at the base of cilia and appears to produce most of its physiologic and cytolytic changes while remaining extracellular. Hydrogen peroxide produced by *M. pneumoniae* (the only human mycoplasma to do so) may be responsible for some in vivo cell damage, as it is for the hemolysis seen when the organisms are grown on blood agar plates. *Mycoplasma* infection activates T and B cells and induces many pro-inflammatory and anti-inflammatory cytokines and chemokines that may play a role in inflammation-related cell destruction.

In the course of *M. pneumoniae* infection, some patients produce cold agglutinins. These oligoclonal M-type immunoglobulins (IgM) cross-react with I antigens, one of the blood group antigens common to almost all mature human erythrocytes, and high titers may cause hemolysis (presumably as a result of complement-activated, Coombs-positive erythrocyte destruction) and lead to some of the complications described in the Clinical Manifestations section. Like other IgM antibodies, the *Mycoplasma*-induced cold agglutinins (Chapter 163) develop early in the disease (7 to 10 days) and are often present by the time the patient seeks medical attention. The titer of these agglutinins peaks at 2 to 3 weeks, and they persist for 2 to 3 months (Fig. 325-1).

Several theories about the factors triggering the formation of cold agglutinins in *Mycoplasma* pneumonia have been proposed. One is that the organism alters the I antigen such that it becomes antigenic to the patient. The hydrogen peroxide elaborated by *M. pneumoniae* could be responsible for this alteration. One study indicated that the I antigen in a sialated state may serve as a receptor for *M. pneumoniae* and that the cold agglutinins are directed at the modified receptor. Other studies indicate that the cold agglutinins are directed at mycoplasmal substructures themselves and merely cross-react with the I antigen (altered or native) on red cells. Given their apparent target, these antibodies could either contribute to cytolysis and exacerbate infection or interfere with cell-to-cell spread by blocking or disrupting the cell receptor for the mycoplasma. High titers of cold agglutinins have also been associated with hemolysis, presumably as a result of the activation of complement-mediated erythrocyte destruction (Chapter 163). Although clinically significant hemolysis is uncommon, subclinical levels of red cell destruction are common.

Sickle cell disease, sickle-related hemoglobinopathies, and hypogammaglobulinemia predispose to increased severity and mortality. Therefore, some of the available pathologic data may be influenced by the pathophysiology of these underlying conditions. Deaths have occurred in patients with diffuse pneumonia, acute respiratory distress syndrome, thromboembolism, and disseminated intravascular coagulation.

In nonfatal cases in which lung biopsy was performed, the inflammatory process involved primarily the trachea, bronchioles, and peribronchial tissue. The lumen of the respiratory tree was filled with a purulent exudate rich in polymorphonuclear leukocytes. The lining of the bronchial and bronchiolar walls showed metaplastic cells, and the walls themselves were infiltrated with monocytic elements, especially plasma cells. There was widening of the peribronchial septa and hyperplasia of type II pneumocytes.

CLINICAL MANIFESTATIONS

In view of the very high incidence of *Mycoplasma* respiratory infection when studied epidemiologically in large populations, versus the rarity of individual sporadic diagnoses, it appears that a specific, confirmed diagnosis of this entity is seldom accomplished in routine clinical practice. There are probably four reasons for this. The first is that *Mycoplasma* pneumonia is usually self-limited and rarely fatal. This fact dampens the zeal to establish the cause of infection. Second, mycoplasmas are relatively fastidious and slow growing; therefore, culture results, if obtained at all, often return after the patient is well. Third, *M. pneumoniae* responds to the empirical antimicrobial therapy suggested for community-acquired pneumonia. Finally, knowledge of the epidemiology and clinical manifestations of infection is deficient, so the diagnosis is often not considered outside the classic age group.

Respiratory Infection

The majority of *M. pneumoniae* infections involve only the upper respiratory tract. After a 2- to 3-week incubation period, the disease has an insidious onset consisting of fever, malaise, headache, and cough (see Fig. 325-1). Cough is the clinical hallmark of *M. pneumoniae* infection. The frequency and

severity of the cough increase over the next 1 to 2 days, and it may become debilitating. The gradual onset of symptoms is in contradistinction to the often fulminant manifestation of respiratory infection caused by influenza virus or adenovirus.

In 5 to 10% of patients, depending somewhat on age, the infection progresses to tracheobronchitis or pneumonia. In these cases, the original manifestations persist, and the cough becomes more severe. It is usually relatively nonproductive but may yield white or occasionally blood-flecked sputum. Gram staining of this sputum reveals inflammatory cells but no predominant bacterial species (part of the definition of atypical pneumonia). With continued cough, parasternal chest soreness may develop as a result of muscle strain, but true pleuritic pain is unusual. Fever is usually at the level of 101 to 102° F and may be associated with chilly sensations. As opposed to pneumonia caused by *Streptococcus pneumoniae* (Chapter 297), that caused by *M. pneumoniae* rarely produces true shaking chills. In comparison to influenza, which can also manifest as an atypical pneumonia syndrome, myalgias and gastrointestinal complaints of nausea and vomiting are unusual. Diarrhea, sometimes a concomitant of adenoviral or *Legionella* pneumonia, is uncommon in *Mycoplasma* infection.

On physical examination, the patient does not appear to be terribly ill. In fact, this disease is the paradigm of the term *walking pneumonia.* The pharynx may be injected and erythematous, usually without the marked cervical adenopathy seen with group A streptococcal pharyngitis. *M. pneumoniae* is not a common cause of isolated pharyngitis in the pediatric or adult population. Much has been made of the finding of bullous myringitis in this disease. Although this abnormality was present in about 20% of volunteers with experimentally induced *M. pneumoniae* infection, true bullous myringitis in naturally occurring *Mycoplasma* disease is rare. In a study involving children, otitis was rarely associated with isolation of *Mycoplasma* and, on the contrary, was often associated with bacterial and viral upper respiratory tract pathogens. Thus, the absence of myringitis, bullous or otherwise, should not dissuade one from a diagnosis of *Mycoplasma* pneumonia.

Examination of the chest in patients with *Mycoplasma* pneumonia is often unrevealing, even in those with severe, productive cough. There may be no auscultative or percussive findings, or only minimal rales may be present. The disparity between physical findings and radiographic evidence of pneumonia in this condition may be the greatest of any of the atypical pneumonia syndromes (Fig. 325-2). Although wheezing can occur in this disease, in one study of asthmatic patients, the presence of wheezing had a negative correlation with isolation of *M. pneumoniae* compared with isolation of viral respiratory pathogens such as respiratory syncytial virus (Chapter 370). *M. pneumoniae* does not seem to be a common pathogen in patients with preexisting chronic obstructive lung disease, either. Bacterial superinfection after *M. pneumoniae* respiratory infection is rare. The radiographic finding of interstitial or patchy alveolar pneumonia does not allow differentiation from any of the other causes of the atypical pneumonia syndrome.

Pleural effusion (usually small) occurs in 5 to 20% of patients with *M. pneumoniae* infection. This low incidence of pleural inflammation is consistent with the rarity of pleuritic pain. If effusion is present, thoracentesis reveals serous fluid that is exudative, with minimal inflammatory reaction. The cell differential count in the fluid is variable, and bloody effusions are rare. It is unusual to isolate *M. pneumoniae* from effusions when they do occur, but several reports of such isolation exist. Although the pneumonia is generally mild and self-limited, fulminant, severe, and lethal cases have been reported in normal young adults and may be underdiagnosed.

Extrapulmonary Involvement

Abnormalities in almost every organ system have been described as examples of the extrapulmonary manifestations of *M. pneumoniae* infection. The frequency of these extrapulmonary manifestations varies greatly from one report to another, and they are much less common when viewed as part of a prospective epidemiologic study rather than as the sum of isolated case reports. The conclusion appears to be that the high prevalence of *Mycoplasma* infection predisposes to the reporting of many concurrent but perhaps unrelated events as though they were part of the mycoplasmal disease. Several clinical syndromes have been reported with sufficient frequency to provide some support for a causal relationship.

Dermatologic Involvement

A wide variety of transient dermatologic conditions have been reported in conjunction with *Mycoplasma* pneumonia, including macular, morbilliform, and papulovesicular eruptions, as well as erythema nodosum and urticaria. Again, the variety and high incidence of these rashes in the absence of *Mycoplasma* infection make it difficult to define the relationships, if any, among these occurrences. Furthermore, the role of concurrent antibiotic therapy in the development of exanthems during *M. pneumoniae* infection is unknown. One skin condition that occurs often enough in concert with *M. pneumoniae* infection to provide some basis for relatedness is erythema multiforme majus, or Stevens-Johnson syndrome (Fig. 325-3). This rash has been reported in up to 7% of patients with *Mycoplasma* pneumonia and consists of erythematous vesicles, plaques, and bullae involving the skin, with particular localization at mucocutaneous junctions. The conjunctivae may also be involved, as well as organs of the gastrointestinal and genitourinary tracts and the joints. Stevens-Johnson syndrome has been associated with isolated cases of many other infections, including some that can manifest as atypical pneumonia syndrome, such as legionnaires' pneumonia, adenovirus respiratory-conjunctivitis syndrome, and influenza B infection. However, the association with *M. pneumoniae* infection is by far the most common. Stevens-Johnson syndrome tends to occur in younger patients with *Mycoplasma* pneumonia and has a definite male preponderance (2:1 to 4:1).

The pathogenesis of Stevens-Johnson syndrome is unclear. It has long been supposed that immunity plays a major role, but several reports have noted the culture of *M. pneumoniae* from the lesions. The relationship to the level of cold agglutinins in this disease is variable. It has been suggested that the development of Stevens-Johnson syndrome may be the result of augmented sensitivity to antibiotics in the presence of *M. pneumoniae* infection, but erythema multiforme majus develops in some patients in the absence of previous or concurrent antibiotic therapy. Most patients clear the lesions in 1 to 2 weeks without scarring unless impetiginization supervenes.

FIGURE 325-2. Chest radiograph showing moderate interstitial pneumonia due to *Mycoplasma pneumoniae* infection in a patient with a paucity of findings on chest auscultation.

FIGURE 325-3. Stevens-Johnson syndrome in a child with *Mycoplasma* pneumonia. (From Baum SG. *Mycoplasma pneumoniae* and atypical pneumonia. In: Mandell GL, Bennett JE, Dolin R, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases,* 6th ed. Philadelphia: Churchill Livingstone; 2005:2274.)

Raynaud's syndrome (Chapter 80), a transient, reversible vasospasm of the digits that develops on exposure to cold, is not technically a dermatologic syndrome; however, it manifests in the skin. This phenomenon occurs in many people, usually women, without any association with infection. It has been reported in patients with acute *Mycoplasma* pneumonia, regardless of whether they exhibited the syndrome before infection. Although the pathophysiology of this condition in *M. pneumoniae* infection is unclear, it may be related to the in vivo action of cold agglutinins (see Diagnosis, later). Other vascular complications reported in *M. pneumoniae* infection include internal carotid artery occlusion and cerebral infarction.

Cardiac Complications

Cardiac abnormalities are among the most commonly reported extrapulmonary manifestations of *M. pneumoniae* infection. Signs and symptoms suggesting involvement of the heart are arrhythmia, congestive failure, chest pain, and electrocardiographic abnormalities, particularly conduction defects. Although cardiac abnormalities have been reported in as many as 10% of cases of *M. pneumoniae* infection, other reports indicate a much lower prevalence. Cardiac complications are more common with increasing age. They prolong the illness but rarely lead to death. The mechanism of heart damage is unknown, but *M. pneumoniae* has been isolated from the pericardial fluid of at least one patient.

Neurologic Complications

There are increasing reports of neurologic complications of *Mycoplasma* infection, but proof of the cause of central nervous system involvement is somewhat tenuous. Aseptic meningitis and meningoencephalitis, transverse myelitis, brain stem dysfunction, Guillain-Barré syndrome, and peripheral neuropathy have all been reported. In the aggregate, these central nervous system manifestations occur in no more than 1 per 1000 patients. Cerebrospinal fluid findings in these cases are variable, but the cellular response is usually minimal, with slightly elevated protein and normal to slightly depressed glucose. Most often, the diagnosis of *Mycoplasma*-related central nervous system involvement is based on the exclusion of other causes, the presence of an antecedent or intercurrent respiratory illness, and a rise in antibody titer to *M. pneumoniae* in serum. Occasionally, *Mycoplasma*-specific antibodies have been demonstrated in cerebrospinal fluid, but these titers have paralleled serum antibody titers. Neurologic complications are usually reversible; however, mortality in patients with central nervous system involvement is higher than in those without such involvement. Although *M. pneumoniae* has been isolated from a few of these patients, polymerase chain reaction (PCR) failed to detect *M. pneumoniae* DNA in the cerebrospinal fluid of 11 patients deemed to have *M. pneumoniae*–related central nervous system disease on serologic grounds. Therefore, immune mechanisms of neural damage have been suggested. Some mycoplasmas elaborate a neurotoxin, but this has not been described for *M. pneumoniae.*

Musculoskeletal, Renal, and Hematopoietic Complications

Polyarthralgias are common in *Mycoplasma* pneumonia, but monoarticular or migratory arthritis is rare. Immune mechanisms have been postulated, but there have been a few reports of the isolation of *M. pneumoniae* from joint fluid. Several of the cases of frank arthritis were reported in patients with hypogammaglobulinemia. Nonhuman mycoplasmas probably cause arthropathy in several animal species, and *M. hominis* has been associated with human arthritis. Rhabdomyolysis has also been reported.

Renal complications associated with immune complex deposition and high-titer cold agglutinins have been reported. There are several case reports of *M. pneumoniae*–associated aplastic anemia.

Conditions Leading to Increased Susceptibility

Several reports have emphasized the unusual severity of *M. pneumoniae* infection in patients with sickle cell disease or sickle-related hemoglobinopathies (Chapter 166). Large pleural effusions and marked respiratory distress may develop in these patients. Functional asplenia and its attendant opsonization deficiencies may contribute to overwhelming infection with *M. pneumoniae,* as they do with *S. pneumoniae* infection. Some patients with sickle cell disease and *M. pneumoniae* infection in whom extremely high cold agglutinin titers develop may experience digital necrosis, as they do with *S. pneumoniae.* A hypothesis about the pathogenesis is provided in the discussion on cold agglutinins in the Diagnosis section. Children with immunodeficiency syndromes have been the subjects of case reports of *M. pneumoniae* infection. Because *Mycoplasma* infections are so common in normal children, the contribution of immunodeficiency is unclear. *M. pneumoniae* is not a very common opportunistic agent in patients with acquired immunodeficiency syndrome (AIDS), but *M. fermentans* (*incognitus* strain) has been identified in these patients. Unusually severe but nonlethal *M. pneumoniae* infection has also been reported in children with Down syndrome.

DIAGNOSIS

The diagnosis of *Mycoplasma* pneumonia is made primarily on clinical grounds. The organism can be grown in cell-free media, but most hospital diagnostic laboratories are not prepared to culture mycoplasmas. Because of this, there is considerable interest in developing rapid diagnostic tests with high sensitivity and specificity. These assays fall into three categories: detection of *M. pneumoniae*–specific immunoglobulins in serum, and detection of *M. pneumoniae*–specific antigens or nucleotide sequences directly in clinical specimens. Diagnostically, the most useful *M. pneumoniae*–specific immunoglobulin to detect is IgM because it is most likely to indicate recent infection. Enzyme-linked immunoassays have been developed to detect IgM and IgG directed against *M. pneumoniae.* When used in patients with positive assays for complement-fixing antibodies, the enzyme immunoassay had a specificity of more than 99% and a sensitivity of 98%. Specificity was retained, but sensitivity dropped to only 46% when IgG alone was the target. Variations on this theme detect IgM antibodies directed at specific *M. pneumoniae* antigens. The tests are simple to perform and have high sensitivity and specificity, but because all these tests are designed to detect IgM antibody, they may be negative early in the course of infection (<7 to 10 days). Therefore, they do not provide the desired confirmation early enough to guide initial therapy.

Detection of *M. pneumoniae* antigens directly in sputum specimens has been accomplished with the use of an antigen-capture, indirect enzyme immunoassay. The specificity of the assay was high, the reagents reacting only with *M. pneumoniae* and *M. genitalium.* Sensitivity was also relatively high (91%) when the assay was used on sputum and nasopharyngeal aspirates from patients who were shown by culture or serologically to have *M. pneumoniae* infection.

The high sensitivity and specificity of real-time PCR performed on sputum, nasopharyngeal aspirate, or throat swab material suggest that this test could serve as a specific and rapid diagnostic method. Detection of *M. pneumoniae*–specific nucleotide sequences directly in clinical material has been accomplished with the use of tests developed locally or by large reference laboratories. These tests, which can be completed in a few hours, detect either *M. pneumoniae* DNA (PCR) or ribosomal RNA (reverse transcriptase nucleic acid amplification). When compared with PCR as the "gold standard" of proven infection, very few of the available antibody assays have acceptable sensitivity and specificity. Although the nucleic acid probe assays show excellent specificity, they fail to detect infection in some antibody-positive patients, and their sensitivity varies considerably, depending on the source of the specimen tested: highest for sputum, but lower for nasopharyngeal aspirate or throat swab material. This latter point is very important when evaluating comparative studies, many of which use different specimen sources for their assays.

In the course of *M. pneumoniae* infection, several classes of antibody are produced. Some of these fulfill the desired role of antibody production—neutralization of the agent—and others appear to be autoantibodies. The latter include agglutinins to lung, brain, cardiolipins, and smooth muscle. The best studied of these autoagglutinins are the cold isohemagglutinins. These agglutinins were found to be capable of clumping erythrocytes at 4° C. Agglutination was reversible by warming the serum-erythrocyte mixture to 37° C and, unlike hemagglutination by myxoviruses and paramyxoviruses, was repeatable with the same sample, indicating that receptor-destroying enzyme (neuraminidase) plays no role in the dissociation at 37° C.

The cold agglutinin phenomenon, when positive, occurs early, but it is neither very sensitive nor specific. Other diseases that can give rise to cold agglutinins are mononucleosis caused by Epstein-Barr virus (anti-i), cytomegalovirus (anti-I), some other viral diseases, and lymphoma. A titer of 1:32 or greater is highly suggestive of infection with *M. pneumoniae.*

When performed in a laboratory, the results of this test will not be available for at least a day and in some cases a week, but a rapid version can be done at the bedside. In this test, 1 mL of the patient's blood is drawn into a tube containing anticoagulant. The type of tube used to collect specimens for prothrombin determination is preferred. Before cooling, examination shows a smooth coating of the tube by red cells. The blood is cooled to 4° C by placing it on liquid ice or in a standard refrigerator. After several minutes, the tube is examined for the presence of macroscopic erythrocyte agglutination.

The tube is then rewarmed to 37° C in an incubator or by exposure to body heat and reexamined. The agglutination should dissociate at 37° C, and the appearance should be as it was before cooling. This temperature-associated agglutination and dissociation can be repeated many times on the same sample. A positive result in the bedside test correlates with a laboratory titer of 1:64 or greater and is therefore less sensitive than the laboratory test. It can be accomplished in minutes, however, and if positive, it is highly suggestive of *Mycoplasma*-related cold agglutination. The presence of cold agglutinins can also artifactually give rise to macrocytic indices secondary to in vitro clumping of erythrocytes, as measured by the Coulter counter method. In this case, the red cell distribution width would be high, indicative of heterogeneity in measured red cell size.

Finally, although PCR should become the gold standard for diagnosis because of its high sensitivity and specificity and the rapidity with which results can be obtained, the test is not available or is rarely ordered, even in microbiology laboratories serving major children's hospitals. There is no commercially available kit for this test, and specimens are generally sent out to large diagnostic laboratories. Even when a home-grown test is available on-site, the low frequency of requests forces only periodic testing of bundled specimens. Both these situations undermine the inherent timeliness of PCR diagnostic results.

TREATMENT

Rx

Despite the number and variety of tests for the rapid diagnosis of *M. pneumoniae* infection, most cases are encountered in the ambulatory setting, and the institution of antimicrobial therapy is empirical and based on clinical recognition of the syndrome.

Antimicrobial therapy is not necessary for mycoplasmal upper respiratory tract infection, and the mycoplasmal cause of this syndrome most often goes undiagnosed. The pneumonia caused by *Mycoplasma* is self-limited and not life-threatening in most cases. However, treatment with effective antimicrobials can shorten the duration of illness and, by reducing cough and the number of organisms per unit volume of sputum, may reduce the spread of infection to contacts.

As would be predicted by the lack of a cell wall, all mycoplasmas, including *M. pneumoniae,* are unaffected by β-lactam antibiotics such as the penicillins and cephalosporins. Aminoglycosides are effective in vitro but have not been evaluated for efficacy in vivo. The mainstays of treatment of *M. pneumoniae* respiratory tract infection are macrolides and tetracyclines. Use of either drug class significantly shortens the duration of illness. The radiographic findings may take a week or longer to resolve, even with appropriate therapy (see Fig. 325-1), and organisms may continue to be cultured from sputum for several weeks after a complete course of clinically effective treatment. This may be a result of the fact that although *M. pneumoniae* causes respiratory disease as an extracellular parasite, it has the capacity to reside intracellularly as well, thus making it difficult to eradicate the organism in vivo as opposed to cell cultures. The effect of therapy on extrapulmonary manifestations is unknown. *M. hominis* is not sensitive to erythromycin.

Although the tetracyclines are very active against *M. pneumoniae,* their use is precluded in young children because of adverse effects on developing teeth and bones. Erythromycin is poorly tolerated by many people because of its gastrointestinal side effects, including nausea, vomiting, abdominal pain, and diarrhea. Erythromycin also raises theophylline levels, a consideration in the few asthmatic patients who may still be taking this drug.

Because of the adverse effects of erythromycin and tetracycline, there is considerable interest in the antimycoplasmal efficacy of other agents. Doxycycline is somewhat better tolerated than tetracycline and can be administered in two daily doses rather than three. In vitro, doxycycline is as effective as tetracycline against *M. pneumoniae,* but it is contraindicated in young children.

Several other classes of antimicrobials have significant in vitro and in vivo activity against *M. pneumoniae* and other *Mycoplasma* species, including the fluoroquinolones, broad-spectrum macrolides (azithromycin, clarithromycin), and members of the macrolide-lincomycin-streptogramin-ketolide (MLSK) class of antimicrobials. There are no good data on the optimal duration of therapy needed to minimize carriage and relapse with these agents.

The macrolides are more active in vitro than the tetracyclines are. Fluoroquinolones have adequate activity for the treatment of these infections. They are more active than the tetracyclines but are at least 100 times less active than the macrolides. The streptogramins are also less active than the macrolides but more active than the tetracyclines. There is a significant cost differential in the use of these drugs. The newer macrolides and quinolones are 50 to 60 times more expensive than the tetracyclines and 6 to 10 times more costly than erythromycin.

Taking all this into account, recommended therapy includes doxycycline 100 mg every 12 hours in older children and adults, or azithromycin 500 mg on day 1 and then 250 mg every 24 hours. Young children should be given erythromycin (10 mg/kg every 6 hours) or an extended-spectrum macrolide (10 to 12 mg/kg on day 1, followed by 5 mg/kg/day).The usual duration of therapy is 14 days; shorter courses may lead to relapse. *M. hominis* is not sensitive to macrolides, but it is sensitive to the other antimicrobials recommended for *M. pneumoniae* infection. Azithromycin (1 g single dose) achieves a significantly higher cure rate for *Mycoplasma genitalium*–associated urethritis than does multi-dose doxycycline.■

PREVENTION

Outbreaks of *M. pneumoniae* respiratory infection among military recruits led to great interest in producing a vaccine to protect against this organism. The resulting vaccines induced specific antibody responses, but protection was limited to no more than 50% of vaccine recipients. Live vaccines using attenuated wild-type and temperature-sensitive mutant mycoplasmas have proved no more effective. In one study, volunteers who received vaccine but did not mount an antibody response had more severe disease when rechallenged with wild-type *Mycoplasma* than did nonvaccinated personnel.

Although *M. pneumoniae* is perhaps the leading cause of atypical pneumonia syndrome in closed populations, the enthusiasm for developing a vaccine for this disease has waned. New technology involving DNA expression library immunization has proved successful in animal studies with nonhuman mycoplasmas, and these methods may breathe new life into *M. pneumoniae* vaccine development.

Secondary Prevention

Prophylactic antibiotic use in family members exposed to *Mycoplasma* decreases clinical disease in these patients, but seroconversion is not prevented. One study showed that azithromycin prophylaxis, given as a 500-mg loading dose and 250 mg/day on days 2 through 5, significantly reduced the secondary attack rate of *M. pneumoniae* infection in a long-term care facility.

326 DISEASES CAUSED BY CHLAMYDIAE

WILLIAM M. GEISLER

DEFINITION

Chlamydiae are obligate intracellular bacteria that cause a variety of human and animal diseases and much morbidity. Chlamydiae were originally classified taxonomically into one genus, *Chlamydia*. However, revision of the chlamydial taxonomy based on sequence analysis of 16S rRNA genes has led to the proposal of two genera: *Chlamydia* and *Chlamydophila*. Within the family are four species: *Chlamydia trachomatis, Chlamydophila pneumoniae, Chlamydophila psittaci,* and *Chlamydophila pecorum*. *C. trachomatis* is classified into three biovars: the trachoma biovar, the lymphogranuloma venereum (LGV) biovar, and the mouse pneumonitis biovar. This chapter is limited to human diseases caused by chlamydiae.

The Pathogen

Chlamydiae have a gram-negative cell wall structure consisting of an outer membrane that contains lipopolysaccharide and an inner cytoplasmic membrane. The outer membrane contains a single 40-kD major outer membrane protein, OmpA (also known as MOMP), and two cysteine-rich minor outer membrane-associated proteins (OmcA and OmcB); through intermolecular and intramolecular disulfide bonding, these proteins form a complex that provides structural rigidity.

Chlamydiae grow only within intracellular membrane-bound vacuoles, termed *inclusions*, that seclude the organism from extracellular and cytoplasmic environments. They share a distinct biphasic developmental cycle (Fig. 326-1) that includes an extracellular, metabolically inactive, infectious form (an elementary body) and an intracellular replicative form (a reticulate body). In vitro studies have shown that chlamydiae may enter a persistent state under certain conditions (penicillin treatment, challenge with certain cytokines, restriction of select nutrients) in which they have reduced metabolic activity and may be more refractory to antibiotic treatment; whether this occurs in vivo is unclear. Chlamydiae are unable to synthesize adenosine triphosphate and therefore depend on the host cell for nutrients to meet their energy requirements.

Additional knowledge of chlamydial cell biology emerged after several chlamydial genomes were sequenced. Polymorphic outer membrane proteins were identified, but their role in pathogenesis is unclear. Chlamydiae were also found to express proteins that localize to the cytoplasmic surface of the inclusion membrane (e.g., Inc A). *C. trachomatis* was demonstrated to have type III secretion genes, which may encode a secretion apparatus providing a means for protein transport. Chlamydiae have small genomes (*C. trachomatis* contains 894 protein-coding genes, and *C. pneumoniae* contains 1052 genes). Most strains of *C. trachomatis* and some strains of *C. psittaci* contain a 7-kilobase cryptic plasmid.

PATHOBIOLOGY

Macrophages are the principal host cells for *C. psittaci* and *C. trachomatis* LGV biovar, whereas the principal host cells for *C. trachomatis* trachoma biovar and *C. pneumoniae* strains are columnar epithelial cells at mucosal sites. Host cell tropism correlates with the type of inflammation elicited by chlamydiae. The LGV biovar and *C. psittaci* produce granulomatous inflammation, characteristic of delayed hypersensitivity reactions. The trachoma biovar produces neutrophilic exudate during acute infection and submucosal mononuclear infiltration with lymphoid follicle formation during later stages of infection.

Chlamydiae elicit both humoral and cellular immune responses. Infection persists or recurs even after an adaptive immune response develops, suggesting that the organism has evolved strategies for immune evasion. Persistent or recurrent infections elicit inflammatory cellular immune responses that cause tissue injury.

CHLAMYDIAL DISEASES

Table 326-1 summarizes the diseases caused by chlamydiae in humans and the associated clinical and laboratory characteristics.

Chlamydia trachomatis

C. trachomatis infection is a common bacterial infection in humans and accounts for significant morbidity worldwide. *C. trachomatis* isolates have been differentiated into 18 major serovars (i.e., OmpA types) based on variations in OmpA that are identified on antigen cross-reactivity in the microimmunofluorescence test. The major diseases caused by *C. trachomatis* are (1) trachoma, caused by serovars A, B, Ba, and C; (2) sexually and perinatally transmitted diseases, caused by serovars D through K (and, rarely, serovars B and Ba); and (3) sexually transmitted LGV, caused by serovars L_1, L_2, L_{2a}, and L_3. Sequencing of the *ompA* gene has led to the recognition of more OmpA variants. Trachoma and LGV are endemic in developing areas of the world

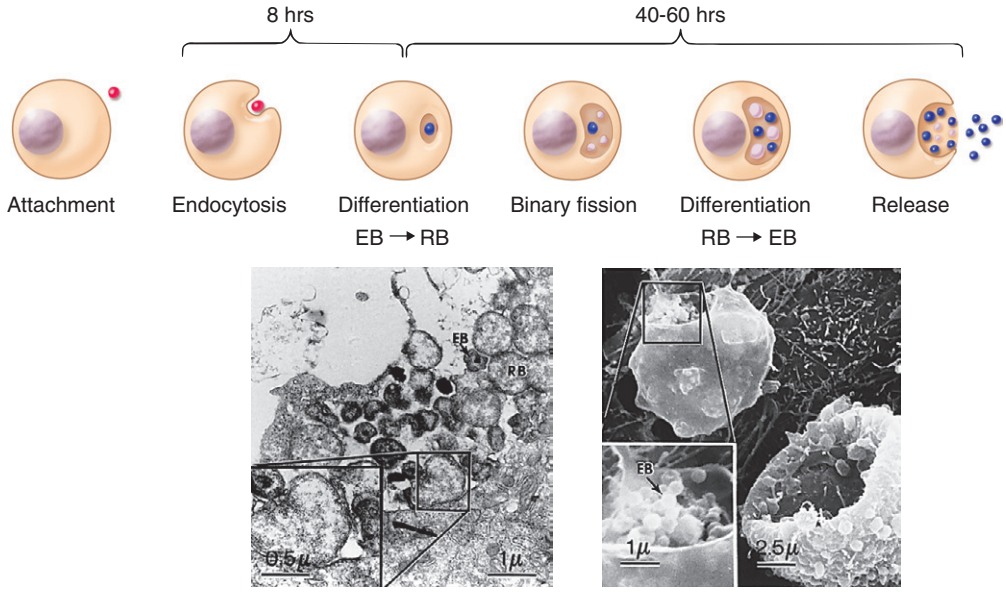

FIGURE 326-1. Developmental cycle of chlamydiae. *The top panel* shows the developmental cycle common to all chlamydiae. The *red circles* represent elementary bodies (EBs), and the *blue circles* represent reticulate bodies (RBs). Chlamydiae infect eukaryotic cells through multiple attachment mechanisms. After attachment, EBs enter the cell within a membrane-bound vacuole that remains unfused with lysosomes. EBs reorganize into RBs and asynchronously replicate 8 to 12 times, with a doubling time of 2 to 3 hours. At the conclusion of the growth cycle, RBs differentiate back to EBs, and each inclusion yields 100 to 1000 new infectious EBs. *The bottom left panel*, a transmission electron micrograph taken 40 hours after infection, shows the large RBs and the smaller EBs, which have a condensed nucleoid structure within their cytoplasm. *The bottom right panel*, a scanning electron micrograph taken 60 hours after infection, shows a membrane-bound vacuole containing many EBs exiting from an infected HeLa cell.

TABLE 326-1 MAJOR DISEASES CAUSED BY CHLAMYDIAE IN HUMANS AND ASSOCIATED CLINICAL AND LABORATORY FEATURES

SPECIES	SEROVAR	DISEASE	TRANSMISSION ROUTE	DIAGNOSIS	PREVENTION
C. trachomatis	A-C	Trachoma	Fomites, eye-seeking flies	Clinical criteria or culture/NAAT	SAFE strategy
	D-K	Urethritis, cervicitis, proctitis, epididymitis, PID	Sexual contact	NAAT	Abstinence/monogamy, education, condoms, partner treatment
	D-K	Inclusion conjunctivitis, infant pneumonia	Perinatal contact	Culture/DFA/NAAT or serology (for pneumonia)	Prenatal chlamydia screening: treat infected mothers
	L1-L3	Lymphogranuloma venereum	Sexual contact	Serology or culture/NAAT + OmpA typing	Abstinence/monogamy, education, condoms, partner treatment
C. pneumoniae	One	Upper respiratory infections, atypical pneumonia, asthma exacerbations	Respiratory droplet	Serology or culture/PCR	None
C. psittaci	Multiple	Psittacosis, atypical pneumonia, febrile illness	Aerosolized bird secretions, dust	Serology	Quarantine and chlortetracycline for imported birds, avoidance or precautions for at-risk subjects

DFA = direct fluorescent antibody test; NAAT = nucleic acid amplification test; PCR = polymerase chain reaction; PID = pelvic inflammatory disease; SAFE = World Health Organization's recommended strategy: acronym for *surgery (for trichiasis), antimicrobials (periodic community-wide treatment), facial cleanliness, and environmental improvement.*

(although LGV outbreaks have also occurred in populations of men who have sex with men in developed countries), whereas sexually and perinatally transmitted chlamydial infections occur worldwide.

TRACHOMA

EPIDEMIOLOGY

Trachoma is a chronic follicular conjunctivitis. The overall incidence is unknown, but is has been estimated to occur in more than 100 million people worldwide, most of whom are young children. Trachoma is endemic in more than 50 countries and is especially common in poor areas of sub-Saharan Africa, where the disease prevalence in children may exceed 40%. It is a major public health problem because scarring from trachoma causes blindness in an estimated 6 million people, and trachoma is the most common preventable cause of blindness worldwide. Active trachoma often occurs in the first few years of life. The inflammation from recurrent and/or persistent trachoma can lead to conjunctival scarring, which can ultimately cause corneal damage and blindness later in life. The *C. trachomatis* serovars that produce trachoma are spread by direct contact with fingers or fomites (e.g., washcloths, handkerchiefs) contaminated with eye discharge from an infected person or by eye-seeking flies. Because of this mode of transmission, trachoma often clusters in households. Risk factors for trachoma include poor facial hygiene, limited access to water, poor sanitation, and close proximity to other infected persons or to a heavy density of eye-seeking flies.

CLINICAL MANIFESTATIONS

There are two stages of trachoma disease, and they can overlap. Initially, trachoma begins as an inflammatory follicular conjunctivitis (i.e., active trachoma). Upon everting the upper eyelid, white to pale yellow lymphoid follicles can be visualized on the superior tarsal conjunctival surface, and papillae may be noted between follicles. Minimal watery or mucoid ocular discharge may also be seen. In more severe active trachoma, the conjunctiva can be thickened and edematous. Subsequently, conjunctival inflammation can progress to cause scarring of the upper tarsal conjunctiva (the cicatricial stage of disease). Scarring deforms the eyelid and can lead to an inward turning of the eyelashes, which can result in corneal abrasion (trichiasis). Over time, trichiasis causes corneal edema, ulceration, vascularization (pannus), scarring, and opacification. The corneal damage leads to decreased vision or blindness, occurring mostly in young adults and middle-aged persons. Viral conjunctivitis (e.g., adenovirus) presents in a similar clinical fashion as active trachoma, but it is self-limited and usually resolves within a week. Trachoma can be complicated by superinfection with other bacterial pathogens (e.g., *Haemophilus influenzae*), which should be considered when purulent ocular discharge or significant inflammation of the bulbar conjunctiva is present.

DIAGNOSIS

Because the majority of trachoma cases occur in developing countries without access to laboratory testing or the necessary resources, trachoma is often diagnosed clinically based on findings of active trachoma (follicles on the upper tarsal conjunctiva or pronounced inflammatory thickening of the tarsal conjunctiva) or cicatricial disease. When laboratories are available, detection of *C. trachomatis* provides definitive evidence of active trachoma and may identify infection in subjects with minimal clinical evidence of active trachoma. Isolation of the organism in cell culture is one means to detect *C. trachomatis*, but the test's sensitivity is less than 50% and the methods are labor intensive. Nonculture tests have higher sensitivities in active trachoma. For instance, nucleic acid amplification tests (NAATs) are the most sensitive diagnostic tests, but they are not widely available in many trachoma-endemic areas. It is uncommon for adults with late scarring to have *C. trachomatis* detected by any of these assays.

TREATMENT

Rx

Active trachoma can be treated with a tetracycline eye ointment twice daily for 6 weeks or oral macrolide therapy. The latter is preferred in part because extraocular sites such as the nasopharynx may be infected in young children. Single-dose oral azithromycin (20 mg/kg; maximum of 1 g) is as effective as tetracycline ointment and is more advantageous in terms of compliance and side effect profile; tetracycline application can irritate the ocular surface.

Surgical intervention is the only effective management for trichiasis. Eyelid rotation surgery prevents the eyelashes from abrading the cornea, preventing blindness and other nonvisual symptoms. Trichiasis recurrence following surgery is a major concern, and recurrence rates are highly variable across studies. Other concerns include accessibility to surgery and patient acceptance.

PREVENTION

The World Health Organization is committed to eliminating blinding trachoma by 2020 and recommends that all countries with endemic trachoma adopt the SAFE strategy: surgery (for trichiasis), antimicrobials (periodic community-wide treatment), facial cleanliness, and environmental improvement. Mass treatment of a community with single-dose oral azithromycin is safe and has dramatically reduced the prevalence of infection for up to 1 year after treatment, without an increase in antimicrobial resistance; it has also been shown to reduce mortality in children.[1] Annual azithromycin treatment is recommended for trachoma-endemic areas. Reintroduction of trachoma following mass treatment has been demonstrated, which may be due in part to decreased herd immunity. Repeated mass treatment (every few months) provides herd protection to the entire community.[2]

Mass antibiotic treatment as the sole intervention for eliminating trachoma is unlikely to be successful if other factors that facilitate transmission are not addressed. Face washing and good hygiene help reduce the risk of transmission through contact with fingers and flies. Although the promotion of facial cleanliness through educational campaigns may be one of the most

FIGURE 326-2. Clinical manifestations of genital *Chlamydia trachomatis* infection. A, Cloudy urethral discharge of urethritis. **B,** Urethral specimen Gram stain revealing nongonococcal urethritis findings: five or more polymorphonuclear cells per oil field (1000×) and the absence of intracellular gram-negative diplococci. **C,** Purulent endocervical discharge of mucopurulent cervicitis. (**A,** Courtesy James Sizemore, MD; **B** and **C,** From *Practitioner's Handbook for the Management of Sexually Transmitted Disease*. http://depts.washington.edu/nnptc/online_training/std_handbook. Accessed May 12, 2011.)

important interventions, sustaining such behavioral changes can be challenging. Achieving better environmental conditions through measures that reduce household and community fly density and improve waste management and access to clean water can also limit transmission. Improvement in socioeconomic conditions in a community correlates with a decline in trachoma prevalence.

SEXUALLY AND PERINATALLY TRANSMITTED CHLAMYDIAL INFECTIONS

EPIDEMIOLOGY

Chlamydia is the most prevalent bacterial sexually transmitted infection in the United States. Currently, more than 1.2 million infections are reported to the Centers for Disease Control and Prevention (CDC) annually. The number of reported cases is increasing each year; this may reflect increased chlamydia screening efforts rather than a true increase in infection burden, but this remains unclear. Taking into account underreporting and underscreening, it is estimated that more than 3 million new chlamydial infections occur annually in the United States. Higher chlamydia prevalence rates have been associated with younger age (sexually active adolescents and young adults), select minority ethnic groups (especially African Americans), and new or multiple sexual partners. Chlamydia prevalence is higher in women than in men; it is unclear whether this is due to higher screening rates in women or whether women may be more susceptible to infection acquisition or persistence. Chlamydia prevalence is highest in the southeastern United States. The estimated total cost attributable to chlamydial disease in the United States exceeds $2.4 billion annually. From a global perspective, there are an estimated 90 million new chlamydial infections annually. In addition to the adverse effects on the reproductive health of women, chlamydia has a substantial impact on perinatal outcomes and facilitates the transmission of human immunodeficiency virus (HIV).

CLINICAL MANIFESTATIONS

Urethritis

C. trachomatis is the most common cause of nongonococcal urethritis in men, being responsible for 20 to 55% of cases. Although the majority of men with chlamydial urethritis are asymptomatic, studies in high-prevalence venues (e.g., sexually transmitted disease clinics) have reported that 40 to 60% of men with chlamydial urethritis are symptomatic. The most frequent symptoms are urethral discomfort (itching or pain) with urination and urethral discharge. On examination, a mild to moderate amount of clear or cloudy/mucoid (rarely purulent) urethral discharge may be visualized (Fig. 326-2A). Urethral discharge sometimes becomes apparent only after stripping the urethra from the base of the penis to the glans; this should be considered in men reporting urethral symptoms but without urethral discharge on initial inspection. Gram stain from a urethral swab specimen demonstrates five or more polymorphonuclear leukocytes (PMNs) per oil field (1000×) in the majority of chlamydial infections (Fig. 326-2B). Chlamydial organisms cannot be visualized on Gram stain. Up to 20% of men with chlamydial urethritis have fewer than five PMNs per oil field on urethral Gram stain, reflecting the fact that minimal inflammation may be elicited in some cases of chlamydial urethritis. Urethral inflammation can also be detected by a positive urinary leukocyte esterase test on unspun first-void urine.

C. trachomatis urethritis also occurs in women, who may be asymptomatic or present with an acute urethral syndrome characterized by dysuria, urinary frequency, and pyuria. This acute urethral syndrome mimics a urinary tract infection, and chlamydia should be suspected in women with pyuria but negative urine nitrite or negative urine culture, especially in sexually active adolescents and young adults. Mild urethral discharge may be seen. Pelvic examination should be performed in women with suspected chlamydia urethritis to search for other clinical findings of chlamydia (e.g., cervicitis).

Epididymitis

Chlamydia can spread from the urethra to the epididymis, causing epididymitis in up to 1 to 3% of infected men. Symptoms include testicular pain and scrotal erythema and swelling that are typically unilateral. On examination, there is palpable swelling and tenderness of the epididymis; accompanying findings may include testicular tenderness, scrotal erythema and swelling, urethral discharge, or hydrocele. In men younger than 35 years, *C. trachomatis* is the principal cause of epididymitis, whereas in men older than 35 years, complicated urinary tract infection with uropathogens is a more common cause, especially in those with prostate disorders. Up to 15% of epididymitis cases are complicated by chronic pain that is usually idiopathic and often unresponsive to antibiotics. Other complications include decreased fertility and, rarely, testicular abscess.

Cervicitis

C. trachomatis is the most common cause of cervicitis, being responsible for up to 50% of cases. The majority of women with endocervical chlamydial infection are asymptomatic. Symptoms, when present, are often mild and nonspecific for chlamydia and include the following: vaginal discharge, intermenstrual vaginal bleeding, dysuria, and pain during intercourse (dyspareunia). Approximately 10% of women with asymptomatic cervical chlamydial infection have mucopurulent cervicitis detected on pelvic examination (Fig. 326-2C); this is characterized by a purulent or cloudy endocervical discharge visible in the endocervical canal or on the tip of an endocervical swab. A similar proportion may have endocervical bleeding that is easily induced with passage of a swab through the cervical os. Nonspecific findings may include vaginal discharge and edematous ectopy (a darker red area of columnar epithelium visible on the face of the cervix). Gram stain of an endocervical sample usually shows more than 10 PMNs per oil field. A vaginal wet mount often shows more than 5 to 10 PMNs per 400× field.

Pelvic Inflammatory Disease

Chlamydia can spread from the cervix to the endometrium (causing endometritis), fallopian tubes (causing salpingitis), and peritoneum (causing peritonitis or perihepatitis). These upper genital tract infections are collectively referred to as *pelvic inflammatory disease* (PID). Estimates of the proportion of cervical chlamydial infections that progress to PID vary greatly but are most commonly around 10 to 20%. The majority of PID cases are subclinical or silent. PID symptoms include pelvic or lower abdominal pain (especially during menses or the first 2 weeks of the menstrual cycle) and nausea. Fever is less common. Examination findings include cervical motion tenderness or tenderness of the uterus or adnexa. Although most cases of chlamydial PID are due to the natural progression of infection, they may also occur post partum or following pregnancy termination. The long-term consequences of PID include infertility, ectopic pregnancy, and chronic pelvic pain.

Complications during Pregnancy

There is conflicting evidence on whether genital chlamydial infection during pregnancy leads to adverse outcomes. Reported adverse outcomes include preterm labor, low birthweight, miscarriage, and stillbirth.

Reactive Arthritis

Reactive arthritis, characterized by the classic triad of trigger infection (e.g., chlamydia), conjunctivitis, and arthritis, can complicate chlamydial infection (Chapter 273). There is a male predominance in reactive arthritis cases triggered by chlamydia, and it has been estimated that reactive arthritis occurs in about 1% of men presenting with chlamydial urethritis.

Proctitis

Proctitis caused by non-LGV *C. trachomatis* OmpA types is usually asymptomatic. Subjects with acute symptomatic proctitis may report rectal pain and/or bleeding, tenesmus, pruritus, rectal discharge, or diarrhea. Anoscopy or sigmoidoscopy may reveal friable mucosa and a mucoid or mucopurulent discharge. A rectal swab Gram stain often reveals many PMNs per oil field.

Conjunctivitis

An acute follicular conjunctivitis may rarely occur in adolescents or adults with genital chlamydial infection. The presumed mode of acquisition is autoinoculation with infected genital secretions. The typical clinical presentation is subacute or chronic infection characterized by unilateral conjunctival redness, mucoid or mucopurulent ocular discharge, a foreign body sensation, and preauricular adenopathy.

Oropharyngeal Infection

C. trachomatis has been detected in the oropharynx of sexually active subjects, but the clinical significance and transmissibility of *C. trachomatis* detected at this site are unclear.

Infant Inclusion Conjunctivitis and Pneumonia

Because the prevalence of chlamydia in pregnant adolescents and young adults in the United States can be high (>5%), the morbidity associated with perinatally transmitted chlamydia is considerable. Neonates exposed to *C. trachomatis* during passage through the birth canal may develop inclusion conjunctivitis (≈20 to 40%) or pneumonia (≈10 to 20%). The conjunctivitis—termed *inclusion conjunctivitis* because the cytoplasmic chlamydia inclusion bodies demonstrated in neonatal conjunctival scrapings are the same as those seen in genital scrapings from adults with genital chlamydia—usually develops 5 to 12 days after birth but may occur as long as 4 to 6 weeks after birth. Clinical manifestations include conjunctival injection and thickening, a clear or mucopurulent ocular discharge, and eyelid swelling. Chlamydia pneumonia in infants usually occurs subacutely between 1 and 3 months of age. Characteristic clinical features include a repetitive staccato cough and absence of fever. Other clinical findings may include tachypnea, crackles on auscultation of the lungs, nasal discharge, and eosinophilia. Chest radiographs may reveal bilateral diffuse infiltrates.

Lymphogranuloma Venereum

LGV is a sexually transmitted infection caused by *C. trachomatis* LGV OmpA types. In contrast to infection with non-LGV strains, LGV is a more invasive systemic infection that involves lymphoid tissue (causing lymphadenitis) and can be ulcerative. LGV is endemic in Africa, India, Southeast Asia, South America, and the Caribbean. LGV is uncommon in the United States, with fewer than 100 cases reported annually. Since 2003, LGV outbreaks have occurred in Europe and Canada, primarily involving HIV-positive men who have sex with men who also had proctitis and were infected with LGV OmpA variant L_{2b}.

The clinical manifestations of LGV differ in early versus later stages of infection. In the early stage (3 to 30 days after acquisition) of genital LGV, a primary skin lesion or lesions may develop on the genital mucosa or adjacent skin in the form of a papule, ulcer, or herpetiform lesion. The lesion is usually asymptomatic and goes unnoticed, but it may be erosive; it heals quickly without scarring. Early genital LGV may also present as a nonspecific inflammatory syndrome (e.g., urethritis and cervicitis), similar to infection with non-LGV strains. Genital LGV can progress to an inguinal syndrome 2 to 4 weeks later, characterized by painful, erythematous inguinal lymphadenopathy (buboes; see Fig. 320-3 in Chapter 320) and systemic manifestations including fever, headache, arthralgias, myalgias, and leukocytosis. The buboes are commonly unilateral, and about one third spontaneously rupture and drain pus, which can be complicated by fistulas or sinus tracts; unruptured buboes usually heal. In later stages, genital tract fibrosis can lead to complications such as infertility, elephantiasis, strictures, fistulas, and subcutaneous sclerosis.

LGV may also present as an anogenital syndrome with invasive proctitis. Symptoms include fever, tenesmus, anal pruritus, and a rectal discharge that may be mucoid or, less commonly, mucopurulent or bloody. The rectal mucosa is friable, with multiple superficial ulcerations, and biopsy may reveal submucosal granulomas and crypt abscesses; these clinical and histopathologic findings resemble Crohn's disease (Chapter 143). Late complications include rectal strictures, anal fistulas, and lymphorrhoids (perianal growths of lymphatic tissue).

Natural History

The natural history of untreated genital *C. trachomatis* infection has not been fully elucidated, in part because ethical considerations limit such research. Outcomes of untreated genital chlamydia include spontaneous resolution (i.e., immune-mediated clearance) and persisting infection; the latter may be subclinical or progress to clinical manifestations (e.g., urethritis cervicitis), which can remain uncomplicated or progress to a complication (e.g., PID). Based on limited evidence in subjects with chlamydia detected initially by a screening test who returned within weeks to months for treatment and were retested, anywhere from 10 to 40% of infections resolve spontaneously before treatment. Some patients with persisting infection develop clinical manifestations before returning for treatment, including a small proportion of females (up to 4%) who develop symptomatic PID. Other sparse data in females suggest that up to 50% of genital chlamydial infections resolve after a year,

but a small percentage (<10%) could persist for several years. An improved understanding of the natural history of chlamydia could impact screening and treatment recommendations.

DIAGNOSIS

C. trachomatis infections are difficult to diagnose clinically because the majority are asymptomatic, and even when symptoms or signs are present, they are nonspecific. Therefore, a definitive diagnosis relies on detecting the organism. Laboratory diagnosis confirms the clinical diagnosis in those with clinical manifestations and detects infection in asymptomatic individuals (i.e., screening). The CDC recommends annual chlamydia screening for sexually active women aged 25 years and younger, as well as for older women with risk factors (e.g., new or multiple sexual partners). Select studies have demonstrated that chlamydia screening reduces the prevalence of chlamydia in women and the rate of PID. Universal chlamydia screening in men is not recommended; selective screening is appropriate in venues with high prevalences (e.g., sexually transmitted disease clinics, correctional facilities), for high-risk men, or for symptomatic men.

The reference standard for the detection of *C. trachomatis* has been isolation of the organism in cell culture. Development of nonculture tests was important because culture is technically demanding, expensive, and not widely available. Earlier nonculture tests included enzyme immunoassay, direct fluorescent antibody, and nucleic acid hybridization. These tests were less expensive and less technically demanding than culture but had lower sensitivities (lower limit of detection $\geq 10^3$ elementary bodies) and therefore detected fewer infections. These earlier tests have been replaced in most laboratories by nucleic acid amplification tests (NAATs), which are now the recommended diagnostic tests for chlamydia. NAATs have the highest sensitivity (detecting a small number of elementary bodies) and can be performed on genital swabs and on noninvasively collected specimens (first-void urine or self-collected vaginal swabs) with similar accuracy. The CDC's recommended specimens for NAATs are first-void urine in males and vaginal swabs in females. NAATs have not been cleared by the Food and Drug Administration for use with rectal, oropharyngeal, or conjunctival swab specimens; however, some laboratories have validated the assays to meet Clinical Laboratory Improvement Amendments (CLIA) requirements.

The role of serology in diagnosing *C. trachomatis* infection is limited primarily to two indications: (1) infant pneumonia syndrome, the diagnosis of which is suggested by a *C. trachomatis* immunoglobulin M antibody titer of 1:32 or greater using the microimmunofluorescence (MIF) assay, and (2) LGV, the diagnosis of which is suggested by a complement fixation (CF) antibody titer greater than 1:64 or MIF antibody titer greater than 1:256 in the appropriate clinical context; MIF has a higher specificity than CF. LGV can also be diagnosed by demonstrating an LGV OmpA type on *C. trachomatis* DNA from infected material.

TREATMENT

C. trachomatis is susceptible to tetracyclines, macrolides, and select quinolones (ofloxacin and levofloxacin, but not ciprofloxacin). The CDC's recommended treatment for uncomplicated genital chlamydia is either doxycycline 100 mg orally twice daily for 7 days or azithromycin 1 g orally in a single dose. A meta-analysis of clinical trials that used primarily chlamydia culture revealed that these regimens are equally efficacious, with cure rates around 97 to 98%.[3] Recent studies in women using the more sensitive NAATs suggest that the cure rate may be a slightly lower (≈92%). Azithromycin is a little more expensive than doxycycline, but treatment compliance is higher. Alternative treatment regimens include erythromycin base 500 mg orally four times a day for 7 days, ofloxacin 300 mg orally twice daily for 7 days, or levofloxacin 500 mg orally once a day for 7 days. Azithromycin is the recommended treatment for chlamydia-infected pregnant women. *C. trachomatis* epididymitis and PID should be treated with doxycycline for 10 and 14 days, respectively. Treatment of these syndromes is usually empirical before test results are available; therefore, ceftriaxone 250 mg intramuscularly in a single dose is added to doxycycline to cover gonorrhea. LGV should be treated with doxycycline for 3 weeks; some experts recommend azithromycin 1 g orally weekly for 3 weeks as an alternative. Infant chlamydial infections are treated with erythromycin base 50 mg/kg/day divided into four daily doses for 14 days; data on other macrolides are limited.

A test of cure (approximately 3 weeks after completion of chlamydia treatment) is recommended only for pregnant women. Sexual partners (including current partners and those with contact in the preceding 60 days) and parents of chlamydia-infected infants should be evaluated and treated empirically.

Expedited partner therapy, whereby chlamydia-infected patients are offered medication or a prescription to give to their sexual partners, or clinicians provide medication to contacts without an examination, may reduce the risk for recurrent chlamydia. Patients and their partners should remain abstinent until treatment is completed.

PREVENTION

Education and the provision of condoms are preventive measures that should accompany chlamydia treatment. Recurrent chlamydia occurs in approximately 10 to 20% of chlamydia-infected subjects within a few months of treatment, so repeat chlamydia testing is recommended approximately 3 months after treatment.

Chlamydophila pneumoniae

In 1986 a new chlamydial pathogen that caused acute respiratory tract infections was identified and designated *Chlamydia* strain TWAR. It was initially thought to be a novel *C. psittaci* strain but was later recognized as the species *C. pneumoniae* in 1989. Pneumonia and upper respiratory tract infections (bronchitis, pharyngitis, and sinusitis) are the most frequently identified diseases caused by *C. pneumoniae.* However, *C. pneumoniae* may also contribute to exacerbations of chronic bronchitis and asthma. Recent evidence suggests that *C. pneumoniae* may contribute to atherosclerosis and possibly to select central nervous system disorders.

EPIDEMIOLOGY

The majority of adults in the United States and other developed countries are seropositive for *C. pneumoniae*, exceeding 80% in some populations. Seroconversion often occurs during childhood or adolescence and may be subclinical. Studies incorporating culture or polymerase chain reaction (PCR) suggest that infection is not uncommon in children younger than 5 years. *C. pneumoniae* causes an atypical pneumonia syndrome, with an estimated annual incidence of 1 case per 1000 population; epidemiologic studies suggest a 4-year cycle of increased pneumonia incidence. Approximately 10% of community-acquired pneumonias are attributed to *C. pneumoniae*, and coinfection with other respiratory pathogens such as *Streptococcus pneumoniae* and *Mycoplasma pneumoniae* is not uncommon. The organism is believed to be acquired through the inhalation of infected respiratory droplets from persons with disease and possibly asymptomatic carriers. This mode of transmission can facilitate the spread of infection among household members and can cause epidemics in enclosed populations, such as persons in military barracks, nursing homes, and schools.

Association with Atherosclerosis

There is evidence that *C. pneumoniae* may cause or contribute to atherosclerosis (Chapter 70) and cardiovascular disease. Seroepidemiologic studies have demonstrated a higher prevalence of *C. pneumoniae* antibodies in patients with atherosclerosis, although the serologic tests used and seropositivity criteria varied across studies. In addition, *C. pneumoniae* has been identified in atherosclerotic plaques by culture, immunohistochemical staining, and PCR. Animal studies have demonstrated that *C. pneumoniae* infection can initiate or enhance the progression of atherosclerosis, and sparse animal studies have demonstrated that antibiotics prevent atherosclerosis. However, large-scale randomized treatment trials have failed to show that *C. pneumoniae* treatment prevents cardiovascular events or mortality; some of these studies differed in terms of study populations, macrolide used, and length of treatment. Currently, antibiotics are not recommended for the prevention of adverse atherosclerotic cardiovascular events.

Association with Asthma

Epidemiologic and clinical studies have demonstrated an association between *C. pneumoniae* infection and asthma, both acute exacerbations and more severe chronic asthma. It is thought that persistent *C. pneumoniae* infection contributes to airway inflammation and hyperresponsiveness. Select randomized clinical trials have demonstrated improvement in asthma disease (symptoms, inflammatory markers, or peak expiratory flow) following antimicrobial treatment of presumed or proven *C. pneumoniae* infection, especially during acute exacerbations. However, it is difficult to determine how much of the improvement may have been due to the immunomodulatory effects of the antibiotics rather than their antimicrobial activity. Although the role of antibiotic treatment for *C. pneumoniae* infection in asthmatics remains

somewhat controversial, treatment for *C. pneumoniae* infection is currently recommended for patients with acute exacerbations of asthma and clinical evidence of infection.

Association with Chronic Neurologic Diseases

C. pneumoniae infection has been implicated in the pathogenesis of multiple sclerosis and Alzheimer's disease, based on some studies demonstrating detection of the organism at a higher frequency in affected neurologic tissue. However, to date, the studies are contradictory, and a causal relationship between *C. pneumoniae* infection and either multiple sclerosis or Alzheimer's disease has not been established.

CLINICAL MANIFESTATIONS

Most *C. pneumoniae* infections occur in children, who often have mild clinical manifestations or are asymptomatic. Clinical manifestations are more evident in adults, especially the elderly, who have the highest incidence of *C. pneumoniae* pneumonia. *C. pneumoniae* causes an atypical pneumonia that is usually of mild to moderate severity. The incubation period may be several weeks, and the disease onset is gradual. A nonproductive cough is usually present and is often preceded or accompanied by nasal congestion, sore throat, and hoarseness. Headache may occur in up to half of patients. Fever and dyspnea occur less commonly. On examination, localized pulmonary crackles or rhonchi are often heard. Chest radiography shows pneumonitis, most often evident as a single subsegmental lower lobe infiltrate. The leukocyte count is usually normal. *C. pneumoniae* may also present as isolated bronchitis, sinusitis, laryngitis, or nonexudative pharyngitis. The clinical course of these upper respiratory tract infections may be protracted over several weeks.

DIAGNOSIS

C. pneumoniae infection is usually diagnosed by serology or direct detection of the organism in respiratory specimens using cell culture or other nonculture methods. Serology is the test used in most clinical settings, with the MIF assay considered the reference standard for serodiagnosis. However, serology is limited by its specificity, reproducibility, and clinical correlation. *C. pneumoniae* can be isolated in cell culture, but culture is technically challenging and time-consuming. Antigen detection using fluorescent monoclonal antibodies has a lower sensitivity than culture and is also technically challenging. *C. pneumoniae* PCR is more sensitive than culture, and real-time PCR appears to have advantages over conventional PCR. Although there are still issues involving the standardization of PCR methods for *C. pneumoniae* detection, PCR is promising and will likely become the test of choice.

TREATMENT Rx

C. pneumoniae is susceptible to tetracyclines, macrolides, and fluoroquinolones. Treatment trials using culture have demonstrated that select macrolide and fluoroquinolone regimens eradicate *C. pneumoniae* in approximately 70 to 85% of subjects with pneumonia. The clinical response to treatment may be slow, and some patients may need re-treatment. The suggested treatment duration for most regimens is typically 10 to 14 days, except that shorter courses may be effective for azithromycin (10 mg/kg on day 1, followed by 5 mg/kg over the next 4 days; up to 1.5 g orally over 5 days). Chronic *C. pneumoniae* infections may require even longer courses of treatment (e.g., 6 weeks), and macrolides are suggested in this setting.

Chlamydophila psittaci

EPIDEMIOLOGY

C. psittaci naturally infects a variety of mammals and birds. *C. psittaci* strains appear to be host specific, and most human infections are linked to contact with an infected bird. *C. psittaci* infection in humans is termed *psittacosis*, in part because exposure to psittacine birds (parrots, parakeets, and budgerigars) is commonly implicated in infections. However, because human cases have been linked to exposure to finches, pigeons, pheasants, ducks, turkeys, chickens, seagulls, and other birds, *ornithosis* may be a more appropriate term. Psittacosis disease in birds ranges from an asymptomatic carriage state to a mild symptomatic illness manifested by ruffled feathers, anorexia, shivering, dyspnea, diarrhea, and/or depression. Infected birds shed *C. psittaci* in urine, feces, or secretions from their beaks or eyes. Their feathers and surrounding environment become contaminated. Transmission to humans is primarily by inhalation of aerosolized bird secretions or dust. Infected birds may shed the organism for months. Person-to-person transmission rarely occurs.

Human psittacosis is a rare infection, due in part to antibiotic-laced bird feed and a mandated quarantine for imported birds. The number of cases of psittacosis in the United States has been stable for the past 10 years, with fewer than 50 confirmed cases reported annually; a larger number of cases are reported but not confirmed.

CLINICAL MANIFESTATIONS

Psittacosis initially involves the lungs and then spreads to the reticuloendothelial system. The clinical spectrum of infection ranges from asymptomatic to fulminant, and clinical manifestations may resemble Q fever, typhoid fever, or legionnaires' disease. After an incubation period of 5 to 14 days, some patients may present with a nonspecific virus-like illness or a mononucleosis-like syndrome. The presentation most suggestive of psittacosis is an acute febrile atypical pneumonia. Patients initially have an abrupt onset of shaking chills and a fever as high as 40.5° C. Temperature-pulse dissociation (i.e., elevated temperature with a normal pulse) may occur. Constitutional symptoms, including headache, myalgias, and arthralgias, are prominent. A cough, usually nonproductive, appears early in the illness and may accompany chest pain, which is usually nonpleuritic. Auscultation may be normal or reveal bilateral crackles. Chest radiograph findings are usually more dramatic than lung examination findings; the most common finding is single lower lobe consolidation, but multiple localized bronchopneumonic patches, diffuse ground-glass changes, or a miliary pattern have been described. Small pleural effusions may be seen. In contrast to *C. pneumoniae* pneumonia, psittacosis is more severe, with high fever and absent or minimal upper respiratory complaints.

Extrapulmonary findings frequently occur in psittacosis. Splenomegaly is common. A faint erythematous, blanching, maculopapular rash (Horder's spots), resembling the rose spots of typhoid fever, can occur, as can erythema nodosum. Signs of hepatitis, endocarditis (culture negative), pericarditis, myocarditis, meningoencephalitis, hemolytic anemia, or disseminated intravascular coagulation may be noted.

DIAGNOSIS

Psittacosis should be suspected in patients with a febrile illness (especially atypical pneumonia) who report exposure to sick or imported birds or who have regular exposure to birds, including bird owners, pet shop workers, veterinarians, zookeepers, and poultry processing plant workers. The diagnosis can be made with serology or by isolating the organism in cell culture. *C. psittaci* is a biocontainment level 3 agent owing to its stability in the environment and aerosol transmission. Because laboratory-acquired *C. psittaci* infections are well documented, culture is discouraged and serology is preferred. If culture is attempted, laboratory staff should be notified in advance so that appropriate precautions can be taken. A serologic diagnosis of psittacosis is made by demonstrating (1) a four-fold or greater rise in CF or MIF antibody against *C. psittaci* to a titer of at least 1:32 from acute to convalescent sera collected at least 2 weeks apart (3 to 6 weeks is recommended), or (2) an immunoglobulin M titer of 1:16 or greater against *C. psittaci* by MIF.

TREATMENT Rx

Untreated psittacosis can be fatal, but mortality is rare with prompt antimicrobial treatment. Because of the delay in laboratory diagnosis of psittacosis, empirical therapy should be provided based on clinical suspicion. *C. psittaci* susceptibility has been demonstrated to tetracyclines, macrolides, and some of the newer fluoroquinolones. The recommended treatment regimen, based on clinical experience, is either tetracycline 500 mg four times a day or doxycycline 100 mg twice a day for 10 to 21 days. Further studies on the clinical efficacy of azithromycin and newer fluoroquinolones are needed. The initial treatment response can be dramatic, with defervescence and marked clinical improvement within 24 to 48 hours. Full recovery may take several weeks, and relapse or reinfection can occur. Endocarditis treatment includes prolonged antibiotic treatment and consideration of valve replacement.

PREVENTION

Epidemic psittacosis is preventable by a 30-day period of quarantine for all imported psittacine birds and their treatment with feed containing chlortetracycline. The U.S. Department of Agriculture recommends extending treatment for an additional 15 days after quarantine. Prevention of epidemic and endemic psittacosis also relies on avoidance of or protection from exposure to dust or body secretions from birds or their living areas, as well as avoiding the handling of sick birds. Environmental sanitation is another important preventive measure, considering the organism's resistance to drying.

327 SYPHILIS

EDWARD W. HOOK III

DEFINITION

Syphilis, which is a chronic infectious disease caused by the bacterium *Treponema pallidum,* is usually acquired by sexual contact with another infected individual. Syphilis is remarkable among infectious diseases for its large variety of clinical manifestations. It progresses, if untreated, through primary, secondary, and tertiary stages. The early stages (i.e., primary and secondary) are infectious. Spontaneous healing of early lesions occurs, followed by a long latent period. In about 30% of untreated patients, late disease of the heart, central nervous system (CNS), or other organs may develop years after the initial infection. Although the disease is less common now than previously, it remains a challenge to clinicians because of its protean manifestations, and it is of interest to biologists because of the prolonged, tenuous balance between the host and the invading spirochete.

The Pathogen

The causative agent of syphilis, *T. pallidum,* is closely related to other pathogenic spirochetes (Chapter 328), including those causing yaws (*T. pallidum* subspecies *pertenue*) and pinta (*Treponema carateum*). *T. pallidum* is a thin, helical bacterium approximately 0.15 µm wide and 6 to 15 µm long. The organism has 6 to 14 spirals and is tapered on either end. It is too thin to be seen by ordinary Gram stain microscopy but can be visualized in wet mounts by dark-field microscopy or in fixed specimens by silver stain or fluorescent antibody methods.

Unlike most bacteria, which have protein-rich outer membranes, the *T. pallidum* outer membrane appears to be composed of predominantly phospholipids, with few surface-exposed proteins. It has been hypothesized that because of this structure, syphilis can progress despite the brisk antibody response to non–surface-exposed internal antigens, which is the basis for serologic tests for the diagnosis and management of syphilis. Between the outer membrane and the peptidoglycan cell wall are six axial fibrils; three are attached at each end, and they overlap in the center of the organism. They are structurally and biochemically similar to flagella and are in part responsible for the organism's motility.

It is possible to culture *T. pallidum,* but sustained in vitro cultivation is not yet possible, and yields are very low. Culture is of limited use in research and of no use in clinical practice. All isolates studied have been susceptible to penicillin and are antigenically similar. The only known natural hosts for *T. pallidum* are humans and certain monkeys and higher apes.

EPIDEMIOLOGY

With the exception of congenital syphilis, syphilis is acquired almost exclusively by intimate contact with the infectious lesions of primary or secondary syphilis (e.g., chancres, mucous patches, condylomata lata). Disease is usually acquired through sexual intercourse, including anogenital and orogenital intercourse. Health care workers are sometimes infected during the unsuspecting examination of patients with infectious lesions. Infection by contact with fomites is extremely uncommon. Before the advent of modern blood banking techniques, syphilis was occasionally transmitted through the transfusion of blood from persons with *T. pallidum* bacteremia, and occasional parenteral transmission still occurs as a result of the sharing of contaminated needles.

Syphilis is most common in large cities and in young, sexually active individuals. The highest rate is found in men between the age of 20 and 29 years. In 2008, 69% of the 3141 U.S. counties reported no cases of primary or secondary syphilis, and just 26 locales accounted for about 50% of all reported infections. The disease is most prevalent in the Southeast.

Syphilis spares no class, race, or group but is more prevalent among persons living on the margins of society. U.S. syphilis rates are about eightfold greater in African Americans than in non-Hispanic whites (17.3 vs. 2.2 cases per 100,000 people). Increased numbers of different sexual partners and perhaps the indiscriminate choice of partners increase the risk of acquiring sexually transmitted disease (Chapter 293). Patients with primary and secondary syphilis name, on average, nearly three different sexual contacts within the previous 90 days. A traditional cornerstone of syphilis control has been the epidemiologic investigation and treatment of sexual contacts of patients with primary or secondary lesions and patients with early latent disease. As syphilis has become associated with drug use and anonymous sex, epidemiologic investigations have become less efficacious.

The incidence of syphilis has generally declined worldwide for more than 100 years, with the exception of periods of war or social upheaval. With the introduction of penicillin, there was a rapid decline in primary and secondary syphilis, to approximately 4 cases per 100,000 people in 1957. This decline was followed by reductions in federal expenditures for syphilis control, which resulted in a resurgence of infectious primary and secondary syphilis in the United States; peaks of more than 12 cases per 100,000 people were attained several times from 1965 through the mid-1990s. Because many cases of syphilis are not reported, the true incidence is much higher.

Over the past 40 years, syphilis epidemics have occurred serially in at least three U.S. population subgroups. In the 1970s and 1980s, men who had sex with other men accounted for a disproportionate number of the total cases of infectious syphilis. Similar trends occurred in other countries. Then, after a period of decline, U.S. syphilis rates nearly doubled from 1986 to 1990, with 50,578 cases reported in 1990 in an epidemic disproportionately affecting multiracial heterosexual men and women and occurring contemporaneously with an epidemic of crack cocaine use. After 1990, syphilis rates again declined; in 2001, there were 6103 cases of primary and secondary syphilis reported, one of the lowest numbers since 1959. The epidemic of the late 1980s probably contributed to the spread of human immunodeficiency virus (HIV) infection (see Syphilis-HIV Interactions) and to dramatic increases in the rate of congenital syphilis. Since 2000, syphilis rates have begun to increase in men, especially men infected with HIV, and they have been increasing since 2005 in women.

Patients with clinically evident late syphilis, particularly those with cardiovascular or gummatous syphilis, are becoming less common, perhaps as a result of the effectiveness of penicillin therapy for early syphilis. However, surveys indicate that there are still significant numbers of patients with untreated neurologic syphilis, especially in older age groups.

Natural Course of Untreated Syphilis

The incubation period from the time of exposure to development of the primary lesion averages approximately 21 days (range, 10 to 90 days). Initially, a painless papule develops at the site of inoculation and soon breaks down to form a clean-based ulcer—the chancre—with raised, indurated margins (Fig. 327-1A). The chancre persists for 2 to 6 weeks and then heals spontaneously. Several weeks later, a secondary stage characterized by low-grade fever, headache, malaise, generalized lymphadenopathy, and a mucocutaneous rash typically develops. There may be involvement of visceral organs. The secondary eruption may occur while the primary chancre is still healing or up to several months after disappearance of the chancre. Secondary lesions also heal spontaneously within 2 to 6 weeks, and the infection then becomes latent. In more than 20% of patients with untreated latent syphilis, relapsing lesions later develop, similar to those of the secondary stage; rarely, the relapse takes the form of recurrence of the primary chancre. In the era before antibiotics, late, destructive tertiary lesions involving the eyes, the CNS, the heart, and other organs, including the skin, eventually developed in about a third of untreated patients. These lesions may occur a few years to as long as 25 years after infection.

The incidence of late complications of untreated syphilis is currently unknown, but it seems to be less than that seen previously. Cases of gumma are now so rare as to be reportable.

PATHOBIOLOGY

T. pallidum may penetrate through normal mucosal membranes and minor abrasions on epithelial surfaces. In experimental rabbit syphilis, spirochetes can be found in the lymphatic system within 30 minutes of inoculation and are detected in blood shortly thereafter. There have been a few instances of transfusion syphilis in humans, resulting from the use of blood from a bacteremic donor who was in the incubation stage of the disease. The first lesions appear at the site of primary inoculation. In laboratory animals, there is an inverse relationship between the number of treponemes inoculated and the time required for development of the primary cutaneous lesion. The minimal number of treponemes needed to establish infection is not known but may be as low as one. Multiplication of organisms is slow, with a division time in rabbits of approximately 33 hours. The slow growth of treponemes in humans

FIGURE 327-1. Syphilis lesions. A, Chancre in primary syphilis. **B,** Palmar lesions of a coppery color in secondary syphilis. **C,** Mucous patch in secondary syphilis. **D,** Condylomata lata in secondary syphilis (**A, C,** and **D,** From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003; **B,** From Habif TP, Cambell JI, Quitadamo MJ, et al. *Skin Disease: Diagnosis and Treatment*. St. Louis: Mosby; 2001.)

probably accounts in part for the protracted nature of the illness and for the relatively long incubation period.

Syphilis is a systemic disease from the onset. Treponemes are capable of specific attachment to host cells, but it is not known whether attachment results in damage to the host cells. Most treponemes are found in the intercellular spaces, but they are occasionally seen within phagocytic cells. However, there is no evidence of prolonged intracellular survival of treponemes. *T. pallidum* is not known to produce toxins.

The primary pathologic lesion of syphilis is a focal endarteritis with an increase in adventitial cells, endothelial proliferation, and the presence of an inflammatory cuff around affected vessels. Lymphocytes, plasma cells, and monocytes predominate in the inflammatory lesion, and polymorphonuclear cells are seen in some cases. The vessel lumen is frequently obliterated. With healing, there is considerable fibrosis. Treponemes may be seen in most early lesions of syphilis and in some of the late lesions, such as the meningoencephalitis of general paresis.

Granulomatous reaction is common in secondary and late syphilis. The granulomas are histologically nonspecific, and cases of syphilis have been incorrectly diagnosed as sarcoidosis or other granulomatous diseases. Human inoculation studies suggest that the pathogenesis of the gumma, which is a granulomatous lesion, involves hypersensitivity to small numbers of virulent treponemes introduced into a previously sensitized host.

Intracutaneous inoculation of partially purified antigens of *T. pallidum* into patients with syphilis in various stages has shown that delayed cellular hypersensitivity develops only late in secondary syphilis but is uniformly present in latent syphilis. There may be temporary hyporesponsiveness of lymphocytes to treponemal antigens in patients with primary and secondary syphilis. It is possible that the waxing and waning of lesions in early syphilis depend on the balance between the development of effective cellular immunity and the suppression of thymus-derived lymphocyte function.

The host also responds to infection by producing numerous antibodies; in some instances, circulating immune complexes may be formed as well. For example, nephrotic syndrome has occasionally been recognized in secondary syphilis, and renal biopsy specimens from such patients have shown membranous glomerulonephritis characterized by focal subepithelial basement membrane deposits containing immunoglobulin G (IgG), C3, and treponemal antibody.

CLINICAL MANIFESTATIONS

Primary Syphilis

The typical lesion of primary syphilis, the chancre, is a painless, clean-based, indurated ulcer (see Fig. 327-1A). The chancre starts as a papule, but then superficial erosion results in ulceration. The borders of the ulcer are raised, firm, and indurated. Occasionally, secondary infections change the appearance and cause a painful lesion. Most chancres are single, but multiple ulcers are sometimes seen, particularly when skin folds are apposed (i.e., kissing chancres). An untreated chancre heals in several weeks and leaves a faint scar. The chancre is usually associated with regional adenopathy, which may be unilateral or bilateral. The regional nodes are movable, discrete, and rubbery. If the chancre occurs in the cervix or the rectum, the affected regional iliac nodes are not palpable.

Chancres can occur at any site of potential inoculation by direct contact, with most occurring in anogenital locations. Chancres may also be seen in the pharynx, on the tongue, around the lips, on the fingers, on the nipples, and in other diverse areas. The morphology depends in part on the area of the body where they occur and on the host's immune response. Chancres in previously infected individuals may be small and remain papular. Chancres of the finger may appear more erosive and can be quite painful. Chancres of the anal canal may be missed in men who have sex with men unless a careful examination is undertaken.

Secondary Syphilis

Between 4 and 8 weeks after the appearance of the primary chancre, signs and symptoms of secondary syphilis typically develop. Symptoms may include malaise, fever, headache, sore throat, and other systemic complaints. Most patients have generalized lymphadenopathy, including involvement of the epitrochlear nodes. Approximately 30% of patients have evidence of a healing chancre, although many patients (including a disproportionate number of women and of men who have sex with men) give no history of a primary lesion.

At least 80% of patients with secondary syphilis have cutaneous or mucocutaneous lesions at some point in their illness. The diagnosis is generally first suspected on the basis of the cutaneous eruption. The rash is often minimally symptomatic, and many patients with late syphilis do not recall primary or secondary lesions. The rashes are quite varied in appearance but have certain characteristic features. The lesions are usually widespread, are symmetrical in distribution, and are frequently pink, coppery, or dusky red (particularly the earliest macular lesions). They are generally nonpruritic, although occasional exceptions have been reported, and they are rarely vesicular or bullous in adults. They are indurated, except for the very earliest macular lesions, and frequently have a superficial scale (i.e., papulosquamous lesions). The lesions tend to be polymorphic and rounded, and on healing, they may leave residual pigmentation or depigmentation. They may be quite faint and difficult to visualize, particularly on dark-skinned individuals.

The earliest pink macular lesions are typically seen on the trunk, with later spread to the rest of the body. The face is often spared, except around the mouth. Subsequently, a papular rash appears that is usually generalized but is quite marked on the palms and soles (Fig. 327-1B). These rashes are often associated with a superficial scale and may be hyperpigmented. When the rash occurs on the face, it may be pustular and resemble acne vulgaris. Occasionally, the scale may be so great that it resembles psoriasis. Ulceration may occur and produce lesions resembling ecthyma. In malnourished or debilitated patients, extensive and destructive ulcerative lesions with a heaped-up crust may occur, the so-called rupial lesions. Lesions around the hair follicles may result in patchy alopecia of the beard or scalp.

Ringed or annular lesions may occur, especially around the face, and particularly on dark-skinned individuals. A lesion at the angle of the mouth or the corner of the nose may have a central linear erosion, the so-called split papule.

The palate and pharynx may be inflamed. In approximately 30% of secondary syphilis patients, so-called mucous patches (Fig. 327-1C) develop; these slightly raised, oval areas are covered by a grayish white membrane that, when raised, reveals a pink base that does not bleed. These lesions may be seen on the genitalia, in the mouth, or on the tongue; like condylomata lata, they are highly infectious.

In warm, moist areas such as the perineum, large, pale, flat-topped papules may coalesce to form condylomata lata (Fig. 327-1D). Papules may also be

seen in the axilla and rarely occur in a generalized form. They are extremely infectious. These papules are not to be confused with the common venereal warts (i.e., condylomata acuminata), which are small, often multiple, and more sharply raised than condylomata lata.

Other manifestations of secondary syphilis include hepatitis, which has been reported in up to 10% of patients in some series. Jaundice is rare, but an elevated alkaline phosphatase level is common. Liver biopsy reveals small areas of focal necrosis and mononuclear infiltrate or periportal vasculitis. Spirochetes can often be visualized with silver stains. Periostitis with widespread lytic lesions of bone has been reported occasionally; bone scanning appears to be a sensitive test for early syphilitic osteitis. An immune complex type of nephropathy with transient nephrotic syndrome has been documented rarely. There may be iritis or an anterior uveitis. Between 10 and 30% of patients have pleocytosis in cerebrospinal fluid (CSF), but symptomatic meningitis is seen in less than 1% of patients. Symptomatic gastritis may occur.

Relapsing Syphilis

After resolution of the primary or secondary skin lesions, 20 to 30% of patients experience cutaneous recurrences. Recurrent lesions may be fewer or more firmly indurated than the initial lesions. Like the typical lesions of primary or secondary syphilis, they are infectious for exposed sexual partners.

Latent Syphilis

By definition, latent syphilis is the stage at which there are no clinical signs of syphilis and the CSF is normal. Latency, which begins when the first attack of secondary syphilis has passed and may last for a lifetime, is usually detected by reactive serologic tests for syphilis (see Diagnosis). Congenital syphilis must also be excluded before the diagnosis of latent syphilis can be made. Patients may or may not have a clinical history of earlier primary or secondary syphilis.

Latency has been divided into two stages: early and late. Most infectious relapses occur in the first year, and epidemiologic evidence shows that the most infectious period is during the first year of infection. Early latency is therefore defined as the first year after resolution of the primary or secondary lesions, or as a newly reactive serologic test for syphilis in an otherwise asymptomatic individual who has had a negative serologic test within the preceding year. Late latent syphilis is ordinarily not infectious, except for pregnant women, who can transmit infection to the fetus after many years. Most cases of latent syphilis are most accurately called latent syphilis of unknown duration and should be treated in the same manner as late latent syphilis (see later).

Late Syphilis

Late syphilis (Table 327-1) is usually slowly progressive, although certain neurologic syndromes may have a sudden onset because of endarteritis and CNS thrombosis. Late syphilis is not infectious through sexual contact. Any organ of the body may be involved, but three main types of disease can be distinguished: late benign (gummatous), cardiovascular, and neurosyphilis.

TABLE 327-1 NEWLY DIAGNOSED TERTIARY SYPHILIS IN 105 PATIENTS IN DENMARK, 1961-1970

TYPE OF TERTIARY SYPHILIS	NO. OBSERVED*
Neurosyphilis	72
Asymptomatic	45
Tabes dorsalis	11
General paresis	13
Meningovascular	1
Optic atrophy	2
Cardiovascular syphilis	44
Aortic insufficiency	16
Aortic aneurysm	13
Uncomplicated aortitis†	15
Late benign syphilis (gumma)	4

*Some patients had more than one form of late syphilis.
†Autopsy diagnoses only.

Late Benign Syphilis

In the penicillin era, gummas are rare. They typically develop 1 to 10 years after initial infection and may involve any part of the body. Although gummas may be destructive, they respond rapidly to treatment and are therefore relatively benign. Histologically, the gumma is a granuloma.

Gummas may be solitary or multiple and most often come to medical attention as space-occupying lesions. They are usually asymmetrical and are often grouped. Gummas may start as a superficial nodule or as a deeper lesion that breaks down to form punched-out ulcers. They are ordinarily indolent, slowly progressive, and indurated on palpation. There is often central healing, with an atrophic scar surrounded by hyperpigmented borders. Cutaneous gummas may resemble other chronic granulomatous ulcerative lesions caused by tuberculosis, sarcoidosis, leprosy, and other deep fungal infections. Precise histologic diagnosis may not be possible. However, syphilitic gummas are the only such lesions to heal dramatically with penicillin therapy.

Gummas may also involve deep visceral organs, particularly the respiratory tract, gastrointestinal tract, and bones. In addition, they may involve the larynx or the pulmonary parenchyma. Gummas of the stomach may masquerade as carcinoma of the stomach or lymphoma. Gummas of the liver were once the most common form of visceral syphilis and often manifested as hepatosplenomegaly and anemia and occasionally as fever and jaundice. Skeletal gummas typically produce lesions in the long bones, skull, and clavicle; a characteristic symptom is nocturnal pain. Radiologic abnormalities, when present, include periostitis and lytic or sclerotic, destructive osteitis.

Cardiovascular Syphilis

The primary cardiovascular complications of syphilis are aortic insufficiency (Chapter 75) and aortic aneurysm (Chapter 78), usually of the ascending aorta. Less commonly, other large arteries may be affected, and involvement of the coronary ostia rarely results in coronary insufficiency. All these complications are caused by obliterative endarteritis of the vasa vasorum, with resultant damage to the intima and media of the great vessels. This damage results in dilation of the ascending aorta, but the valve cusps remain normal. An aneurysm occasionally manifests as a pulsating mass bulging through the anterior chest wall. Syphilitic aortitis may also involve the descending aorta proximal to the renal arteries.

Cardiovascular syphilis usually begins within 5 to 10 years of the initial infection but may not manifest clinically until 20 to 30 years later. Cardiovascular syphilis does not occur after congenital infection—a phenomenon that remains unexplained.

Asymptomatic aortitis is best diagnosed by visualizing linear calcifications in the wall of the ascending aorta by radiography. The signs of syphilitic aortic insufficiency are the same as for aortic insufficiency of other causes. In aortic insufficiency resulting from dilation of the aortic ring, the decrescendo murmur is often loudest along the right sternal margin. Syphilitic aneurysms may be fusiform but are more typically saccular and do not lead to aortic dissection. Between 10 and 20% of patients with cardiovascular syphilis have coexistent neurosyphilis.

Neurosyphilis

CNS involvement occurs throughout the natural history of syphilis. Neurosyphilis can be divided into five groups: asymptomatic, syphilitic meningitis, meningovascular syphilis, tabes dorsalis, and general paresis. Asymptomatic neurosyphilis can occur at any time, whereas syphilitic meningitis is most common during the secondary stage of infection. Meningovascular syphilis, tabes dorsalis, and general paresis are typically manifestations of late syphilis. The divisions are not absolute, and overlap between syndromes is typical. Current cases of neurosyphilis are likely to be variants of the classic syndromes, possibly as a result of the use of antimicrobial agents for other diseases.

Syphilitic Meningitis

Acute to subacute aseptic meningitis can occur at any time after the primary stage, but it usually occurs within the first year of infection. It frequently involves the base of the brain and may result in unilateral or bilateral cranial nerve palsies. Mild aseptic meningitis may be relatively common in patients with early syphilis, but severe disease occurs in only about 1.5% of untreated patients. Syphilitic meningitis typically resolves without treatment.

Meningovascular Syphilis

Some patients have sufficient endarteritis and perivascular inflammation to result in cerebrovascular thrombosis and infarction, generally 5 to 10 years

after the initial infection. Patients frequently have associated aseptic meningitis. Most cerebrovascular accidents are not caused by syphilitic arteritis, even in patients with a reactive serologic test result for syphilis. However, syphilis should be considered a potential cause in relatively young patients with a history of syphilis and without other risk factors for cerebrovascular accidents.

Tabes Dorsalis

Tabes dorsalis, which appears to be far less common than in the pre-penicillin era, is a slowly progressive, degenerative disease that involves the posterior columns and posterior roots of the spinal cord and results in progressive loss of peripheral reflexes, impairment of vibration and position sense, and progressive ataxia. There may be chronic destructive changes in the large joints of the affected limbs in far-advanced cases (i.e., Charcot's joints). Incontinence of the bladder and impotence are common. Sudden and severely painful crises of uncertain origin are a characteristic part of the syndrome. These features typically involve the lower extremities but can occur at any site. Severe, sharp abdominal pain may lead to exploratory surgery. These attacks may be triggered by exposure to cold or other stresses or may arise with no obvious precipitating cause.

Optic atrophy is seen in 20% of cases. In 90% of patients, the pupils are bilaterally small and fail to constrict further in response to light, but they do respond normally to accommodation (i.e., Argyll Robertson pupils).

The onset of tabes dorsalis is usually first noticed 20 to 30 years after the initial infection. Its cause is unclear, and spirochetes cannot be demonstrated in the posterior column or dorsal root.

General Paresis

This form of neurosyphilis is a chronic meningoencephalitis resulting in the gradual and progressive loss of cortical function. It typically occurs 10 to 20 years after the initial infection. Pathologically, there is a perivascular and meningeal chronic inflammatory reaction, with thickening of the meninges, granular ependymitis, degeneration of the cortical parenchyma, and abundant spirochetes in tissues. In the United States, first admissions to mental hospitals because of syphilitic psychosis declined from 7694 in 1940 to 154 in 1968, the last year for which definite figures are available.

In its early stages, general paresis results in nonspecific symptoms of early dementia, such as irritability, fatigability, headaches, forgetfulness, and personality changes. Later, there is impaired memory, defective judgment, lack of insight, confusion, and often depression or marked elation. Patients may be delusional, and seizures sometimes occur. There may also be loss of other cortical functions, including paralysis or aphasia.

Physical signs are primarily those of the altered mental status. Cranial nerve palsies are uncommon, and optic atrophy is rare. The complete Argyll Robertson pupil is also uncommon, but irregular or otherwise abnormal pupils are not infrequent. Peripheral reflexes are often somewhat increased.

Syphilis-HIV Interactions

Syphilis, like other genital ulcer diseases, is associated with a three- to five-fold increased risk for acquisition of HIV infection. Presumably, genital ulcers act as portals of entry through which HIV may more readily infect exposed individuals. As a result, HIV serologic testing 3 months after a diagnosis of syphilis is recommended for all patients. Conversely, in individuals with HIV infection who acquire syphilis, the natural history of the infection may be modified. HIV-infected syphilis patients are somewhat more likely than non-HIV-infected patients to present initially with secondary syphilis. HIV-infected secondary syphilis patients are also more likely than HIV-negative secondary syphilis patients to have coexistent chancres, suggesting that the healing of chancres is delayed or the appearance of secondary manifestations is accelerated in the presence of HIV coinfection.

Congenital Syphilis

Congenital syphilis results from the transplacental, hematogenous spread of syphilis from the mother to the fetus. The incidence of congenital syphilis diagnoses in the United States fell below 1000 per year for the first time in 1975, and fewer than 500 cases occurred each year until 1988, when the epidemic of syphilis in adults led to parallel increases in congenital infections. From 1990 through 1993, more than 3000 new cases of congenital syphilis were reported each year. A Venereal Disease Research Laboratory (VDRL) test should be performed in all expectant mothers at the beginning of pregnancy and should be repeated near the end of pregnancy in women living in areas where syphilis is relatively common.

The risk for fetal infection is greatest in the early stages of untreated maternal syphilis and declines slowly thereafter, but the mother can infect her fetus during at least the first 5 years of her infection. Adequate treatment of the mother before the 16th week of pregnancy usually prevents clinical illness in the neonate. Later treatment may not prevent late sequelae of the disease in the child. Untreated maternal infection may result in stillbirth, neonatal death, prematurity, or syndromes of early or late congenital syphilis in surviving infants.

Manifestations of early congenital syphilis are often seen in the perinatal period but may not develop until the infant has been discharged from the hospital. The disease resembles secondary syphilis in adults, except that the rash may be vesicular or bullous. The child often has rhinitis, hepatosplenomegaly, hemolytic anemia, jaundice, and pseudoparalysis (i.e., immobility of one or more extremities) as a result of painful osteochondritis. There may be thrombocytopenia and leukocytosis. The early stages of congenital syphilis must be differentiated from congenital rubella, cytomegalovirus infection, toxoplasmosis, bacterial sepsis, and other diseases.

Late congenital syphilis is defined as congenital syphilis diagnosed more than 2 years after birth. The disease may remain latent, with no manifestations of late damage. Cardiovascular alterations have not been observed in patients with congenital syphilis. Neurologic manifestations are common and may include eighth cranial nerve deafness and interstitial keratitis. Periostitis may result in prominent frontal bones of the skull, depression of the bridge of the nose (saddle nose), poor development of the maxilla, and anterior bowing of the tibias (saber shins). There may be late-onset arthritis of the knees (Clutton's joints). The permanent dentition may show characteristic abnormalities known as Hutchinson's teeth; the upper central incisors are widely spaced, centrally notched, and tapered in the manner of a screwdriver. The molars may show multiple poorly developed cusps (mulberry molars).

DIAGNOSIS

Dark-Field Examination

The most definitive means of syphilis diagnosis is finding spirochetes of typical morphology and motility in lesions of early acquired or congenital syphilis. Dark-field examination is often positive in cases of primary syphilis and in patients with the moist mucosal lesions of secondary and congenital syphilis. The result may occasionally be positive for aspirates of lymph nodes in secondary syphilis. False-negative results may occur in primary syphilis because of the application of soaps, antiseptics, or other compounds toxic to *T. pallidum* to the lesions. A single negative result is therefore insufficient to exclude syphilis. For high-risk individuals (e.g., drug users, homosexually active men), it is appropriate to treat presumptively based on suspicious lesions after performing serologic tests. Confusion may also arise because of the presence of spirochetes that are morphologically indistinguishable from *T. pallidum* organisms in the mouth, particularly around the gingival margins. Living *T. pallidum* organisms demonstrate gradual motion to and fro, rotational movement around the long axis, and rather sudden 90-degree flexing near the center of the organism. Because most physicians do not have the proper equipment and are not familiar with dark-field microscopy techniques, public health authorities can be called for assistance. *T. pallidum* may also be demonstrated in biopsy or pathologic specimens by fluorescent antibody stains or by silver stains.

Serologic Tests

Two basic types of serologic tests (Table 327-2) are widely used to diagnose infection with *T. pallidum:* (1) nontreponemal tests that detect antibodies reactive with diphosphatidylglycerol (cardiolipin), which is a normal component of many tissues, and (2) tests that detect antibodies to specific treponemal antigens.

Nontreponemal Tests

The standard tests to detect anticardiolipin antibody are the VDRL and rapid plasma reagin (RPR) tests, which are slide flocculation tests. The VDRL and RPR are readily quantified, so they are the tests of choice for monitoring patients' responses to treatment. The relative proportion of patients with a false-positive VDRL result depends on the prevalence of syphilis in the community; the lower the prevalence of syphilis, the higher the proportion of reactive VDRL test results from nonsyphilitic causes.

The VDRL test begins to turn positive less than 1 week after onset of the chancre; thus, a nonreactive VDRL test does not exclude primary syphilis, particularly if the lesion is less than 1 week old. The VDRL test result is positive in 99% of patients with secondary syphilis (Table 327-3). Patients with

TABLE 327-2 SEROLOGIC TESTS FOR SYPHILIS

TYPE	USE
NONTREPONEMAL (ANTICARDIOLIPIN) ANTIBODIES	
VDRL (slide flocculation)	Screening, quantitation of response to treatment
RPR (circle card) (agglutination)	Screening, quantitation of response to treatment
SPECIFIC TREPONEMAL ANTIBODIES	
FTA-ABS (immunofluorescence with absorbed serum)	Confirmatory, diagnostic; not for routine screening
TP-PA (microhemagglutination)	Similar to FTA-ABS but can be quantified and automated
EIA	Confirmatory and increasingly used for screening; automated

EIA = enzyme immunoassay; FTA-ABS = fluorescent treponemal antibody absorption test; RPR = rapid plasma regain test; TP-PA = *Treponema pallidum*–particle agglutination; VDRL = Venereal Disease Research Laboratory.

TABLE 327-3 FREQUENCY OF POSITIVE SEROLOGIC TESTS IN UNTREATED SYPHILIS

STAGE	VDRL (%)	FTA-ABS (%)	TP-PA (%)
Primary	70	85	50-60
Secondary	99	100	100
Latent or late	70	98	98

FTA-ABS = fluorescent treponemal antibody absorption test; TP-PA = *Treponema pallidum*–particle agglutination; VDRL = Venereal Disease Research Laboratory.

advanced HIV infection may have negative test results, and some patients have such high titers of antibody that they are in antibody excess; dilution of their serum paradoxically results in conversion of a negative test result to a positive one, the so-called prozone reaction. VDRL reactivity tends to diminish in later stages of syphilis, and only about 70% of patients with cardiovascular or neurosyphilis have positive VDRL test results.

The *quantitative titer* of the VDRL or RPR test is somewhat useful in diagnosis and is quite useful for monitoring the therapeutic response. The titer is reported as the highest dilution that gives a positive response. Most patients with secondary syphilis have titers of at least 1:16. Most patients with false-positive VDRL test results have titers of less than 1:8. No single titer is diagnostic by itself. Significant rises (four-fold or greater) in paired sera, however, strongly indicate acute syphilis.

Treponemal Tests

Several types of treponemal tests are widely used. In the fluorescent treponemal antibody absorption (FTA-ABS) test, the patient's serum is absorbed first with extracts of nonpathogenic, cultivable treponemes to remove cross-reacting treponemal antibodies; then with *T. pallidum;* and finally with fluorescein-conjugated antihuman antibody. Agglutination of particles to which *T. pallidum* antigens have been fixed is the basis of the *T. pallidum* particle agglutination (TP-PA) test. More recently, treponemal enzyme immunoassays (EIAs) have become available from several manufacturers and have gained favor because of their low cost and ease of use.

The treponemal tests are best used to confirm that persons with reactive nontreponemal tests have antibodies to *T. pallidum.* Results of treponemal tests are not reliably quantified. They are sensitive and have a high degree of specificity, in that only approximately 1% of normal individuals have reactive treponemal tests. They are reactive in 85% of patients with primary syphilis, 99% with secondary syphilis, and at least 95% with late syphilis. They may therefore be the only test with a positive result in patients with cardiovascular or neurologic syphilis. For patients with late syphilis, treponemal tests often remain reactive for life, despite adequate therapy. The FTA-ABS test is reported in terms of relative brilliance of fluorescence, from borderline to 4 plus, and most laboratories report only tests with 2 plus or greater reactivity as positive. For patients lacking historical or clinical evidence of syphilis but with a reactive FTA-ABS test result, the test should be repeated. Use of another treponemal test, such as the TP-PA test, may be helpful in problem cases. The TP-PA test is slightly less sensitive than the VDRL or FTA-ABS test in primary syphilis. Its sensitivity and specificity are otherwise nearly identical to those of the FTA-ABS test.

EIAs for the detection of antitreponemal antibodies use cloned *T. pallidum* antigens generated from bacterial expression systems. EIA serologic tests permit the screening of large numbers of sera and have performance characteristics (sensitivity, specificity, predictive values) similar to those of other treponemal tests. Persons with syphilis diagnosed by treponemal antigen EIAs should be tested with quantitative nontreponemal tests such as the VDRL or RPR for confirmation and to permit the use of these tests to evaluate the subsequent response to therapy.

Differential Diagnosis

The differential diagnosis of a genital ulcer (Chapter 293) includes genital herpes (Chapter 382), chancroid (Chapter 309), lymphogranuloma venereum (Chapter 326), and a number of other ulcerative processes. Classically, herpetic ulcers are multiple, painful, superficial, and, if seen early, vesicular. However, atypical manifestations may be indistinguishable from a syphilitic chancre. Genital herpes is much more common than syphilis and is now the most common cause of a "typical chancre" in North America. Syphilitic chancres may also be coinfected with herpes simplex virus in about 15% of cases. The ulcers of chancroid are usually painful, often multiple, and frequently exudative and nonindurated. Lymphogranuloma venereum may produce a small, papular lesion associated with regional adenopathy. Other conditions that must be distinguished include granuloma inguinale (Chapter 324), drug eruptions, carcinoma, superficial fungal infections (Chapter 446), traumatic lesions, and lichen planus (Chapter 446). In most cases, the final distinction is based on dark-field examination, which is positive only in syphilis, and on serologic test results.

The differential diagnosis of the skin lesions of secondary syphilis includes pityriasis rosea (Chapter 446), which can be differentiated by the occurrence of lesions along lines of skin cleavage and frequently by the presence of a herald patch. Drug eruptions, acute febrile exanthems, psoriasis, lichen planus, scabies, and other diseases must also be considered in some cases. A mucous patch may superficially resemble oral candidiasis (i.e., thrush). Infectious mononucleosis (Chapter 385) may appear very similar to secondary syphilis, with sore throat, generalized adenopathy, hepatitis, and a generalized rash. Hepatitis (Chapter 150) may also cause confusion.

False-Positive Serologic Test Results for Syphilis

The VDRL or RPR test is reactive in patients with other treponemal diseases such as pinta, yaws, and endemic syphilis (Chapter 328). These tests may also be falsely reactive in persons who do not have treponemal infections based on a negative clinical history or negative results of serum treponemal tests.

Acute (<6 months) false-positive VDRL test results occur with low frequency in patients with atypical pneumonia, malaria, and other bacterial or viral infections, and they may occur after smallpox or other vaccinations as well. Chronic false-positive VDRL test results (persisting >6 months) are relatively common in patients with autoimmune disorders such as systemic lupus erythematosus (SLE; Chapter 274), parenteral drug users, HIV-infected patients, patients with leprosy, and the aged. Between 8 and 20% of patients with SLE have false-positive VDRL test results. Chronic false-positive VDRL test results in female patients 20 years or younger indicate a significant risk for the future development of SLE, thyroiditis, or other autoimmune disorders. As many as a third of parenteral drug users have false-positive VDRL test results. More than 1% of persons 70 years old and 10% of those older than 80 also have low-titer, false-positive VDRL test results. In most cases of false-positive VDRL tests, the titer is less than 1:8, although a few patients with lymphoma and other diseases have very high-titer, false-positive results.

There is also an increased incidence of false-positive treponemal test results in other chronic inflammatory diseases associated with hyperglobulinemia, including rheumatoid arthritis and biliary cirrhosis. Occasionally, reproducible positive FTA-ABS results are obtained in patients with no clinical or historical evidence of syphilis and no evidence of diseases typically associated with false-positive FTA-ABS results. If the diagnosis is in doubt and if the patient is not allergic to penicillin, it is often prudent to treat for possible syphilis.

Neurosyphilis

Asymptomatic neurosyphilis is diagnosed when there are CSF abnormalities, such as lymphocytic pleocytosis, protein elevation, or a reactive VDRL test result, in a syphilis patient in the absence of signs and symptoms of

neurologic disease. Although numerous other processes can cause CSF pleocytosis or protein elevations, false-positive CSF VDRL test results are rare in the absence of a traumatic tap. If the CSF is normal 2 years or longer after the initial infection, a positive CSF finding is not likely to develop later. Routine lumbar punctures to examine CSF are not indicated in early syphilis unless the patient is known to have HIV infection. Lumbar puncture in HIV-infected persons with early syphilis is the subject of controversy. Although a nonreactive CSF FTA-ABS result may be useful to rule out the diagnosis, no diagnosis of neurosyphilis should be based solely on the CSF FTA-ABS test.

In syphilitic meningitis, the CSF shows a lymphocytic pleocytosis, with increased protein and usually normal glucose concentrations. The CSF VDRL test is nearly always reactive. Rarely, the CSF glucose concentration is decreased. Without treatment, syphilitic meningitis generally resolves, similar to the course of other manifestations of early syphilis. This syndrome can mimic tuberculous or fungal meningitis or nonpurulent meningitis of various causes.

In tabes dorsalis, the VDRL test for serum is nonreactive in as many as 30 to 40% of patients, and 10 to 20% of patients (even before the advent of penicillin) have normal CSF VDRL results. The FTA-ABS test for serum is nearly always reactive.

In general paresis, the CSF is nearly always abnormal, with lymphocytic pleocytosis and an increased total protein concentration. The VDRL test is usually reactive for CSF and serum.

Congenital Syphilis

Because many infants with congenital syphilis may be clinically normal at birth but develop serious, symptomatic disease some weeks later, it is important to determine whether a newborn with a reactive VDRL or FTA-ABS test result has passively transferred maternal antibody or is actively infected. If the mother has been adequately treated for syphilis during pregnancy and the infant is clinically normal at birth, one option is to monitor the infant carefully by serial examinations and VDRL titers. If the reactive VDRL result for the infant is caused by passively transferred maternal antibody, the titer will fall markedly in the first 2 months of life; a rising titer indicates active disease and the need for treatment. However, the risk of improper follow-up of VDRL-positive but clinically normal neonates makes the immediate empirical administration of effective therapy an attractive alternative.

TREATMENT

Rx

T. pallidum is inhibited by less than 0.01 µg/mL of penicillin G. Because treponemes divide slowly and penicillin acts only on dividing cells, it is necessary to maintain serum levels of penicillin for many days (Table 327-4).

Early Infectious Syphilis

Early syphilis (<1 year) can be treated with a single injection of 2.4 million U of benzathine penicillin G, which provides low but effective serum levels for more than 2 weeks and cures approximately 95% of patients. It is not necessary to examine CSF at this stage because penicillin prevents the later development of neurosyphilis.

Individuals with other sexually transmitted diseases may have been exposed to syphilis at the time they became infected. Treatment with a single dose of β-lactam antibiotics (penicillins, cephalosporins), which provide relatively high serum levels for a brief period, is ineffective in established early syphilis but is curative if the disease is still in the incubating stage. The ceftriaxone regimen used for gonorrhea (Chapter 307) is probably curative for incubating syphilis, but careful follow-up is indicated if there is reason to suspect exposure to syphilis in a patient treated for gonorrhea with ceftriaxone. Single-dose therapy with 2.0 g of azithromycin administered orally was as effective as benzathine penicillin therapy in several studies of early syphilis, but treatment failures have been reported in persons with coexistent HIV infection.[1] Currently, azithromycin should not be used for the treatment of early syphilis unless close follow-up can be ensured.

For patients allergic to penicillin, 100 mg of doxycycline orally twice daily for 14 days is recommended. Particularly careful follow-up is necessary for patients treated with drugs other than penicillin because they may not be fully compliant with these prolonged courses of oral therapy and these regimens have been less fully evaluated clinically. Ceftriaxone, given in doses of 500 mg to 1.0 g intramuscularly daily for 10 days, may be effective but has been studied only in small numbers of patients with syphilis. Quinolone antibiotics have essentially no effect on syphilis.

Syphilis of More than 1 Year's Duration

Prolonged therapy with intramuscular injections of 2.4 million U of benzathine penicillin G weekly for 3 weeks is recommended for the treatment of late latent syphilis and latent syphilis of unknown duration. Limited evidence suggests that treating latent syphilis with a total dose of 7.2 million U of benzathine penicillin over a 3-week period is curative, even if the patient has asymptomatic neurosyphilis. However, because of the possible lack of efficacy of benzathine penicillin G in some patients with CNS syphilis, CSF examination should be considered in those with latent syphilis to exclude asymptomatic neurosyphilis, particularly HIV-positive patients, in whom the prevalence of asymptomatic neurosyphilis is higher. Alternatively, a lumbar puncture can be performed at the conclusion of the follow-up period (2 years); if the CSF is normal, the patient can be reassured that neurosyphilis will not develop.

Larger doses of penicillin are recommended for persons with proven neurosyphilis (see Table 327-4). General paresis responds well to penicillin therapy if administered early, although progressive neurologic decline may develop later in as many as a third of treated patients. Carbamazepine in doses of 400 to 800 mg/day reportedly treats the lightning pains of tabes dorsalis effectively. Published studies show that a total of 6.0 to 9.0 million U of penicillin G results in a satisfactory clinical response in approximately 90% of patients with neurosyphilis who do not have HIV infection. There are anecdotal reports of increased treatment failures in patients with concomitant HIV infection, and there is considerable rationale to treat these patients with intravenous penicillin G (20 million U/day for at least 10 days). Therapy for neurosyphilis can result in increased CSF pleocytosis for 7 to 10 days after starting treatment and may transiently convert a normal CSF to abnormal.

Although there is no evidence that therapy with antimicrobial drugs is clinically beneficial in patients with cardiovascular syphilis, treatment is recommended to prevent further progression of disease and because approximately 15% of patients with cardiovascular syphilis have associated neurosyphilis. If patients are allergic to penicillin, it is mandatory that the CSF be examined before therapy is undertaken; if the CSF is abnormal, desensitization to penicillin is generally recommended. With a normal CSF, tetracycline (500 mg orally four times a day) or doxycycline (100 mg orally two times a day) taken for 4 weeks is probably effective.

Syphilis in Pregnancy

Because of the risk to the fetus, evaluation and treatment of a pregnant VDRL-positive patient must be rapid, particularly those first seen in the later stages of pregnancy. If a confirmatory FTA-ABS test is positive and the patient has not been treated, penicillin should be administered in doses appropriate for early or late syphilis, as outlined earlier. For penicillin-allergic patients, penicillin desensitization is preferred; patients should not be treated with tetracycline or erythromycin because of toxicity (tetracycline) or lack of efficacy (erythromycin). For patients who are VDRL positive but FTA-ABS negative and have no clinical signs of syphilis, treatment may be withheld; a quantitative VDRL test and another FTA-ABS test should be repeated in 4 weeks. If the VDRL titer has risen four-fold or more, or if clinical signs of syphilis have developed, the patient should be treated. If, after repeat examination, the diagnosis remains equivocal, the patient should be treated to prevent possible disease in the neonate. After treatment, a quantitative VDRL titer should be monitored monthly; if it rises four-fold, the patient should be treated a second time.

Congenital Syphilis

Proper treatment of the mother usually prevents active congenital syphilis in the neonate. However, infected infants may be clinically normal at birth, and the infant may be seronegative if the mother's infection was acquired late in pregnancy. The infant should be treated at birth if the mother has received no treatment or inadequate treatment or has been treated with drugs other than penicillin, if the mother has not yet responded to possibly effective therapy, or if the infant cannot be carefully monitored for several months after birth. The infant's CSF should be examined before treatment. If the CSF is normal, the child can be treated with a single intramuscular injection of 50,000 U/kg (up to 2.4 million U) of benzathine penicillin G. If the CSF is abnormal, the infant should be treated with 50,000 U/kg of aqueous penicillin G given intramuscularly or intravenously twice daily for a minimum of 10 days. Alternatively, a single daily intramuscular injection of 50,000 U/kg of procaine penicillin may be given for 10 days. Antimicrobial agents other than penicillin are not recommended for treating congenital syphilis.

Jarisch-Herxheimer Reactions

Up to 60% of patients with early syphilis and a significant proportion of patients with later stages of syphilis experience a transient febrile reaction after therapy for syphilis. The pathogenesis is unclear, but it may be caused by the liberation of antigens from spirochetes.

This reaction usually occurs in the first few hours after therapy, peaks at 6 to 8 hours, and disappears within 12 to 24 hours of therapy. Occasionally, Jarisch-Herxheimer reactions are mistaken for allergic reactions to syphilis therapy. Temperature elevation is usually low grade, and there is often associated myalgia, headache, and malaise. The skin lesions of secondary syphilis are frequently exacerbated during the Jarisch-Herxheimer reaction, and cutaneous lesions that were not visible may become visible. The reaction is generally

TABLE 327-4 PENICILLIN TREATMENT FOR SYPHILIS AS RECOMMENDED BY THE U.S. PUBLIC HEALTH SERVICE

	Dosage and Administration†	
INDICATIONS FOR SYPHILIS THERAPY*	**BENZATHINE PENICILLIN G**	**AQUEOUS BENZYLPENICILLIN G OR PROCAINE PENICILLIN G**
Primary, secondary, and early latent syphilis (<1 yr); epidemiologic treatment	Total of 2.4 million U; single IM dose of two injections of 1.2 million U in one session	Total of 4.8 million U IM in doses of 600,000 U/day for 8 consecutive days
Late latent (>1 yr) or when CSF was not examined in "latency"; cardiovascular syphilis, late benign (cutaneous, osseous, visceral gumma)	Total of 7.2 million U IM in doses of 2.4 million U at 7-day intervals over a 21-day period	Total of 9 million U IM in doses of 600,000 U/day over a 15-day period
Symptomatic or asymptomatic neurosyphilis	2-4 million U aqueous (crystalline) penicillin G IV q4h for at least 10 days	2-4 million U procaine penicillin IM daily and probenecid 500 mg orally four times daily, for 10-14 days
Congenital		
Infants	CSF normal: Total of 50,000 U/kg IM in a single or divided dose at one session	CSF abnormal: Total of 50,000 U/kg/day IM for 10 consecutive days‡
Older children	CSF normal: Same as for early congenital syphilis, up to 2.4 million U	CSF abnormal: 200,000-300,000 U/kg/day aqueous crystalline penicillin IV for 10-14 days

*In *pregnancy,* treatment depends on the stage of syphilis.
†Individual doses can be divided for injection in each buttock to minimize discomfort.
‡For aqueous penicillin, give in two divided intravenous doses per day; for procaine penicillin, give as one daily dose intramuscularly.
CSF = cerebrospinal fluid.

of no clinical significance and in most cases can be treated with salicylates. Corticosteroids have been used to prevent adverse effects of the Jarisch-Herxheimer reaction, but there is no evidence that they are clinically beneficial (other than reducing fever) or necessary. Institution of treatment with small doses of penicillin does not prevent the reaction.

PREVENTION

All patients with syphilis should be reported to public health authorities. In the absence of an effective vaccine, control of syphilis depends on finding and treating persons with infectious lesions of primary and secondary syphilis before they can transmit the disease, as well as finding and treating individuals with incubating syphilis before infectious lesions develop. All patients with early syphilis (primary, secondary, or early latent) should be carefully interviewed by qualified persons to determine the nature of their recent sexual contacts. Approximately 16% of the named recent contacts of patients with early syphilis are found to have active, untreated syphilis on examination, and a similar proportion of individuals named as suspects or associates also have active syphilis.

Treatment of the sexual contacts of patients with early syphilis with 2.4 million U of benzathine penicillin G intramuscularly is recommended even if the contacts are clinically and serologically normal on examination. This is because syphilis eventually develops in 30% of clinically normal contacts who are untreated. In general, preventive treatment is given to all sexual contacts in the past 90 days, although nearly all cases of syphilis in contacts develop within 60 days of exposure.

PROGNOSIS

Follow-up Examinations

All HIV-seronegative patients with early or congenital syphilis should return for quantitative VDRL titers and clinical examination 6 and 12 months after treatment. For HIV-positive patients, serologic tests should be repeated at 1, 2, 3, 6, 9, and 12 months. Patients with late latent syphilis should also be examined 24 months after therapy.

In about 85% of patients with early (i.e., primary, secondary, or early latent) syphilis, quantitative VDRL titers decline two or more dilutions (four-fold) by 6 and 12 months after therapy. Prolonged reactive VDRL test results are associated with higher initial VDRL titers, prolonged infection, more advanced stage (primary < secondary < early latent), or repeated infection. Chronic, low-titer VDRL reactivity after therapy is much more common in cases of late syphilis and should not be viewed with alarm. Treponemal tests may remain positive for years despite adequate therapy. A four-fold or greater rise in VDRL titer after therapy is sufficient evidence for repeat treatment. Patients with treated early syphilis are susceptible to reinfection, and many clinical and serologic relapses after therapy are probably reinfections. As such, they represent failures of proper epidemiologic case finding and preventive therapy for the patient's sexual contacts.

Patients with neurosyphilis should be monitored with serologic tests for at least 3 years and with repeat CSF examinations at 6-month intervals. CSF pleocytosis is the first abnormality to disappear, but cell counts may not be normal for 1 to 2 years. Elevated CSF protein levels fall even more slowly, followed by a change in the positive CSF VDRL test, which may take years to become negative. It is not known whether high-dose intravenous penicillin therapy accelerates the return of CSF to normal. Rising CSF cell counts, protein, and VDRL titer obtained at follow-up are an indication for repeat treatment.

Antibiotic therapy should ultimately cure essentially all patients with early or secondary syphilis, although treatment failures may occur in patients with concomitant HIV infection. In tabes dorsalis, penicillin usually arrests progression but does not reverse the symptoms. Meningovascular syphilis generally responds well, except for residual damage resulting from ischemic infarcts.

328

NONSYPHILITIC TREPONEMATOSES

EDWARD W. HOOK III

DEFINITION

The nonsyphilitic treponematoses—yaws, endemic syphilis (previously known as bejel), and pinta—are the spirochetal diseases caused by *Treponema pallidum* subspecies (yaws and endemic syphilis) or by the closely related organism *Treponema carateum* (pinta). Like syphilis, the nonsyphilitic treponematoses are usually transmitted through direct contact with an infectious cutaneous or mucosal lesion. The natural history of the nonsyphilitic treponematoses also has a number of similarities to that of syphilis (Chapter 327).

The Pathogen

Yaws is caused by *T. pallidum* subspecies *pertenue,* pinta is caused by *T. carateum,* and endemic syphilis is caused by *T. pallidum* subspecies *endemicum.* The *T. pallidum* subspecies causing nonsyphilitic treponematoses are closely related to *T. pallidum* subspecies *pallidum,* which causes venereal syphilis; there is a high degree of DNA homology, and they share unique pathogen-restricted antigens. Analyses of recently described genetic sequence variations among *T. pallidum* subspecies promise the eventual clarification of pathophysiologic differences among the subspecies, as well as answers to the age-old question of the origins of syphilis. Like *T. pallidum,* these treponemes are spirochetal bacteria with helical structures and measure about 0.2 µm in diameter and 10 µm in length. They are visible by dark-field microscopy but cannot be cultivated for prolonged periods in vitro.

EPIDEMIOLOGY

Worldwide, the nonsyphilitic treponematoses are rare. However, rates appear to be increasing (particularly for yaws) in some regions where previous World Health Organization (WHO)–coordinated control programs had dramatically reduced disease prevalence. Yaws is prevalent in moist, humid regions, including rural areas of tropical Africa, the Americas, Southeast Asia, and Oceania. The highest incidence occurs in children between 2 and 5 years of age. Endemic syphilis occurs in more arid climates, including Africa, eastern Mediterranean countries, the Arabian peninsula, central Asia, and Australia. Pinta occurs in rural areas of tropical Central and South America and affects mostly older children and adolescents. Humans are the only known carriers of the nonsyphilitic treponematoses. The spirochete enters the skin only after it is broken, such as by a scratch or an insect bite. Transmission is believed to occur by contacting the skin directly or by indirect contamination through hands or fomites; it is facilitated by conditions of poor personal hygiene and crowding.

PATHOBIOLOGY

Primary nodular or ulcerative lesions typically develop at sites of inoculation after an incubation period of several weeks. Untreated primary lesions serve as a source for local spread through scratching or for hematogenous dissemination, which gives rise to a secondary stage of infection characterized by the development of widespread manifestations involving the skin, lymph nodes, and bone or cartilage. Without therapy, the primary and secondary manifestations of infection resolve, and the infection becomes latent; however, periodic recurrent secondary manifestations may occur for several years. A proportion of persons with long-standing untreated infection are at risk for late sequelae, which may include bony deformity, destruction of nasal cartilage, or chronic skin changes. Unlike syphilis, the nonsyphilitic treponematoses are primarily diseases of children, are not transmitted across the placenta, and do not invade the central nervous system.

CLINICAL MANIFESTATIONS

Yaws, the most common nonsyphilitic treponematosis, produces a skin papule at the inoculation site after an incubation period of 3 to 4 weeks. The most common sites are the legs and buttocks. The papule enlarges, ulcerates, and forms a serous crust from which treponemes can be recovered. Regional lymphadenitis may accompany the papule, which heals spontaneously within

6 months. A generalized secondary rash occurs before or after the initial lesion heals; this rash is also papular and is often covered with brown crusts. Relapsing crops of lesions can occur. Papillomas may result, and the plantar surfaces of the feet are involved with hyperkeratotic lesions. Periostitis of the long bones leads to tenderness, and fever may be present. Relapsing lesions of early yaws may occur over a period of several years and result in chronic ulcerations and destructive gummatous lesions affecting the skin and bones.

Endemic syphilis produces patches on the mucous membranes of the oral cavity and pharynx and can cause split papules at the mucocutaneous junction of the oral angles. Anal, genital, and other intertriginous skin areas can be affected by lesions that resemble secondary syphilis. Regional lymphadenitis is common, and generalized rashes are rare. Healing of these early lesions is followed by latency, manifested as seropositivity, or by late lesions that resemble gummatous tertiary syphilis. Lesions include nodular skin ulcers, bone deformities, and ulcerative lesions that can perforate the palate.

Pinta starts similarly as a cutaneous papule with regional lymphadenitis, followed by a generalized maculopapular eruption. One to 3 years after healing of the initial lesion, large hyperpigmented brown or blue macules develop; they subsequently lose their pigment and become white. The time required for lesions to pass through these stages varies, so the same patient may have coexisting areas of increased pigment and loss of pigment.

DIAGNOSIS

The clinical differentiation of the nonsyphilitic treponematoses from one another and from syphilis may be challenging, requiring the integration of epidemiologic features, clinical findings, and supportive but not diagnostic laboratory test results. The skin lesions of the endemic treponematoses may resemble other cutaneous processes, including impetigo (Chapter 447), cutaneous fungal infections (Chapter 446), and other diseases. By dark-field microscopy, the causative spirochetes from early skin lesions can be observed directly. There is no specific test for any of the nonsyphilitic treponematoses, but serologic tests for syphilis detect cross-reacting antibodies in these diseases. The rapid plasma reagin (RPR) test, the Venereal Disease Research Laboratory (VDRL) test, and the fluorescent treponemal antibody absorption (FTA-ABS) test, as well as other specific treponemal tests, give positive results if serum is obtained at least 2 weeks after the lesions initially appear.

PREVENTION

The prevalence of these diseases was reduced in the 1950s by mass penicillin treatment campaigns in areas where they were prevalent. The WHO treated about 53 million cases of yaws and 350,000 cases of pinta in the 1950s, with good results. These campaigns, however, were not adequate to eradicate the disease, and in recent years, the prevalence of yaws has increased, with foci of infection now reported in sub-Saharan Africa; several Pacific islands, including Indonesia; and the Amazon region of South America. Current estimates are that as many as 2.5 million persons are infected worldwide, 75% of whom are younger than 15 years. Although penicillin is effective for the prevention of infection in exposed persons, it has been suggested that reduction in transmission requires improvements in sanitation and in the economic standards of people living in endemic areas.

TREATMENT AND PROGNOSIS

Rx

Single-dose, long-acting benzathine penicillin G, 1.2 million U intramuscularly, is the preferred treatment in patients with early lesions. For patients with late manifestations, this therapy should be repeated twice at approximately 7-day intervals. The early lesions heal rapidly, and most seropositive cases convert to seronegative status. Late destructive lesions take longer to show improvement.

329

LYME DISEASE

GARY P. WORMSER

DEFINITION

Lyme disease (also known as Lyme borreliosis) is a zoonotic infection transmitted by certain *Ixodes* tick species and caused by a group of related spirochetes referred to formally as *Borrelia burgdorferi* sensu lato or, more simply, as Lyme borrelia. Lyme disease was first described in 1977 following the investigation of a cluster of cases of arthritis among children living in the area of Lyme, Connecticut. With more than 25,000 cases reported annually, it is the most common vector-borne infection in the United States; Lyme disease is also an infection of public health importance in both Europe and Asia. The most common clinical manifestation is a characteristic skin lesion called erythema migrans. This lesion is a result of inflammation associated with the centrifugal spread of the spirochete within the skin from the site where the tick deposited the microorganism. The spirochete may also spread hematogenously to other skin locations, resulting in secondary erythema migrans skin lesions, or to nonskin sites such as the joints, nervous system, or heart, leading to a variety of extracutaneous clinical manifestations.

The Pathogen

In the United States, the only species of Lyme borrelia known to cause human infection is *B. burgdorferi* (also referred to as *B. burgdorferi* sensu stricto). Although *B. burgdorferi* also causes Lyme disease in Europe, collectively, other species of Lyme borrelia that can be distinguished genotypically account for the majority of infections there, especially *Borrelia afzelii* and *Borrelia garinii*. The fact that at least six species of Lyme borrelia cause infection in Europe has created serodiagnostic challenges and accounts for a wider variety of clinical manifestations there than occur in the United States (see later). *B. garinii* appears to be the most neurotropic and *B. burgdorferi* the most arthritogenic among the species of Lyme borrelia.

Lyme borrelia are motile, microaerophilic, spirochetal bacteria with 3 to 10 loose coils arranged in a helical shape. The cells are 10 to 30 µm long and 0.2 to 0.5 µm wide and contain at least seven periplasmic flagella that are responsible for the organism's motility. Borrelia are too thin to be seen by Gram stain, but live organisms can be visualized by dark-field or phase-contrast microscopy. In tissues they can be recognized by light microscopy after application of silver stains or by fluorescent microscopic methods. *B. burgdorferi* was the first spirochete for which the complete genome was sequenced. Genetic studies suggest the nearly complete absence of biosynthetic pathways, making the microorganism dependent on its environment for nutritional requirements. Lyme borrelia can be grown in vitro in a highly enriched culture medium.

EPIDEMIOLOGY

In the United States, more than 90% of human cases are concentrated in just 10 middle Atlantic, northeastern, and north-central states. New York and the nearby states of Connecticut, Pennsylvania, and New Jersey have the largest number of cases. *Ixodes scapularis* (also known as the deer tick or black-legged tick) is the tick vector in these 10 states. *Ixodes pacificus* is the vector for the cases that occur in the northwestern United States. Lyme disease also occurs in limited areas of Canada. Cases of Lyme disease occur throughout the temperate regions of Europe and are especially common in Scandinavia and the countries of central Europe such as Slovenia, Austria, and Germany. *Ixodes ricinus* transmits the infection in Europe, and *Ixodes persulcatus* is the vector in Asian Russia, China, and Japan.

The principal reservoirs for Lyme borrelia (i.e., the source of infection for ticks) in the United States and Eurasia are small mammals such as mice and certain species of birds. Deer play an essential role in the life cycle of the *I. scapularis* tick, but they are not a competent reservoir for *B. burgdorferi*.

Although Lyme borrelia exist in enzootic cycles in the southern United States, cases of Lyme disease arising indigenously have not been well documented in states south of Virginia. A skin lesion that resembles erythema migrans does occur in the southern United States, but it is associated with the bite of the *Amblyomma americanum* tick, a species that is not a competent

FIGURE 329-1. From left to right is an unfed nymphal stage *Ixodes scapularis* tick, a nymphal stage *I. scapularis* tick after about 48 hours of feeding, a nymphal stage *I. scapularis* tick after about 126 hours of feeding, and a sesame seed. The distance between the ruler marks is 1 mm. (Courtesy Kam Truhn, Fordham University.)

vector for *B. burgdorferi*. This condition, whose cause is unknown, is referred to as southern tick-associated rash illness (STARI).

The likelihood of acquiring Lyme disease is directly related to exposure to environments where infected ticks are present. Of the three feeding stages in the life cycle of *I. scapularis*, the second, or nymphal, stage is most important epidemiologically for the transmission of infection to humans. Ticks in the first, or larval, stage are uninfected and cannot transmit the infection because transovarian transmission of this spirochete does not occur. Although ticks in the third, or adult, stage are more likely to be infected with *B. burgdorferi* than those in the nymphal stage, they are less important in terms of transmission to humans because they are present in smaller numbers in the environment and there is less human activity outdoors during the periods in the spring and fall when the ticks are seeking blood meals. In addition, adult ticks are larger, and their bites cause more skin irritation than the bites of nymphal ticks, thereby increasing the likelihood that they will be noticed and detached by a person who has been bitten. If not removed, *Ixodes* ticks usually feed for at least 3 days (Fig. 329-1). Transmission of *B. burgdorferi* by *I. scapularis* or *I. pacificus* ticks is typically delayed for more than 36 hours from the start of the blood meal, providing the opportunity to prevent infection simply by finding and removing the tick. Transmission of *B. afzelii* by the European tick *I. ricinus* is considerably faster, often occurring within the first 24 hours of feeding.

Most cases of erythema migrans in the United States occur from June through August, coinciding with exposure to the nymphal stage of the tick. Like most tick-borne infections, there is a slight male predominance. There is a bimodal age distribution, with the highest incidences in children aged 5 to 9 years and in adults aged 55 to 59 years, but individuals of all ages are at risk. The reported incidence of Lyme disease in the United States is rising, partially as a result of an expansion of the deer population and the spread of infected *I. scapularis* ticks to new geographic areas.

Extracutaneous manifestations are somewhat less likely than erythema migrans to occur in June through August because the interval between infection and the onset of these manifestations is longer. Because adult *I. scapularis* ticks may become active on warm days during the winter, cases of erythema migrans occasionally occur in the colder months.

PATHOBIOLOGY

B. burgdorferi resides in the midgut of the *Ixodes* tick through attachment of its outer surface protein A (OspA) to the cells lining this site. With the onset of the blood meal, changes in pH, temperature, and probably other factors induce the spirochete to increase in number and undergo a sequence of phenotypic changes, including downregulation of OspA expression and upregulation of another outer surface protein, OspC. This series of events releases the spirochete from the midgut and permits its migration to the salivary gland. At that site, OspC binds Salp 15, a salivary protein induced during the blood meal in borrelia-infected ticks; this protects the spirochete from antibody-mediated killing and aids in transmission to a vertebrate host. *Ixodes* tick saliva also contains other components with anti-inflammatory and immunomodulatory effects that serve to promote infection with Lyme borrelia and other tick-transmitted pathogens. Expression of OspC by the spirochete in the mammalian host is essential for infection to be established; in some manner, this protein protects the microorganism from immediate elimination by the innate immune system.

The spirochete is deposited by the tick into the skin rather than directly into the blood stream. Hematogenous dissemination seems to be responsible for spread of the spirochete to other sites, but much remains to be learned about the precise properties of the microorganism-host interaction that enable this event to take place. One important factor is the strain of Lyme borrelia causing the infection. Unlike patients who are bacteremic with more conventional pathogens, patients with spirochetemia rarely appear septic. In one study, only 5% of 93 spirochetemic patients were febrile when the blood culture was obtained, and almost no one was found to have leukocytosis. The lack of fever and other clinical signs of sepsis may be due to the absence of lipopolysaccharide within the borrelial cell wall.

Infection of humans or animals elicits innate and adaptive immune responses resulting in both macrophage- and antibody-mediated killing of the spirochete. The inflammatory response in tissue typically shows an infiltration of lymphocytes, macrophages, and plasma cells, although granulocytes predominate in synovial fluid samples of Lyme arthritis patients. The potential for persistence of infection despite a robust humoral and cellular immunologic response is typical of infection with Lyme borrelia, as it is with *Treponema pallidum* infection. The virulence factors responsible for the persistence of infection include the spirochete's ability to downregulate the expression of certain immunogenic surface-exposed proteins, including OspC, and to rapidly and continually alter by recombination the antigenic properties of a surface lipoprotein known as variable major protein-like sequence expressed (VlsE). In addition, the ability of the spirochete to bind avidly to various components of the extracellular matrix may contribute to persistence.

All the objective clinical manifestations of Lyme disease are thought to be due to an inflammatory response to live spirochetes or to their undegraded antigens. Obliterative endarteritis has been seen histologically in synovial tissue, but its importance in pathogenesis is unclear. Lyme borrelia are not known to produce toxins. So far, the only role established for host genetic factors in humans is in the development of antibiotic-refractory Lyme arthritis, which is seen most often in patients with certain human leukocyte antigen (HLA) DR alleles, some of which coincide with those associated with rheumatoid arthritis.

CLINICAL MANIFESTATIONS

The clinical manifestations are often categorized as follows:

- Early localized infection, typically manifested by a single erythema migrans skin lesion, with or without viral infection–like symptoms, but without objective extracutaneous manifestations.
- Early disseminated infection, usually manifested by multiple erythema migrans skin lesions or by an objective manifestation of early neurologic Lyme disease or Lyme carditis.
- Late disease, usually manifested by arthritis but possibly including certain rare neurologic manifestations or the skin condition known as acrodermatitis chronica atrophicans.

Children and adults have similar clinical manifestations. The expected frequency of the various clinical presentations is well illustrated by a study of 313 cases of Lyme disease diagnosed in Wurzburg, Germany, over a 12-month period. In this series, erythema migrans by itself was seen in 89% of cases, early neurologic manifestations in 3%, cardiac manifestations in less than 1%, borrelial lymphocytoma in 2%, arthritis in 5%, and acrodermatitis chronica atrophicans in 1%. None of the patients had late neurologic Lyme disease. A similar distribution has been seen in recent case series in the United States, except for the absence of borrelial lymphocytoma and acrodermatitis chronica atrophicans. In earlier U.S. studies from the 1980s, a much higher proportion of patients had neurologic, cardiac, or joint manifestations. This may have been due to a bias of ascertainment in the older studies or to improved recognition and treatment of patients with erythema migrans more recently, thereby preventing the development of the extracutaneous complications that occur later.

Early Localized Infection

Single Erythema Migrans Skin Lesion

As indicated earlier, erythema migrans is by far the most common clinical manifestation of Lyme disease. Although the appearance of the skin lesion is often rather distinctive (Fig. 329-2), it is not pathognomonic for Lyme

FIGURE 329-2. Erythema migrans skin lesion on the posterior aspect of the right thigh.

TABLE 329-1 CLINICAL SYMPTOMS AND SIGNS PRESENT IN AT LEAST 20% OF PATIENTS WITH ERYTHEMA MIGRANS

	Percentage Exhibiting the Characteristic (95% CI)	
CHARACTERISTIC	**UNITED STATES**	**EUROPE**
Viral infection–like symptoms	65 (52-76)	37 (27-49)
Fatigue	47 (37-58)	—
Headache	36 (27-46)	20 (14-29)
Myalgias	35 (26-45)	—
Arthralgias	35 (25-46)	—
Fever	33 (23-43)	—
Stiff neck	31 (21-43)	—
Lymphadenopathy	22 (13-33)	—
Dysesthesia	20 (12-32)	35 (25-47)

CI = confidence interval.
Modified from Tibbles CD, Edlow JA. Does this patient have erythema migrans? *JAMA*. 2007;297:2617-2627.

disease. Erythema migrans appears 7 to 14 days (range, 3 to 30 days) after tick detachment and is characterized by an expanding, flat to slightly raised, erythematous skin lesion (usually ≥5 cm in diameter) that is round or oval in shape. The mark from the preceding tick bite can sometimes be identified at or near the center of the lesion and is called a punctum. Approximately 80% of patients in the United States with erythema migrans have a single skin lesion. Nonspecific viral infection–like symptoms or signs such as malaise, neck pain, headache, fatigue, migratory arthralgias, or chills and fever may be present (Table 329-1) but are more common in patients infected with *B. burgdorferi* or *B. garinii* than with *B. afzelii*. Prominent respiratory or gastrointestinal symptoms are highly atypical for Lyme disease. An acute febrile illness in the absence of a skin lesion or other objective clinical manifestation has been attributed to early Lyme disease, but the possibility of misdiagnosis is greater in this situation owing to the potential for false-positive serologic testing.

Erythema migrans skin lesions can vary in appearance. Some lesions (especially those of short duration) are nearly uniform in color, whereas others may show central clearing or have a target-like appearance. About 5% have a vesicular-pustular center. Erythema migrans on the lower extremities is sometimes purpuric. Erythema migrans lesions may be scaly when they are long-standing and fading or if topical corticosteroid creams have been applied. The most common locations include the thigh, back, shoulder, and calf. Lesions are often asymptomatic but can be mildly painful or pruritic, and tender regional lymphadenopathy may be present. The majority of U.S. patients with erythema migrans do not recall a preceding tick bite.

Certain signs and symptoms described in small numbers of patients with erythema migrans in early case series, such as hepatomegaly, splenomegaly, sore throat, conjunctivitis, or testicular swelling, may have been coincidental findings. There has been no microbiologic confirmation of borrelia infection at these sites.

Borrelial Lymphocytoma

Borrelial lymphocytoma is a rare cutaneous manifestation of Lyme disease that almost never occurs in the United States. It often presents at or near a preceding tick bite as a solitary bluish red swelling up to a few centimeters in diameter. The most common locations are the earlobe in children and the breast in adults. Histologic examination shows a dense polyclonal infiltration of the cutis and subcutis by predominantly B lymphocytes, frequently with germinal center formation. Histologic evaluation may be necessary to exclude malignancy for patients with suspected borrelial lymphocytoma at a location other than the earlobe.

Early Disseminated Infection

Multiple Erythema Migrans Skin Lesions

In the United States, approximately 20% of patients with erythema migrans have multiple skin lesions at the time of presentation. Secondary erythema migrans skin lesions can be smaller than 5 cm, do not have a punctum, and are usually not tender or pruritic. They arise from hematogenous dissemination to the skin rather than from additional tick bites.

Early Neurologic Lyme Disease

Within weeks to several months after infection, patients may develop neurologic manifestations, the most common of which are cranial neuropathy, particularly peripheral seventh nerve palsy, which may be bilateral; lymphocytic meningitis; and sensory (often painful) radiculopathy. Less common manifestations include mononeuritis multiplex (multifocal involvement of anatomically unrelated nerves) and brachial or lumbosacral plexopathies. A pseudotumor cerebri–like picture has occasionally been reported in children. The presence of a concomitant erythema migrans lesion or the patient's recollection of a recent lesion consistent with erythema migrans may be helpful diagnostically. Studies suggest that approximately 90% of children with Lyme meningitis in the United States have at least one of the following three findings: concomitant erythema migrans, cranial nerve palsy, or papilledema.

Cardiac Lyme Disease

Weeks to months after infection, patients may develop cardiac manifestations of Lyme disease, most often fluctuating degrees of atrioventricular heart block or other manifestations of a myopericarditis, which may cause complaints of lightheadedness, palpitations, dyspnea, chest pain, or syncope. Heart block is typically at or above the atrioventricular node. Erythema migrans is often but not invariably present concurrently. Valvular dysfunction is not known to occur, and chronic cardiomyopathy has only rarely been reported in Europe.

Late Lyme Disease

Lyme Arthritis

If patients with erythema migrans are not treated with antibiotics, approximately 60% will develop a mono- or oligoarticular arthritis at a mean time of 6 months after disease onset (range, 4 days to 2 years). In untreated patients, Lyme arthritis is characterized by intermittent attacks of synovitis that last for a few weeks to several months. One or two joints are involved at a time. Primarily large joints are affected, but there may be involvement of the temporomandibular joint, small joints, and periarticular sites. The most commonly involved joint is the knee. Baker's cysts may form and rupture. Joint swelling is often pronounced, but pain is usually relatively modest. Particularly in children there may be concomitant fever, but adults are often minimally symptomatic aside from the arthritis.

In about 10% of adult patients with Lyme arthritis in the United States, involvement of a large joint (almost always the knee) may persist despite appropriate antibiotic treatment. Erosion of cartilage or bone may develop in such cases.

Late Neurologic Lyme Disease

After months to years of infection, late neurologic manifestations may develop. These include encephalomyelitis, peripheral neuropathy, or encephalopathy. Because most patients with Lyme disease are now diagnosed and treated early in the course of infection, these more indolent forms of neurologic Lyme disease are quite rare.

In untreated patients, encephalomyelitis is monophasic and slowly progressive, mainly involving white matter. It is the most severe neurologic manifestation and is more common (though still infrequent) in Europe (where it

most often affects the spinal cord) than in the United States. Cerebrospinal fluid (CSF) examination typically shows a lymphocytic pleocytosis, a moderately elevated protein level, and a normal glucose level, with evidence of intrathecal production of antibody to borrelia. Magnetic resonance imaging of the affected part of the brain or spinal cord can demonstrate areas of inflammation, typically with increased signal on T2 and FLAIR imaging and enhancement following contrast administration.

In the United States, peripheral neuropathy typically presents as a mild, diffuse "stocking-glove" process. Patients typically complain of intermittent limb paresthesias and sometimes radicular pain. The most common abnormality on neurologic examination is reduced vibratory sensation of the distal lower extremities. Electrophysiologic studies show a patchy axonal neuropathy. Nerve biopsy shows axonal loss and small perivascular collections of lymphocytes without spirochetes. CSF findings are often normal, without evidence of intrathecal antibody production.

Encephalopathy is an imprecisely defined clinical entity characterized by mild abnormalities of memory and/or other cognitive functions that are demonstrable on either a careful mental status examination or formal neuropsychological testing. CSF examination may be completely normal or may show intrathecal antibody production, mild protein elevation, or a mild pleocytosis. Cranial imaging studies occasionally demonstrate focal areas of presumed parenchymal inflammation, but findings are usually normal.

Acrodermatitis Chronica Atrophicans

Acrodermatitis chronica atrophicans is a late skin manifestation of Lyme disease that is most commonly seen in women older than 40 years. This skin lesion develops insidiously several years after the initial infection, usually on the extensor surfaces of the hands and feet. Early lesions are characterized by a slight bluish red discoloration and doughy swelling. Histologic examination shows lymphocytes and plasma cells in the skin and sometimes in the subcutis, with or without atrophy. Initially unilateral, the lesion may later become bilateral. Over time, the edema resolves, and the skin atrophies. Nodules may develop over bony prominences. About two thirds of patients have an associated peripheral neuropathy of the affected extremity, manifesting primarily as local sensory loss.

Although presumably any species of Lyme borrelia can cause acrodermatitis chronica atrophicans, by far the most common etiologic agent is *B. afzelii*. Therefore, this manifestation is rarely seen in the United States.

DIAGNOSIS

General Laboratory Testing

White blood cell count, hemoglobin and hematocrit levels, and platelet count are usually normal in Lyme disease, unless coinfection with *Anaplasma phagocytophilum*, *Babesia microti*, or a tick-borne encephalitis virus is present (see later). Lymphopenia may be found in the absence of a recognized coinfection. In approximately 35% of patients with erythema migrans, abnormal liver function tests (particularly mild elevations of aspartate and alanine aminotransferase levels) are seen. The erythrocyte sedimentation rate may be modestly elevated in all stages of Lyme disease, but values greater than 80 mm/hour are distinctly uncommon.

CSF examination in Lyme meningitis typically shows a pleocytosis with greater than 90% lymphocytes, a modestly elevated protein level, and a normal glucose level. Synovial fluid examination in Lyme arthritis typically shows approximately 25,000 white cells/mm^3 (range, 500 to 110,000/mm^3), with a polymorphonuclear predominance.

Skin Examination

Erythema migrans skin lesions may go unnoticed owing to the absence of prominent local symptoms and their occurrence on parts of the body that are difficult for the patient to visualize. Therefore, a complete skin examination should be performed in any patient suspected of having early localized or disseminated Lyme disease. Erythema migrans is the only clinical manifestation sufficiently distinctive to allow a clinical diagnosis in the absence of a supporting laboratory test. Erythema migrans is diagnosed based on the characteristic appearance of the skin lesion in a person who lives in or recently traveled to a Lyme disease–endemic area. Owing to the short duration of infection at this stage, serologic assays for antibodies to Lyme borrelia are seldom positive and should be obtained only in atypical cases, followed by convalescent-phase serologic testing 2 to 4 weeks after obtaining the acute sample (Table 329-2).

TABLE 329-2 DIAGNOSIS OF LYME DISEASE

DIAGNOSTIC MODALITY	APPLICATION	COMMENT
Visual inspection	Erythema migrans	Usually seronegative at time of presentation
Two-tier serology with a positive IgM and/or IgG immunoblot	Lyme carditis	Look for concomitant erythema migrans
	Early neurologic Lyme disease	Intrathecal antibody may be detectable before serum antibody in Europe; PCR sometimes positive on CSF
	Borrelial lymphocytoma	Biopsy may be needed to exclude malignancy
Two-tier serology with a positive IgG immunoblot	Lyme arthritis	PCR often positive on synovial fluid
	Late neurologic Lyme disease	Intrathecal antibody positivity expected in Lyme encephalomyelitis
	Acrodermatitis chronica atrophicans	

CSF = cerebrospinal fluid; Ig = immunoglobulin; PCR = polymerase chain reaction.

Serologic Testing

For non–erythema migrans presentations of Lyme disease, the mainstay of laboratory diagnosis is two-tier serologic testing in which the first-tier test is usually a sensitive enzyme immunosorbent assay (EIA). If the EIA is positive or equivocal, separate immunoglobulin (Ig) M and IgG immunoblots are performed on the original serum sample. If symptoms have persisted for at least 4 weeks, the IgG immunoblot should be positive for the results to be interpreted as evidence of seropositivity. Untreated patients who remain seronegative for 6 to 8 weeks are unlikely to have Lyme disease, and other diagnoses should be pursued.

Omitting the first-tier EIA or interpreting the immunoblot using alternative criteria that are not evidence based can decrease the specificity of testing and is not recommended. False-positive results on the IgM immunoblot may be due to cross-reactive antibodies that arise from polyclonal B-cell stimulation. Probably the most common cause of false-positive results, however, is the overreading of nonspecific weak bands. Background rates of seropositivity, which may exceed 4% in highly endemic areas of the United States and may be even higher in Europe, can also confound the interpretation of seroreactivity. Therefore, a positive serologic test does not necessarily mean that the patient has active Lyme disease. The positive predictive value is most informative when the pretest probability based on clinical features is at least 20%. Serologic testing is not indicated in the routine follow-up of patients after treatment because either IgM or IgG borrelial antibodies can persist for many years in successfully treated patients.

Testing for borrelial antibody produced locally in the central nervous system (i.e., intrathecal antibody) may be helpful in the diagnosis of neurologic Lyme disease and has been reported to precede the detection of serum antibody in a minority of European patients. Positive tests for intrathecal antibody may persist, however, for long periods after successful antibiotic treatment.

Other Diagnostic Modalities

Culture for Lyme borrelia is not routinely performed or available to diagnose Lyme disease. It is unnecessary for patients with erythema migrans and too insensitive for patients with extracutaneous manifestations of Lyme disease. In contrast, polymerase chain reaction (PCR) for the detection of borrelial DNA is positive on synovial fluid specimens in up to 80% of untreated patients with Lyme arthritis, and a positive result supports this diagnosis in a patient who is IgG seropositive. The sensitivity of PCR in CSF tends to be much lower, however, and was only about 5% in a recent study of children from the United States with early neurologic Lyme disease. A negative PCR result on either type of fluid does not exclude Lyme disease.

Differential Diagnosis

Erythema Migrans

Tick-bite hypersensitivity reactions can be mistaken for erythema migrans, but these reactions occur within 48 hours of a tick bite, are usually pruritic,

and tend to wane within a few days. In contrast, erythema migrans skin lesions in untreated patients last for a median of approximately 4 weeks in the United States and even longer in Europe. Bacterial cellulitis rarely occurs at the most common sites of erythema migrans and does not demonstrate central clearing or a target-like appearance. Erythema migrans, unlike erythema multiforme, does not involve the mucous membranes, palms, or soles. STARI is the most likely diagnosis in patients with erythema migrans–like skin lesions who were bitten by an *A. americanum* tick or developed this lesion in the southern United States. Other conditions that can usually be readily distinguished include tinea (often pruritic, with a thin, raised, scaly border), nummular eczema (symmetrical pruritic lesions with a tendency to scale and crust), granuloma annulare (acral location, especially on the dorsum of hands and feet; relatively fixed in size and <5 cm in diameter), contact dermatitis (pruritic, with streaking along the area of contact and a vesicular component), urticaria (raised, pruritic, and usually <5 cm in diameter), fixed drug eruption (usually on the genitalia, hands, feet, or face and fixed in size), pityriasis rosea (multiple, moderately pruritic lesions with peripheral scale and relatively fixed in size), and spider bite (often very painful and necrotic with a central eschar).

Extracutaneous Lyme Disease

Included in the differential diagnosis of early neurologic Lyme disease is Bell's palsy. Even in highly endemic areas of the United States, other causes of seventh nerve palsy outnumber Lyme disease by a margin of three to one. Viral meningitis and mechanical radiculopathy may be confused with manifestations of early neurologic Lyme disease. Viral or other causes of myopericarditis may resemble cardiac Lyme disease. Many causes of synovitis might be considered in the differential diagnosis of Lyme arthritis, but the pattern of joint involvement, such as symmetrical small joint involvement in rheumatoid arthritis, is often distinctly different from that found in Lyme arthritis. Lyme encephalomyelitis may occasionally be confused with a first episode of relapsing-remitting multiple sclerosis or primary progressive multiple sclerosis. Testing for borrelial antibody in serum (and in CSF, for the last condition) usually suffices to differentiate these conditions from Lyme disease.

TREATMENT

Rx

In vitro studies have shown that Lyme borrelia are highly susceptible to tetracyclines, most penicillins, and many second- and third-generation cephalosporins. *B. burgdorferi* is resistant to certain fluoroquinolones, rifampin, and first-generation cephalosporins. Whether macrolides are active in vitro depends on the borrelial strain tested and the assay technique used. Although most manifestations of Lyme disease resolve spontaneously without treatment, antibiotic therapy may hasten resolution and prevent progression.

Oral antibiotic therapy is used to treat patients with erythema migrans (Table 329-3). Doxycycline, amoxicillin, and cefuroxime axetil are each highly effective and are the preferred agents for this indication. Macrolides such as azithromycin are somewhat less effective than other oral antibiotics and are not recommended as first-line therapy.

Among the first-line agents, only doxycycline is effective against *A. phagocytophilum* coinfection, and it is the only agent for which a prospective clinical trial demonstrated that just 10 days of treatment is effective.■ Doxycycline may cause photosensitivity, however, which is a concern because early Lyme disease occurs most commonly during the summer months; in addition, this drug is relatively contraindicated in children younger than 8 years and in women who are pregnant or breast-feeding. When erythema migrans cannot be reliably distinguished from community-acquired bacterial cellulitis, either cefuroxime axetil or amoxicillin/clavulanate potassium (Augmentin) is preferred because these antimicrobials are generally effective against both infections.

Within 24 hours of the initiation of antimicrobial therapy, up to 15% of patients treated for erythema migrans experience a Jarisch-Herxheimer–like reaction characterized by an increase in the size or intensity of erythema in the skin lesion and more intense viral infection–like systemic symptoms. Fever, if present, should resolve within 48 hours, and the skin lesion should resolve within 7 to 14 days. Other symptoms, such as fatigue or arthralgia, tend to improve but do not invariably resolve within this time frame, lasting for more than 3 months in one quarter of patients. Extending the initial course of treatment does not result in the faster relief of symptoms. Oral antibiotic therapy is also used as first-line treatment for the other cutaneous manifestations of Lyme disease and as the initial treatment for patients with Lyme arthritis.

The preferred parenteral agent for Lyme disease is ceftriaxone because it is highly active against Lyme borrelia in vitro, crosses the blood-brain barrier well, and has a long serum half-life, allowing the convenience of once daily administration. Alternative parenterally administered antibiotics are cefotaxime and penicillin. Parenteral antibiotic therapy is recommended for patients with late neurologic Lyme disease and those with cardiac Lyme disease who are admitted to the hospital for monitoring (see Table 329-3). Parenteral antibiotics are often given to patients with Lyme arthritis who have failed to respond to one or more courses of oral antibiotic treatment.

In the United States, parenteral therapy has been preferred for early neurologic Lyme disease, especially for meningitis and radiculitis, with oral therapy reserved for patients with uncomplicated seventh nerve palsy. Studies conducted in Europe, however, have provided convincing evidence that oral doxycycline is just as effective as ceftriaxone for any of the primary manifestations of early neurologic Lyme disease.■ Although the same may be true in the United States, studies are lacking. Other oral antibiotics such as amoxicillin have been used successfully to treat patients with uncomplicated seventh nerve palsy, but published data on efficacy are much more limited for these agents. Because seventh nerve palsy resolves with or without antibiotic treatment at identical rates, the primary reason to treat such patients is to prevent the subsequent development of complications, particularly Lyme arthritis.

The presence of either papilledema or sixth cranial nerve palsy may indicate the presence of increased intracranial pressure in patients with neurologic Lyme disease. The elevated pressure typically falls in response to antibiotic therapy, but other measures conventionally used to lower pressure may need to be considered in individual cases.

Symptomatic patients with cardiac Lyme disease and those with high-grade first-degree atrioventricular heart block (PR interval ≥300 msec) or second- or third-degree block should be hospitalized and closely monitored. Temporary cardiac pacing may be required. In treated patients, complete heart block generally resolves within 1 week, and lesser conduction disturbances resolve within 6 weeks.

Lyme arthritis typically responds to antibiotic treatment. Patients whose arthritis is improved but not resolved after an initial course of oral therapy can be re-treated with a second course of oral antibiotics, reserving parenteral antibiotic therapy for those without any significant clinical response. Approximately 10% of adult patients in the United States do not respond clinically to antibiotic therapy and are said to have antibiotic-refractory Lyme arthritis; this condition has been defined as persistent synovitis for at least 2 months after completion of a course of intravenous ceftriaxone (or 1 month after completion of two 4-week courses of an oral antibiotic), in conjunction with negative PCR testing on synovial fluid and synovial tissue, if available. Because these patients are no longer believed to be actively infected, they are customarily treated with nonsteroidal anti-inflammatory drugs, intra-articular injections of corticosteroids, or disease-modifying antirheumatic drugs. Arthroscopic synovectomy has also been used successfully in patients with this condition.

Pregnant patients with Lyme disease are generally treated similarly to nonpregnant patients, except that doxycycline should be avoided because of the potential adverse effects on both the fetus and the mother. No published data convincingly support a congenital Lyme disease syndrome.

Post–Lyme Disease Symptoms and Syndrome

The outcome of treatment in the vast majority of patients with erythema migrans is excellent. Studies show, however, that when questioned 6 months or longer after treatment of erythema migrans, approximately 5 to 15% of patients report purely subjective symptoms such as fatigue or musculoskeletal pain. These subjective symptoms are typically mild and may wax and wane in intensity. Patients with these complaints are said to have post–Lyme disease symptoms or syndrome, depending on the symptom duration and severity. The cause of these symptoms is currently unknown. Careful microbiologic evaluations have failed to find evidence of either persistent *B. burgdorferi* infection or coinfection with a second *Ixodes*-transmitted pathogen. Furthermore, re-treatment provides no measurable benefit or a benefit so modest or ambiguous that it is outweighed by the risks associated with antibiotic therapy. Therefore, symptomatic treatment is recommended for such patients. Two prospective studies conducted in Europe that incorporated healthy control groups have challenged the notion that such a syndrome even exists. In each of these studies, the frequency of unexplained subjective symptoms in the Lyme disease group was no higher than that in the control group at 6 months into follow-up.

Chronic Lyme Disease

The term *chronic Lyme disease* is poorly defined but widely used. In Europe, it has been used to refer to the objective manifestations that most authorities prefer to call late Lyme disease. Others have used the term to refer to patients with post–Lyme disease subjective complaints. Most often, the term *chronic Lyme disease* is used as a diagnosis for patients with persistent pain, neurocognitive complaints, and/or fatigue, without objective clinical or serologic

TABLE 329-3 RECOMMENDED THERAPY FOR ADULT PATIENTS WITH LYME DISEASE*

THERAPY	MANIFESTATION	DURATION (DAYS)
Doxycycline 100 mg PO bid *or* Amoxicillin 500 mg PO tid *or* Cefuroxime axetil 500 mg PO bid	Erythema migrans	14
	Borrelial lymphocytoma	14
	Acrodermatitis chronica atrophicans	21
	Lyme arthritis	28
	Lyme carditis—mild	14
	Cranial neuropathy†	14
Doxycycline 100 mg PO bid	Lyme meningitis or radiculopathy in Europe and possibly in U.S.	14
Ceftriaxone 2 g IV daily	Lyme arthritis that failed oral therapy	14-28
	Late neurologic Lyme disease	14-28
	Lyme carditis requiring hospitalization	14
	Lyme meningitis or radiculopathy in U.S.	14
Azithromycin 500 mg PO daily	Erythema migrans in a patient intolerant of doxycycline and β-lactam antibiotics	6-10

*Regardless of the clinical manifestations of Lyme disease, complete response to treatment may be delayed beyond the treatment duration. Relapse may occur with any of these regimens; patients with objective signs of relapse may need another course of treatment.
†Although any one of the first-line oral antibiotics appears to be effective in patients with cranial neuropathy, there is only limited experience in patients with a cranial neuropathy other than seventh nerve palsy or with agents other than doxycycline.
Modified from Wormser GP, Dattwyler RJ, Shapiro ED, et al. The clinical assessment, treatment, and prevention of Lyme disease, human granulocytic anaplasmosis, and babesiosis: clinical practice guidelines by the Infectious Diseases Society of America. *Clin Infect Dis.* 2006;43:1089-1134.

evidence of past or present *B. burgdorferi* infection. In this usage, the term is a misnomer and has become the latest in a series of postulated syndromes that attempt to attribute medically unexplained symptoms to particular infections.

Coinfections

Ixodes ticks may be coinfected with and transmit Lyme borrelia along with other pathogens such as *A. phagocytophilum; B. microti,* the primary cause of babesiosis; or a tick-borne encephalitis virus. The likelihood of coinfection is dependent on the particular species of *Ixodes* tick and on the geographic area. Thus, bites from *I. scapularis* ticks in certain areas may lead to the development of Lyme disease, human granulocytic anaplasmosis, or babesiosis as a single infection or, less frequently, as a coinfection. In addition, this tick species can very rarely transmit a Powassan-like encephalitis virus. In Europe, the most common coinfection is Lyme disease with tick-borne encephalitis virus infection.

Coinfection should be considered in patients from geographic areas endemic for these pathogens who present with more severe initial symptoms than are commonly observed with Lyme disease alone. This is especially true for those who have high-grade fever for more than 48 hours despite antibiotic therapy appropriate for Lyme disease, those who develop recurrent fever, and those who have unexplained leukopenia, thrombocytopenia, or anemia. Coinfection might also be considered when the erythema migrans skin lesion has resolved but there has been either no improvement or worsening of the viral infection–like symptoms.

Reinfection

Patients treated for early Lyme disease do not appear to develop an immunologic response that is adequate to protect against reinfection. Therefore, patients with erythema migrans may become reinfected at a different skin site if they are bitten by another infected tick. Reinfection has been well documented only in patients who were treated for early infection (nearly always erythema migrans), but not after late manifestations of Lyme disease such as Lyme arthritis. Clinical manifestations of reinfection appear to be similar to those of the primary infection.

PREVENTION

Lyme disease can be prevented by avoiding tick-infested environments and by covering bare skin and using tick repellents on skin and clothing when in such environments. The tick density around individual residences can be reduced by removing leaf litter, placing wood chips where lawns abut forests, applying acaricides to property, and constructing fences to keep out deer. Bathing within 2 hours of tick exposure has been shown to decrease the risk of Lyme disease. Daily inspections of the entire skin surface (including scalp) to remove attached ticks is recommended because of the grace period between tick attachment and transmission of *B. burgdorferi.* Removal is accomplished by grasping the tick as close to its mouth parts as possible with a forceps (or tweezers) and gently pulling it out. Clinical studies have demonstrated that without any other intervention, more than 96% of individuals who find and remove an attached *I. scapularis* tick do not develop Lyme disease, even in highly endemic geographic regions. If the tick is not found or removed, the probability of infection approaches the infection rate in the regional tick population (typically, >20% of nymphal stage *I. scapularis* ticks are infected in highly endemic areas of the northeastern and Midwestern United States).

Evidence shows that doxycycline chemoprophylaxis can further reduce the chance of developing Lyme disease after removing an *I. scapularis* tick. A single 200-mg dose of doxycycline was found to be 87% effective in preventing erythema migrans at the tick bite site.■ A single dose of doxycycline within 72 hours of tick removal should be considered for persons in highly endemic areas who are known to have been bitten by a nymphal or adult *I. scapularis* tick estimated to have been attached for at least 36 hours. Given the uncertain efficacy of a short course of amoxicillin in this situation, observation rather than chemoprophylaxis has been recommended for individuals in whom doxycycline is contraindicated. No vaccine is currently available to prevent Lyme disease in humans.

RELAPSING FEVER AND OTHER *BORRELIA* INFECTIONS

WILLIAM A. PETRI, JR.

DEFINITION

Relapsing fever is a spirochetal infection with bacteria of the genus *Borrelia*. There are two modes of transmission: epidemic louse-borne and endemic tick-borne relapsing fever. Disease is characterized by recurrent bouts of fever and spirochetemia separated by short fever-free periods.

The Pathogen

Members of the genus *Borrelia* are motile spirochetes that measure 0.5 μm in diameter and 5 to 40 μm in length. They are aerophilic and require

long-chain fatty acids for growth. Louse-borne relapsing fever is caused by *Borrelia recurrentis*. Tick-borne relapsing fever organisms are named after their tick vector and include the closely related species *Borrelia duttonii* (Old World) and *Borrelia hermsii, Borrelia turicatae*, and *Borrelia parkeri* (North America).

EPIDEMIOLOGY

Louse-borne epidemic relapsing fever is caused by *B. recurrentis* and is carried from person to person by the human body louse (*Pediculus humanus*). There is no animal reservoir. The spirochete lives in the louse hemolymph; infection is transmitted to humans when the louse is crushed on human skin and infective spirochetes penetrate the skin or mucous membranes. Epidemics have occurred during famines and at wartime when breakdown in sanitation favors the transmission of body lice. Louse-borne disease remains endemic in central and east Africa (Ethiopia, Somalia, Chad, and the Sudan) and in the South American Andes (Bolivia and Peru).

Tick-borne endemic relapsing fever occurs throughout the world and is transmitted to humans by *Ornithodoros* soft ticks. The ticks become infected by feeding on wild rodents (including mice, rats, squirrels, and chipmunks), which serve as natural reservoirs for the organisms. In the United States, relapsing fever is limited to humid, mountainous areas of the West at altitudes of 1500 to 8000 ft, where the tick vector *Ornithodoros hermsii* resides in forests of ponderosa pine and Douglas fir trees. A key diagnostic clue has been a history of sleeping in rodent-infested rustic cabins in western U.S. national parks. In Tanzania, where house infestation with *Ornithodoros* tick vectors can be very high, relapsing fever was identified in 11% of children seen at a clinic with fever.

PATHOBIOLOGY

Borrelia infection begins in the skin at the site of the louse or tick bite and is followed by rapid dissemination of the spirochetes through the blood stream. Spirochetes are visible on Wright-stained peripheral blood smears during the initial febrile episode and during each febrile relapse in most patients. The spirochete burden in blood positively correlates with symptom severity. Clearance of spirochetes from blood is associated with the production of serotype-specific immune sera; anti-*Borrelia* antibodies have been shown in animal models to be the major mechanism of immune clearance of infection.

Relapses are associated with cyclic antigenic variation in the variable major proteins (VMPs), which are the abundant outer membrane proteins of the spirochete that carry the serotype-specific epitopes. Antigenic variation is the consequence of recombination events that occur between VMP genes at silent and expression sites on linear plasmids. A single *B. hermsii* bacterium may produce as many as 40 distinct serotypes. Because spirochetes undergo one or several antigenic phases during infection, no specific or standard procedure has been developed for routine serodiagnosis of relapsing fever.

CLINICAL MANIFESTATIONS

An abrupt onset of fever (temperature >39° C in most patients), headache, myalgia, and shaking chills characterizes the onset of illness. Cough, nausea and vomiting, and fatigue are less frequent complaints. Signs include fever, tachycardia, lethargy or confusion, conjunctival injection, and epistaxis. Hepatosplenomegaly, jaundice, and often a truncal petechial rash are common signs in louse-borne relapsing fever. Neurologic findings may occur, including meningitis, meningoencephalitis, and facial palsy, although these entities are more common with tick-borne relapsing fever. Untreated louse-borne disease lasts 6 days, and relapses occur once after an afebrile period of 9 days. The initial illness of tick-borne relapsing fever lasts about 4 days without antibiotic treatment, with an average of two relapses (each after an average 10-day afebrile period) before the diagnosis is made.

Relapsing fever in pregnancy can cause placental damage and intrauterine growth retardation and results in miscarriage in a third of patients. Neonatal infection by both the tick- and louse-borne forms is accompanied by jaundice, hepatosplenomegaly, and often sepsis and hemorrhage. Fever and hepatosplenomegaly are also common signs in children.

DIAGNOSIS

The diagnosis should be considered in patients with fever who are returning from a stay in cabins in the mountainous and high-elevation areas of the western United States. Only a few patients will remember tick exposure because *O. hermsii* is a night feeder, has a painless bite, and remains attached for only 15 minutes. Internationally, relapsing fever can occur sporadically wherever dwellings are infected with *Ornithodoros* ticks, as well as in epidemics with louse-borne disease.

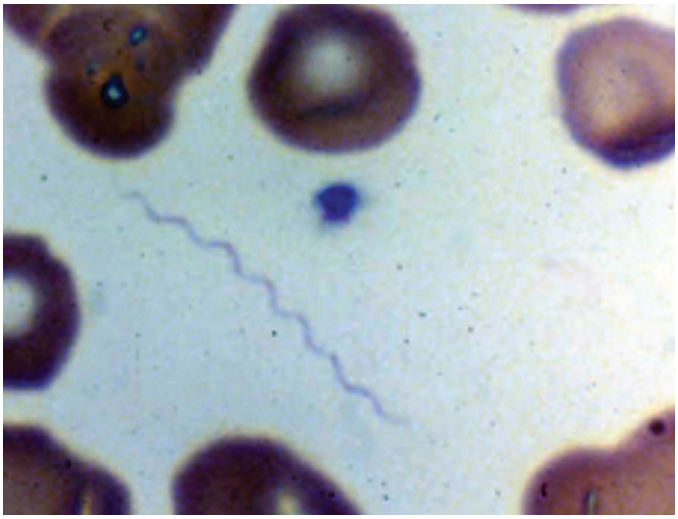

FIGURE 330-1. A single spirochete is seen in a Wright-stained thin blood smear from a patient with relapsing fever.

Because the number of organisms in blood is extremely high, the diagnosis is most often made by direct visualization of the organism in a blood smear (Fig. 330-1), although the diagnosis can also be made with polymerase chain reaction and serodiagnostic tests. Spirochetes can be demonstrated in peripheral blood smears taken during febrile episodes in 70% of patients. Additional sensitivity may be gained by examination of a buffy coat preparation of peripheral blood. Because of their characteristic locomotion, spirochetes can be readily detected by direct visualization of thick blood films under low-power microscopy. Culture of the organism requires a special medium and is not practical in a clinical laboratory setting. The white blood cell count is generally normal, but platelet counts of less than 50,000/mm^3 occur in up to 90% of cases of louse-borne disease. The prothrombin and activated partial thromboplastin times are often prolonged. In louse-borne disease, elevations in liver function test results (serum transaminases and bilirubin) and blood urea nitrogen are common. Urinalysis may reveal proteinuria and microscopic hematuria. Examination of cerebrospinal fluid may show a lymphocytic pleocytosis, and spirochetes may be directly visualized.

TREATMENT

Rx

Borrelia is generally quite sensitive to antibiotics, which has led to recommendations for single-dose treatments. Although this may be sufficient, especially for louse-borne disease, recent reports suggest that silent, residual infections occur and may best be addressed by longer treatments. For tick-borne relapsing infection, treatment duration should extend for 7 days to reduce the risk for persistent infection. Tetracycline, doxycycline, and erythromycin are all effective antibiotics. Erythromycin should be used in pregnant women and children younger than 7 years (in whom tetracyclines can stain the permanent teeth). Penicillin treatment has been reported to clear the spirochetemia more slowly than tetracycline does.

The Jarisch-Herxheimer reaction (typically characterized by a rise in body temperature of 1° C, rigors, a rise in blood pressure followed by a fall, and transient leukopenia) occurs 2 to 3 hours after treatment in many patients with louse-borne disease, less commonly in tick-borne disease, and should be anticipated and managed supportively. Death as a result of shock from the Jarisch-Herxheimer reaction occurs rarely. The Jarisch-Herxheimer reaction has been associated with accelerated phagocytosis of spirochetes by neutrophils and transient elevations in tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), IL-8, and IL-10. In small numbers of patients with louse-borne relapsing fever, anti–TNF-α antibodies have been effective in prevention.

PREVENTION

Prevention of louse-borne relapsing fever hinges on improving hygienic conditions, delousing affected areas, and antibiotic treatment of patients and close contacts. Tick-borne relapsing fever can be prevented by reducing the risk of contact with rodents and ticks, including repair of structural flaws in

cabins and other residences so that rodents cannot nest in or around them, as well as spraying infested indoor environments.

PROGNOSIS

Epidemics of louse-borne relapsing fever have been reported, with mortality rates approaching 40%; as much as 5% of the mortality is related to Jarisch-Herxheimer reactions with treatment. Mortality from tick-borne disease is less than 5%. Autopsies of patients with louse-borne disease have documented intracranial hemorrhage, brain edema, bronchopneumonia, hepatic necrosis, and splenic infarcts.

331 LEPTOSPIROSIS

ALBERT I. KO

DEFINITION

Leptospirosis, which is a major zoonotic health problem in developing countries, has now been recognized as an emerging infectious disease in developed countries. Infection with *Leptospira* spirochetes occurs during contact with animal reservoirs or an environment contaminated with their urine. The clinical course of leptospirosis ranges from a mild acute febrile illness to life-threatening manifestations such as Weil's disease, which consists of the triad of jaundice, acute renal failure, and bleeding. Leptospirosis has also been recognized as an important cause of pulmonary hemorrhage syndrome worldwide.

The Pathogen

The etiologic agent, which can be identified by darkfield microscopy or silver staining procedures, is a motile spirochete 6 to 20 μm in length and 0.1 μm in diameter (Fig. 331-1). Leptospires are obligate aerobes whose relatively large genome (two chromosomes of approximately 4.3 megabase and 350 kilobase) reflects its ability to adapt to external and host environments. *Leptospira* are classified into 20 species and genomospecies, of which 9 (*L. interrogans, L. kirschneri, L. noguchii, L. weilii, L. borgspetersenii, L. santarosai, L. alexanderi, L. alstonii,* and *L. kmetyi)* are pathogenic and 5 (*L. wolffii, L. inadai, L. fanei, L. broomii,* and *L. licerasiae)* are considered intermediately pathogenic. Serologic classification provides more useful information because serogroups and serovars, of which there are more than 25 and 250, respectively, are associated with specific animal reservoirs and vary with respect to their ability to cause severe disease in humans.

EPIDEMIOLOGY

Leptospirosis has a worldwide distribution because of the broad spectrum of animal reservoirs that support persistent renal carriage of pathogenic *Leptospira* spp, including domestic and wild rodents, dogs, pigs, cattle, and sheep. Leptospires colonize the renal tubules, are excreted in urine, and survive for weeks to months in the environment. Transmission to humans occurs when leptospires penetrate the skin or mucous membranes during contact with contaminated water, soil, or vegetation. Abrasions in the skin facilitate entry of the pathogen. Direct contact with urine and tissues is an important mode of transmission in risk groups such as abattoir workers and veterinarians. Ingestion of contaminated food, inhalation of aerosolized droplets, or swallowing of contaminated water, as occurred during a 1998 outbreak among triathletes, occasionally causes infection. Humans are accidental hosts and do not serve as reservoirs because sufficient concentrations of viable organisms are not excreted in urine. Rare human-to-human transmission is associated with transplacental infection and breast-feeding.

Leptospirosis is a major public health problem in developing countries, especially in tropical areas, where it is an endemic disease among subsistence farmers, sharecroppers, and livestock herders. Furthermore, it is the cause of large epidemics in urban slums, where inadequate sanitation favors rodent-borne transmission. Although leptospirosis has traditionally been a sporadic occupation-related disease in developed countries, it has emerged to become a health problem associated with travel, water sports, adventure racing, and recreation (white water rafting, swimming). Outbreaks frequently follow natural disasters, heavy seasonal rainfall, and flooding, as seen during the aftermath of hurricanes in the Caribbean and monsoons in Mumbai. Leptospirosis may also be an under-recognized problem in U.S. inner cities inasmuch as sporadic cases have been reported in this setting.

PATHOBIOLOGY

The development of leptospirosis and disease progression are determined by the virulence characteristics of the infecting strain, the dose of the infecting inoculum, and host susceptibility factors. Leptospires disseminate rapidly to all tissues shortly after infection by means of direct tissue penetration and hematogenous spread. The pathogen is resistant to the alternative pathway of complement activation and evades the innate host immune response during the early stages of infection. Symptoms develop 5 to 14 days after exposure, although the incubation period may vary from 2 to 30 days. Leptospires are cleared from the blood stream primarily by agglutinating antibodies, whose titers rise at the end of the early-phase "leptospiremic" illness, although more recent studies have shown that infection also induces an acquired cell-mediated response. The late-phase immunopathogenic process is responsible for the severe manifestations of the disease. *Leptospira* lipopolysaccharide and lipopeptides are potent stimulators of pro-inflammatory cytokines such as tumor necrosis factor-α, and these cytokines produce a septic shock–like picture. Leptospirosis activates the coagulation cascade. A recent study identified disseminated intravascular coagulation (DIC) (Chapter 178) in approximately 50% of hospitalized patients. However, this DIC is usually a milder and less prominent manifestation in leptospirosis than that observed in gram-negative sepsis. Damage to the vascular endothelium, which is a hallmark of severe leptospirosis, causes capillary leakage, hemorrhage, and in a subset of cases, vasculitis. The pronounced disturbances in hepatic and renal function are believed to be due to the toxic effects of products released from killed organisms because pathologic examination of tissues reveals mild inflammatory cell infiltrates and sparse intact leptospires. Although the immune response eventually eliminates the pathogen, leptospires may persist for prolonged periods in immunoprivileged sites, such as the anterior chamber of the eye and the renal tubules, and then may be shed in urine weeks after resolution of the illness.

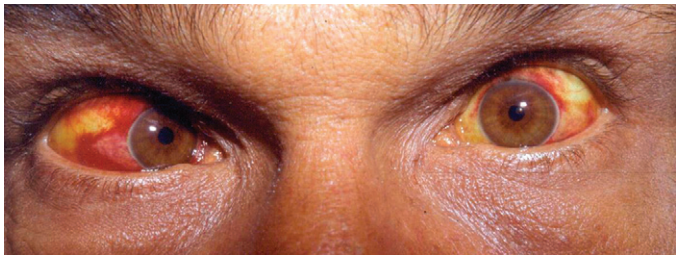

FIGURE 331-2. Conjunctival suffusion in a patient with Weil's disease. Conjunctival suffusion, a characteristic sign of leptospirosis, is best seen along the right upper palpebral border, above the subconjunctival hemorrhage. (Courtesy of Antonio Seguro and Paulo Marotto, Hospital Emílio Ribas and Universidade de São Paulo.)

CLINICAL MANIFESTATIONS

The clinical findings in early-phase leptospirosis (initial 3 to 7 days of illness) are nonspecific. The onset of high fever (temperature of 38 to 40° C), myalgia, and headache (retro-orbital and frontal) may be abrupt and accompanied by symptoms of nausea, vomiting, abdominal pain, diarrhea, cough, and photophobia. Muscle tenderness is pronounced, especially in the calves and lumbar region; if tenderness involves the abdominal wall musculature, it can mimic the symptoms of an acute abdomen. Rash, which occurs in 10 to 20% of patients, has erythematous macular, papular, urticarial, or purpuric components distributed in a truncal or pretibial ("Fort Bragg fever") pattern. Hepatomegaly, splenomegaly, and lymphadenopathy are less common (<20%) findings. Conjunctival suffusion, which is a characteristic manifestation seen in about 30% of patients, develops toward the end of early-phase illness and involves hyperemia of the conjunctival vessels along the palpebral fissures and chemosis (Fig. 331-2).

A minority (5 to 15%) of patients progress to severe late-phase disease. Jaundice is a poor prognostic sign because acute renal failure and hemorrhage are frequently associated complications (Weil's disease). Anicteric leptospirosis tends to be a milder late-phase finding characterized by prolonged fever and aseptic meningitis. Life-threatening complications are hypotension, hemorrhage, and renal and respiratory failure.

Leptospirosis causes nonoliguric, hypokalemic renal insufficiency, with impaired proximal sodium reabsorption, increased distal sodium delivery, and potassium wasting. As volume loss progresses, oliguric renal insufficiency develops as a result of prerenal azotemia and acute tubular necrosis. Acute renal failure occurs in up to 40 to 60% of patients with severe leptospirosis.

Severe thrombocytopenia and anemia secondary to hemolysis or blood loss are observed in up to 30% of patients. The prothrombin and partial thromboplastin times are normal or mildly elevated. Massive spontaneous gastrointestinal bleeding and pulmonary hemorrhage syndrome are major causes of death. Acute lung injury is a prominent feature of pulmonary hemorrhage syndrome but can occur in the absence of documented bleeding.

Cardiac involvement in the form of electrocardiographic (ECG) changes and myocarditis (Chapter 60) may be overlooked because overt pulmonary hemorrhage and hepatorenal manifestations tend to dominate the clinical picture in seriously ill patients. However, a recent autopsy study of 24 patients who had died of leptospirosis noted myocarditis in 96%, endocardial inflammation in 50%, and pericardial hemorrhage and inflammation in 12 and 29% of cases, respectively. Minor ECG changes have been seen in more than half of all patients. Conduction system abnormalities, such as first-degree atrioventricular block, represent the most common change attributable to myocarditis. Fatal myocarditis has been reported. Other late-phase findings include diffuse or focal interstitial pneumonitis and pneumonia, pancreatitis, and rhabdomyolysis.

Aseptic meningitis, which is the most frequent neurologic manifestation, is characterized by cerebrospinal fluid pleocytosis with early neutrophilic and late mononuclear cell predominance. Leptospirosis has also been reported to cause encephalitis, cerebral hemorrhage and arteritis (moyamoya disease), transverse myelitis, and cranial (Bell's palsy) and peripheral neuropathies.

DIAGNOSIS

Few clinical or laboratory findings differentiate early-phase leptospirosis from other causes of an acute febrile illness associated with myalgias and headache. Conjunctival suffusion is a highly specific, but insensitive clinical finding. The white blood cell count may be mildly elevated or normal in early-phase illness.

Severe leptospirosis is often recognized by the classic manifestations of Weil's disease, but severe complications may occur in anicteric disease. Furthermore, aseptic meningitis and uveitis may develop in patients with icteric leptospirosis, manifestations classically associated with anicteric disease.

Laboratory confirmation of leptospirosis is based on the presence of a four-fold rise in antibody titer in the microagglutination test (MAT) or isolation of pathogenic leptospires from a normally sterile site. However, these standard diagnostic methods provide only retrospective confirmation of the disease. MAT requires acute- and convalescent-phase sera and is performed routinely in few reference laboratories worldwide. A positive MAT titer of ≥1:100 from a single acute-phase sample provides suggestive evidence of leptospirosis but must be interpreted with caution in areas of high endemic transmission. Isolation of *Leptospira* requires specific media (Ellinghausen-McCullough-Johnson-Harris or Fletcher medium), and more than 4 weeks may be needed to identify a positive culture. Commercial anti–whole *Leptospira* immunoglobulin M detection kits in enzyme-linked immunosorbent assay or rapid formats are used to provide presumptive confirmation of leptospirosis. However, sensitivity is low (39 to 72%) during acute-phase illness. Polymerase chain reaction–based diagnostic methods have been developed, but their use has been limited to reference laboratory settings.

Differential Diagnosis

Leptospirosis is frequently confused with other causes of acute fever. Its diagnosis is particularly problematic in regions where dengue (Chapter 389) or malaria (Chapter 353) are endemic diseases. Severe leptospirosis must be differentiated from other causes of acute jaundice, renal and respiratory failure, and hemorrhage, such as viral hepatitis (Chapter 150); typhoid fever (Chapter 316); rickettsial disease (Chapter 335); hantavirus-associated hemorrhagic fever–renal syndrome (Chapter 389) and other viral causes of hemorrhagic fever; gram-negative sepsis; endocarditis; and autoimmune disorders. Icteric leptospirosis is associated with elevated serum conjugated bilirubin concentrations and can be differentiated from viral hepatitis by the finding of elevated serum creatine phosphokinase and mild elevations (<400 U/L) in transaminases. The finding of moderate to severe hypokalemia is useful in distinguishing leptospirosis from other infectious causes of acute renal failure. Leptospirosis-associated pulmonary hemorrhage syndrome is difficult to differentiate from the pulmonary manifestations caused by viral hemorrhagic fevers. The presence of massive pulmonary bleeding may increase suspicion for leptospirosis as the underlying cause because this finding is less frequently observed in patients with dengue hemorrhagic fever and hantaviral pulmonary syndrome.

TREATMENT

Rx

Antimicrobial therapy is efficacious for early- and severe late-phase leptospirosis. Mild leptospirosis is treated with oral doxycycline (100 mg twice a day) or ampicillin (500 mg every 6 hours) or amoxicillin (500 mg every 8 hours). Azithromycin (1 g followed by 500 mg once a day for 2 days) is not inferior to and is better tolerated than doxycycline but is more expensive and less readily available.[1] Severe leptospirosis is treated with intravenous penicillin (1.5 million units every 6 hours). Intravenous ceftriaxone (1 g once a day)[2] and cefotaxime (1 g every 6 hours) have equivalent efficacy as penicillin for severe leptospirosis; parenteral doxycycline (100 mg every 12 hours) is a satisfactory alternative.[3]

Other antimicrobial agents may have potential therapeutic use, although at present their efficacy is unproven. *Leptospira* organisms are susceptible in vitro to chloramphenicol and to quinolone and macrolide agents. The duration of antimicrobial therapy is usually 7 days. Although patients require monitoring for Jarisch-Herxheimer reactions during initiation of antimicrobial therapy, this complication is less frequently observed than with other spirochetal infections.

Reducing mortality from severe leptospirosis requires prompt triage of high-risk patients and aggressive supportive care for hypotension, acute renal and lung injury, and hemorrhage. Patients with nonoliguric hypokalemic renal insufficiency have a better overall prognosis and can be treated by volume and potassium repletion. Timely initiation of dialysis is critical to prevent mortality from oliguric renal insufficiency. Continuous hemofiltration is more effective than peritoneal dialysis in treating infection-associated acute renal failure. To date there is no evidence to indicate the use of pulse glucocorticosteroid and desmopressin in the treatment of severe leptospirosis.[4]

PREVENTION

Prevention of leptospirosis is based on controlling animal reservoirs, interrupting transmission routes, and preventing disease in humans. Control

measures that target defined animal populations, such as dogs, pigs, and cattle, are highly effective. Immunization of domestic animals and livestock may reduce carriage and transmission to humans. Chemical pesticides and environmental control of the habitats of domestic rodent reservoirs are important, but difficult to implement, especially in urban slum settings. Control of sylvatic reservoirs is often not feasible. When possible, environmental sources of transmission can be decontaminated with hypochlorite solution and isolated. Protective clothing such as gloves and boots reduces the risk for occupational exposure. Although infection after exposure to human urine has not been documented, precautions need to be taken when handling patients' secretions.

Doxycycline chemoprophylaxis (200 mg orally per week) may be efficacious in preventing clinical disease but does not reduce *Leptospira* seroconversion when used either as postexposure prophylaxis (e.g., in indigenous populations after a flood) or as pre-exposure prophylaxis (e.g., in indigenous populations or deployed soldiers).■ Doxycycline (100 mg orally twice a day for 3 to 7 days) or amoxicillin is used as chemoprophylaxis in situations where exposure to the pathogen has been documented (e.g., laboratory accident–related exposures); however, the efficacy of these regimens has not been evaluated. Bacterin-based vaccines have been used for high-risk groups in several countries and in mass immunization campaigns in Cuba and China; at present, however, the effectiveness and safety of these vaccines are uncertain.

PROGNOSIS

Although leptospirosis is usually a self-limited illness, mortality is high in patients with severe disease manifestations. Case-fatality rates in patients with Weil's disease and pulmonary hemorrhage syndrome are 5 to 40% and higher than 50%, respectively. Prognostic predictors for death are older age (>40 years), oliguria, respiratory insufficiency, pulmonary hemorrhage, cardiac arrhythmias, and altered mental status. Follow-up of patients has found that hepatic and renal function typically returns to baseline levels within 1 month and 6 months, respectively, after acute illness. However, unilateral or bilateral uveitis characterized by iritis, iridocyclitis, and chorioretinitis may develop up to 18 months after systemic illness and persist for years.

TUBERCULOSIS

JERROLD J. ELLNER

DEFINITION

Tuberculosis (TB) is a chronic necrotizing granulomatous disease caused by the acid-fast bacillus (AFB) *Mycobacterium tuberculosis* or the closely related species *Mycobacterium africanum* and *Mycobacterium bovis*. The most common site of disease is the lung, and the most common extrapulmonary sites are the lymph nodes, pleura, bones, and joints. TB is spread from person to person by the inhalation of infectious droplet nuclei aerosolized by patients with pulmonary TB (PTB). TB is a major cause of morbidity and mortality worldwide, but chiefly in resource-limited settings, and has eluded public health measures aimed at its control. The human immunodeficiency virus (HIV) pandemic has led to a resurgence of TB, and the global public health problem of TB has been compounded by increasing drug-resistant disease.

The Pathogen

TB is caused by infection with any of three members of the *M. tuberculosis* complex—*M. tuberculosis*, *M. africanum*, or *M bovis*. The complex also includes the nonpathogenic organisms *Mycobacterium microti* and *Mycobacterium canetti*. The causative organism is a slender, nonmotile, non–spore-forming, non–toxin-producing bacillus that may be beaded and is approximately 2 to 4 μm in length. It is a slow-growing (doubling time of 18 to 24 hours) facultative aerobe that can persist intracellularly for prolonged periods. The organism is identified in clinical specimens as an "acid-fast bacillus." The basis for "acid-fastness" is the waxy coat of the organism, which is composed of mycolic acid and other complex lipopolysaccharides. The organism takes up stain poorly but can be stained with carbol fuchsin by either alkalinization (Kinyoun) or heat (Ziehl-Neelsen) methods. The coat of *M. tuberculosis* precludes decolorization of the stain with a mixture of acid and alcohol. Virulent *M. tuberculosis* may clump or form "cords" in liquid culture.

DNA sequencing of *M. tuberculosis* and other scientific advances have promoted basic understanding of the metabolism and virulence of the organism, its immunodominant antigens, and its capacity to survive adverse conditions and persist intracellularly (Fig. 332-1). These advances have been translated into lead candidates for protective vaccines and targets for drug development. Clinical isolates of *M. tuberculosis* differ in their virulence in experimental models, potential for transmission in humans, and interaction with the host (immunopathology, induction of host cytokines, delayed-type hypersensitivity [DTH]). In the hypervirulent *Beijing* strain family, these differences have been ascribed to overexpression of a phenolic glycolipid that inhibits innate immunity.

A variety of typing systems have been applied to study the lineage of *M. tuberculosis*. Genomic deletion analysis shows six main phylogeographic lineages, each associated with a specific human population. The families differ in geographic distribution. It is not yet clear whether they also differ in their potential for transmission and pathogenesis. Strain typing can be performed by several techniques, such as restriction fragment length polymorphism (RFLP) of the insertional element IS 6110 or spoligotyping. Determining the DNA fingerprint of the causative organism is particularly useful in outbreak investigations. The finding that multiple cases of TB constitute a cluster and are caused by the same strain suggests that they may be epidemiologically linked. Identifying case clusters is important because it suggests recent transmission, possibly in the context of an outbreak.

TB caused by *M. africanum* is clinically identical to that caused by *M. tuberculosis*, and biochemical distinction between the organisms, though feasible, is therefore not generally useful. *M. bovis* has greater than 95% DNA homology with *M. tuberculosis* and can cause disease in humans, cattle, deer, badgers, and other animals. Most strains are resistant to the antituberculosis agent pyrazinamide (PZA). Therefore, the finding that an isolate that appears to be *M. tuberculosis* is monoresistant to PZA raises the possibility that it is, in fact, *M. bovis*, a distinction that can be confirmed only in specialized laboratories.

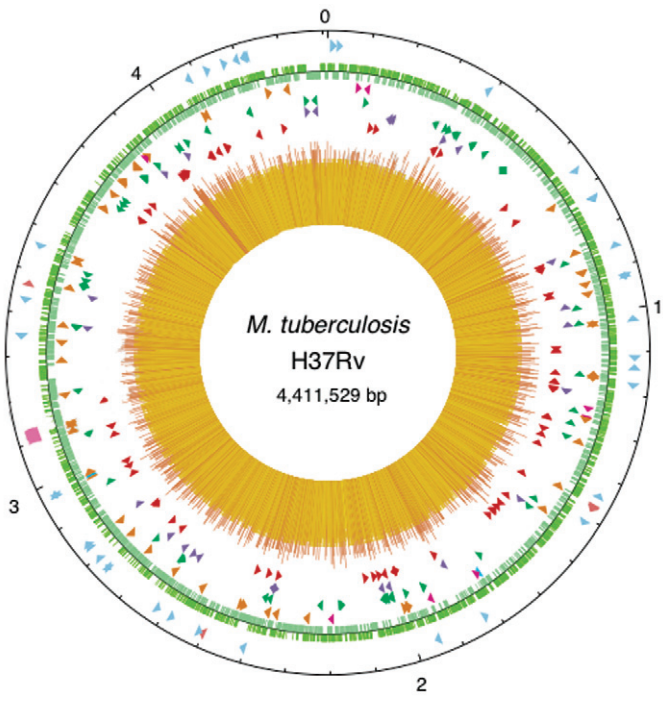

FIGURE 332-1. Circular map of the chromosome of *M. tuberculosis H37Rv*. The outer circle shows the scale in megabases, with 0 representing the origin of replication. The first ring from the exterior denotes the positions of stable RNA genes (tRNAs are *blue;* others are *pink*) and the direct repeat region *(pink cube)*, the second ring inward shows the coding sequence by strand (clockwise, *dark green;* anticlockwise, *light green*), the third ring depicts repetitive DNA (insertion sequences, *orange;* 13E12 REP family, *dark pink;* prophage, *blue*), the fourth ring shows the positions of the PPE family members *(green)*, the fifth ring shows the PE family members (*purple,* excluding PGRS), and the sixth ring shows the positions of the PGRS sequences *(dark red)*. The histogram *(center)* represents G + C content, with <65% G + C in *yellow* and >65% G + C in *red*. The figure was generated with software from DNASTAR. (Reprinted from Cole ST, Brosch R, Parkhill JH, et al. Deciphering the biology of mycobacteria and tuberculosis from the complete genome sequence. *Nature.* 1998;393: 537-544, with permission.)

The main route of transmission of *M. tuberculosis* is person to person through respiratory aerosols generated by coughing. Bacilli in small droplet nuclei (1 to 5 μm in diameter) remain suspended in air for long periods and, once inhaled, can reach the airways, where one to five organisms are sufficient to cause infection. Laryngeal involvement often renders the patient highly infectious with the possibility of transmission by phonation. Direct cutaneous inoculation ("prosector's wart") does occur, but direct transcutaneous inoculation from infected secretions is rare. *M. bovis* can be transmitted by the gastrointestinal route, usually through the ingestion of contaminated milk.

EPIDEMIOLOGY

In 2009 there were an estimated 9.4 million new cases of TB and 1.7 million deaths as a result of TB; 95% of the cases and 99% of the deaths occurred in resource-limited settings. Fifty-five percent of cases of TB occurred in Asia and 30% in Africa. The largest number of cases was in India and China. Worldwide, TB occurs more commonly in males than females, and the prevalence of disease peaks in young adults. HIV infection has a profound effect on the epidemiology of TB by accelerating the natural history of disease and promoting progression from infection to active TB. There are an estimated 1.1 million HIV-infected persons with TB worldwide, 80% of whom reside in sub-Saharan Africa. As a result, the highest case rates of TB are found in sub-Saharan Africa. TB is a leading cause of death in HIV-infected individuals.

In the United States in 2008, the incidence of TB was 4.2 per 100,000, with 12,904 cases reported. The age-specific prevalence of TB in the United States is skewed toward older adults; the case rate was 6.4 per 100,000 in adults older than 65 years versus 3.4 to 5.1 in 15- to 64-year-olds. Fifty-nine percent of cases occurred in the foreign born, most of whom emigrated with existing *M. tuberculosis* infection from areas endemic for TB. Asians had the highest incidence of TB (25.6/100,000). The countries of origin with the highest prevalence were Mexico, the Philippines, Vietnam, India, and China. California, Texas, New York, and Florida accounted for 49% of cases, and the prevalence is highest in inner-city areas. Approximately 10% of TB patients in the United States are infected with HIV. Overall, the prevalence of latent tuberculosis infection (LTBI) (defined as a positive tuberculin skin test [TST] or interferon-γ release assay [IGRA] and no active disease) is approximately 4%, and TB disease is more common in this group (12.9/1000 person years). Other conditions that increase the risk for TB are shown in Table 332-1. Smoking and alcoholism also confer an increased risk for TB, though smaller than the conditions listed.

TB caused by drug-resistant organisms is a particular and emerging threat to public health. Multidrug-resistant (MDR) TB (caused by organisms resistant to isoniazid [INH] and rifampin [RIF]) and extensively drug resistant (XDR) TB (MDR plus resistance to fluoroquinolones [FQs] and a second-line injectable—kanamycin, amikacin, or capreomycin) are much more difficult and expensive to treat and in some cases may be incurable. Resistant disease is more common in re-treatment cases of TB. An estimated 500,000 new cases of MDR TB occur annually, and 5 to 10% of these new cases are XDR. Twenty-seven countries account for 85% of the cases of MDR TB, with most occurring in India, China, and the Russian Federation. In the United States, MDR TB was found in 1.0% of new cases of TB, 76.7% of them foreign born, and in 4.2% of re-treatment cases, 88.2% of whom were foreign born.

PATHOBIOLOGY

Typically, the chain of transmission of TB begins with an infectious case of PTB. Infectiousness of a patient is determined by sputum smear status (3 to 4+ AFB), cough strength and frequency, the presence of cavitary lung disease, and the characteristics of the physical space occupied by the source (ventilation and air recirculation). However, not all strongly AFB smear–positive patients with PTB are equally infectious, and there may be high transmitters. Recent studies, in fact, show that only a third of strongly sputum smear–positive persons with PTB generate aerosols that contain viable organisms.

In both low- and high-prevalence countries, exposure often occurs in the household. Even in this setting, where exposure may be intense and protracted, only half of close contacts become infected. In contrast, in outbreaks in residential shelters, hospitals, and prisons, *M. tuberculosis* infection or disease has been documented after brief exposure. Important variables that may explain differences in transmission include virulence of the organism, innate immunity, and susceptibility of the exposed populations (e.g., HIV infected).

Occasionally, primary TB may be associated with minor clinical manifestations as described later. Two to 13 weeks after primary infection, specific adaptive immunity develops and limits bacterial replication. In this time interval, pleural TB may also occur. Infection is usually recognized by conversion of the TST from negative to positive or the development of a positive IGRA. Primary infection is accompanied by occult dissemination of *M. tuberculosis*, and host factors have a great impact on whether progressive primary TB develops, a condition that is most likely in infants younger than 4 years, who are at risk for TB meningitis and miliary TB, and in those with comorbid conditions. In approximately 40% of HIV-infected persons exposed to individuals with infectious TB, active TB will develop and occur in a compressed time frame (within 120 days). In otherwise normal hosts, there is an approximately 2 to 5% risk of primary infection progressing within the first 2 years to PTB. The risk may be higher if exposure to the index case is particularly intense. Granulomas are the focus of infection and the hallmark of primary TB infection and pleural effusion. Recent evidence suggests that granulomas, long thought to be a key element of protective immunity, may be responsible for local spread of the initial infection. The primary focus heals with fibrosis and possibly calcification. Pleural TB will also resolve without treatment, although there is an increased risk for reactivation.

Most (>95%) infected persons thereafter enter a period of clinical latency. During this period, latency is maintained by the active immune system. Evidence for such latency is the increased risk for reactivation TB once immunosuppression supervenes. In HIV-infected individuals, this risk may approach 5 to 10% per year. In addition, bacterial replication occurs during latency as evidenced by the fact that treatment of latent infection with INH and other agents active only in the growth cycle of replication markedly decreases the risk for reactivation. During the period of clinical latency, the TST and IGRA remain positive in most cases. In some there may, however, be reversion of the TST to negative. It is not clear whether this represents waning of the immune response to the tuberculous focus or a diminished number of replicating organisms.

TABLE 332-1 RISK FACTORS FOR TUBERCULOSIS

RISK FACTOR	RISK FOR RECENT INFECTION*	RISK FOR PROGRESSION OF INFECTION TO DISEASE	TST CUT POINT	TB CASES/1000 PERSON YEARS (TST+)	RELATIVE RISK—TST UNKNOWN
Household contact of person with PTB	X		≥5 mm	12.9	
Solid organ transplant recipients		X	≥5 mm		20-74

*Recent infection per se increases the risk for progressing from infection to disease (12.9 cases per 1000 person years in the first year vs. 1.6 per 1000 person years in the subsequent 7 years).
HIV = human immunodeficiency virus; PTB = pulmonary tuberculosis; TB = tuberculosis; TNF = tumor necrosis factor; TST = tuberculin skin test.

Delayed activation (termed *reactivation*) of TB may follow an overt immunosuppressive event or the development of comorbid conditions or occur without clear antecedent. Predisposing medical risk factors are considered in Table 332-1. Reactivation of TB in a host with preexisting immunity leads to a vigorous inflammatory response and, in the case of pulmonary disease, to the development of caseating granulomas and, ultimately, cavitary lung disease. Immunologically, reactivation TB is associated with transient systemic immunosuppression (and sometimes TST reversion) caused by two pro-inflammatory but immunosuppressive cytokines, transforming growth factor-β and interleukin-10. These cytokines are overproduced by activated circulating monocytes, regulatory T cells, or both.

The lung is the site of most cases of reactivation TB. The hallmark of the pathology is granuloma formation with caseation necrosis and multinucleated Langerhans giant cells. The caseous material contains AFBs. *M. tuberculosis* multiplies exuberantly in the liquid caseum. Immunologically, expectorated sputum contains cytokines and both upregulators and downregulators of the immune and inflammatory response, the latter being dominant. Bronchoalveolar lavage shows a lymphocytic alveolitis with an influx of immature macrophages, apparently representing monocytes attracted from blood. In sum, there is an active but downregulated immune response concomitant with bacterial replication. As a consequence of the inflammation, extensive apoptosis occurs and may lead to the deletion of *M. tuberculosis*–responsive T cells, a factor that may play a role in the requirement for a long duration of therapy and in the relapses that may represent reinfection TB. In HIV-infected persons with advanced immunosuppression, granulomas may be poorly formed or absent. There is infiltration with foamy epithelioid cells, which are actually macrophages laden with AFBs. Caseation may or may not be present, but there may be extensive inflammation and necrosis.

Extrapulmonary TB can involve any organ. Persistence of organisms in areas that are relatively well oxygenated has been cited to explain the more frequent sites of reactivation, such as the apices of the lung, cortices of the kidney, and vertebral bodies.

Several forms of extrapulmonary TB have a shared pathogenesis: discharge of a contiguous tuberculous focus into a serosal cavity, a brisk inflammatory reaction based on previous DTH, fever, frequently negative smears of exudative fluid for AFBs, and sometimes a transiently negative TST. The focus that discharges may be a long-standing focus or one seeded during recent dissemination during primary infection. This basic scenario occurs in pleural TB, TB pericarditis, TB meningitis (the parameningeal focus is called a "Rich focus"), TB peritonitis, and TB arthritis.

Pleural TB represents an in situ DTH reaction with activation of T_H1 helper T cells, abundant cytokines, including interferon-γ and tumor necrosis factor-α, and apoptosis. In non–HIV-infected individuals, organisms are sparse, which may be why self-cure of pleural TB can take place. However, in the absence of chemotherapy for TB, there is a high risk for recurrence of TB, usually as PTB on the side contralateral to the effusion.

In addition to reactivation of a latent focus, reinfection with *M. tuberculosis* may occur and progress to disease. Reinfection is more likely to occur if the host is immunosuppressed or there is repeated or intense exposure.

CLINICAL MANIFESTATIONS

Primary Tuberculosis

Most cases of primary TB are asymptomatic and diagnosed by conversion of the TST. There may be fever, shortness of breath, nonproductive cough, and occasionally erythema nodosum. Crepitations and focal wheezes may be present. Chest radiographs show small patchy opacities in the midlung fields, often with unilateral hilar lymphadenopathy. Upper or middle lobe collapse as a result of bronchial compression by enlarged nodes or transient pleural effusion may also be seen. This regresses without specific therapy because of the development of an adaptive immune response. During the subsequent period of clinical latency, evidence of the primary infection may be found as a small calcified parenchymal scar in the midlung fields (Ghon complex), sometimes associated with similar findings in the draining hilar nodes (Ranke complex) (Fig. 332-2A). Small scars caused by arrested lesions in the apices of the lung are called a Simon focus. Pleural TB may be a manifestation of primary or reactivation TB and is discussed later.

Progressive Primary Tuberculosis

Failure to develop adaptive immunity is most common in young children, the elderly and the immunocompromised. Progressive primary TB manifested as TB meningitis, miliary TB, or PTB may develop in this scenario. These syndromes are indistinguishable clinically, regardless of whether they are a manifestation of primary progressive or delayed reactivation TB, and are described subsequently.

Reactivation Tuberculosis

The terms *reactivation TB* and *postprimary TB* are used interchangeably to connote that primary TB is followed by a variable period of clinical latency, after which TB develops and occurs in the setting of DTH/adaptive

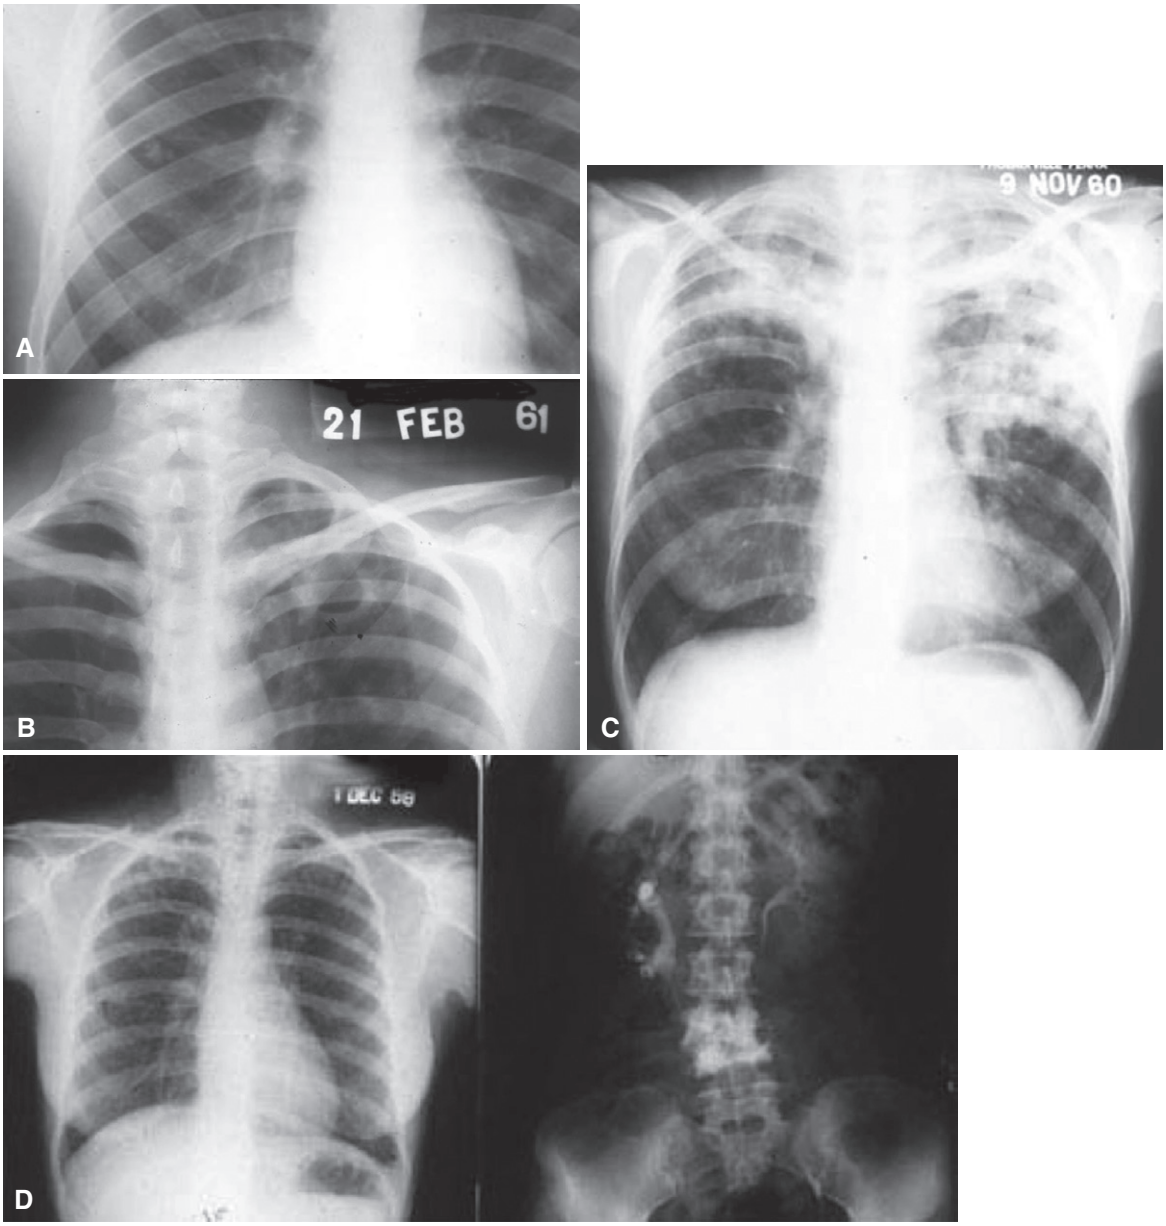

FIGURE 332-2. **A,** Ghon complex. **B,** Moderately advanced pulmonary tuberculosis. **C,** Far advanced pulmonary tuberculosis. **D,** Pulmonary and extrapulmonary tuberculosis. (Radiographs provided courtesy of Thomas M. Daniel, MD.)

immunity, which contributes importantly to the pathogenesis and clinical manifestations.

PTB is the most common form of reactivation TB. The typical findings consist of the insidious onset of a productive cough, night sweats, anorexia, and weight loss. Fever is present in approximately half of those affected. Patients may be asymptomatic and the diagnosis suggested by a chest radiograph obtained for other reasons. The sputum may be purulent, blood streaked, or frankly bloody. Pleuritic chest pain may occur when there is subpleural inflammation. Dyspnea is not a hallmark of PTB, in part because thrombosis of vessels limits the perfusion of inflamed areas, so hypoxemia is not a prominent clinical feature. Physical examination may show dullness to percussion, low-pitched amphoric (hollow sounding) breath sounds, and occasionally crepitations that may be post-tussive. Chest radiographs often reveal more disease than suggested by physical examination (see Fig. 332-2B and C). Typically, lesions are found in the apical and posterior segments of the upper lobes and the superior (dorsal) segment of the lower lobe. There is a progression from patchy opacities and consolidation to cavitation reflective of caseation, liquefaction, and rupture into bronchi. Intrabronchial spread may lead to disease in multiple areas, including the other lung ("TB bronchopneumonia"). There may also be involvement of the larynx and middle ear. Early cavities are thin walled. Ten percent of all cavities have an air-fluid level. There may be an associated pleural effusion or, with rupture of cavities into the air space, rarely pyopneumothorax. If the disease is minimal, it may best be seen on apical lordotic chest radiographs or on computed tomography (CT). Rarely, chest radiographs are normal and the accompanying symptoms and positive sputum smears may be the result of endobronchial lesions or rupture of a tuberculous node into bronchi. With healing, fibrosis and contraction obliterate small cavities, although large cavities may persist and even become the eventual nidus for an aspergilloma.

In immunocompromised persons, the opacities may be located in the mid and lower lung fields and be manifested as poorly resolving lobar or segmental pneumonitis, atelectasis, nodules, and cavities. Early in the course of HIV infection when the $CD4^+$ count exceeds 200/μL, PTB may be typical in its manifestation. At lower $CD4^+$ counts, mid and lower lung abnormalities are more common. At a $CD4^+$ count below 100/μL, the findings may be quite atypical, with prominent hilar and mediastinal adenopathy, pleural disease, interstitial or miliary opacities, or any combination of these manifestations. This picture resembles primary TB and, in fact, may represent progressive primary TB or reinfection disease. Chest radiographs are normal in up to 20% of persons with culture-confirmed TB, sometimes in the presence of a smear that contains AFBs. In this CD4 strata, disseminated and extrapulmonary disease is the rule, with or without concurrent PTB.

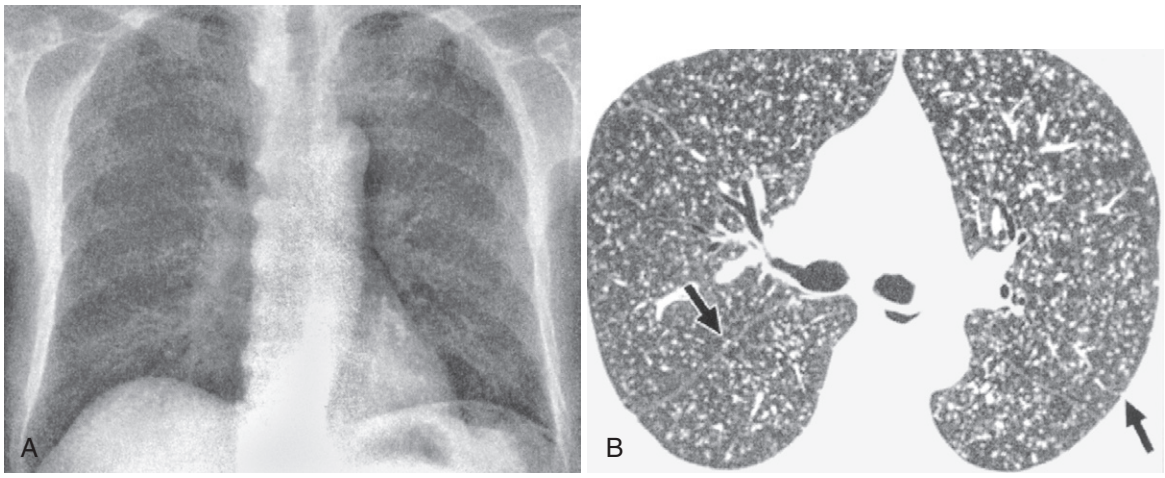

FIGURE 332-3. Miliary tuberculosis in a 70-year-old man. A, A posteroanterior chest radiograph shows evenly distributed, discrete, uniformly millet-sized nodular opacities in both lungs. **B,** High-resolution computed tomography (1.0-mm section thickness) at the level of the right upper lobar bronchus shows uniformly sized small nodules randomly distributed throughout both lungs. Note the subpleural and subfissural nodules (*arrows*). (From Jeong YJ, Lee KS. Pulmonary tuberculosis: up-to-date imaging and management. *AJR Am J Roentgenol.* 2008;191:834-844.)

Reinfection Tuberculosis

Reinfection TB is clinically indistinguishable from other forms. A shift in the drug susceptibility profile, a documented change in the DNA fingerprint, or occurrence in an outbreak setting may be the only evidence supporting the diagnosis of reinfection TB.

Extrapulmonary Tuberculosis

Approximately 20% of cases of TB in non–HIV-infected populations are extrapulmonary. In areas endemic for TB, extrapulmonary TB often occurs concurrently with PTB and is more common in children and young adults, in whom it represents progressive primary infection. By contrast, in low-prevalence areas, isolated extrapulmonary TB is more common and there is a shift to the elderly that represents reactivation TB. HIV infection is associated with a higher frequency of extrapulmonary disease, including the more serious forms disseminated TB and TB meningitis.

Pleural Tuberculosis

Pleural TB occurs by direct extension when a subpleural caseous focus discharges into the pleural space or through hematogenous seeding. There may be concurrent PTB. Its peak occurrence is 3 to 6 months after primary infection. The typical manifestation is the abrupt onset of fever, pleuritic chest pain, and cough. Occasionally, there is an insidious manifestation consisting of fever, weight loss, and malaise. If the pleural effusion is large enough, shortness of breath may be seen. Physical examination shows dullness to percussion and decreased breath sounds. Above the area of dullness there may be true egophony. Chest radiographs typically show unilateral pleural effusion, more frequently in the right hemithorax. Bilateral disease occurs in 10% of cases. Pleural effusions may be medium sized, large, or uncommonly massive.

Miliary Tuberculosis

Miliary TB usually has an insidious manifestation consisting of fever, weight loss, night sweats, and little in the way of localizing symptoms or signs. There may be concurrent TB meningitis with associated symptoms. Physical examination may show choroidal tubercles (pathognomonic raised white-yellow plaques on funduscopic examination, present in 15% of cases), lymphadenopathy, and hepatomegaly. Chest radiographs may show multiple bilateral small opacities, termed *miliary infiltrates* because of their resemblance to millet seeds. The findings on initial chest radiographs are often subtle and may be clear-cut only in retrospect after 3 months of follow-up. Performance of CT or high-resolution CT is useful because of its increased sensitivity (Fig. 332-3). A variant of miliary TB is "disseminated areactive TB," as may occur in HIV-infected patients or those treated with tumor necrosis factor inhibitors. In this entity, chest radiographic findings may be even more minimal. In the HIV infected with advanced immunodeficiency, blood cultures are positive for *M. tuberculosis* in 20 to 40% of patients and may be the only manifestation of TB.

Tuberculous Meningitis

TB meningitis is usually characterized by less than 2 weeks of fever, headache, and meningismus. There may be depressed levels of consciousness, diplopia, and rarely, hemiparesis. Physical examination shows a stiff neck and, occasionally, cranial neuropathy (VI, III, IV, VII in order of frequency) and long-tract signs. Chest radiographs may be consistent with PTB or miliary TB. CT of the head may show contrast enhancement over the basilar meninges, hypodense areas consistent with infarcts, hydrocephalus, and sometimes focal inflammatory lesions (tuberculomas).

Tuberculous Lymphadenitis

Lymphadenitis may be the sole manifestation of TB or, more frequently, particularly in the HIV infected, may accompany PTB. Patients with isolated lymph node disease may be afebrile. The supraclavicular and posterior cervical lymph nodes are most frequently involved. This is in contrast to scrofula from atypical mycobacteria or *M. bovis* and is often seen in children, in whom submandibular and high anterior cervical adenopathy predominates. The lymphadenitis is not usually painful, and aspiration of the lymph node with the finding of AFBs is an excellent approach to establish the diagnosis.

Tuberculous Pericarditis

The usual manifestation of TB pericarditis is chronic but may occasionally be subacute with fever, night sweats, chest pain, shortness of breath, pedal edema, and other signs of right heart failure. Physical examination shows signs of pericardial disease, right-sided heart failure, and tamponade (in about 10%). Pericardial aspiration and biopsy are the diagnostic procedures of choice. When tamponade is present, a pericardial window can be both diagnostic and therapeutic.

Tuberculous Peritonitis

TB peritonitis may be accompanied by abdominal pain and fever, at times mimicking an acute abdomen. Alternatively, there may be an insidious manifestation consisting of abdominal pain, swelling, night sweats, and weight loss. The clinical syndrome is caused by discharge of tuberculous lymph nodes into the peritoneal space. Exudative ascites is usually present unless TB is superimposed on preexisting transudative ascites, as in alcoholic liver disease. On physical examination the abdomen has been described as "doughy" because matted loops of bowel may be palpable. A variant of this syndrome is perhaps best termed *abdominal TB*. In this case the abdominal pain is subacute, the associated findings on physical examination less striking, and ascites less prominent or absent. The best method for diagnosis when ascites is present is laparoscopically guided peritoneal biopsy. In areas endemic for TB and HIV, the finding of intra-abdominal lymphadenopathy on abdominal ultrasound or CT is often used to support the diagnosis of abdominal TB.

Gastrointestinal Tuberculosis

Patients with gastrointestinal TB have fever, abdominal pain, and gastrointestinal bleeding or obstruction. Roentgenograms of the small bowel and abdominal CT show involvement of the terminal ileum, similar to Crohn's disease. The diagnosis is made on clinical suspicion in areas endemic for TB and HIV or by the finding of TB elsewhere. Occasionally, intraluminal biopsy

of the terminal ileum or other involved sites is used to establish the diagnosis.

Renal Tuberculosis

There may be few symptoms and signs associated with renal TB, although occasionally dysuria, hematuria, and flank pain are present. The diagnosis is often suggested by the finding of sterile pyuria or hematuria as initial abnormalities that trigger evaluation. Physical examination is usually unremarkable. Intravenous pyelography or CT shows cortical scarring, occasionally with mass or cavitary lesions, papillary necrosis with calyceal and ureteral dilation, or "beading" of the ureter because of ureteral strictures (see Fig. 332-2D).

Vertebral Osteomyelitis

The initial site of disease is the subchondral region of the anterior portion of the vertebral body. The lower thoracic and lumbar vertebrae are involved most commonly. The disc space is initially spared but becomes involved late with spread to adjacent vertebrae. Paravertebral "cold abscesses" may dissect through tissue planes. Patients have back and sometimes radicular pain. Occasionally and more often with cervical disease, there may be weakness of the lower extremities and incontinence of stool and urine. Physical examination may show a gibbus deformity caused by anterior compression fractures or paraparesis. Radiographs of the spine, as well as CT and magnetic resonance imaging, may show abnormalities in adjacent vertebrae with anterior compression (Fig. 332-2D). Cold abscesses may be appreciated as well.

Other Forms of Extrapulmonary Tuberculosis

TB of the bone or joints may be manifested subacutely as a combination of synovitis and osteomyelitis. The joints involved may have sustained previous trauma. TB of the female genital tract may result in pelvic pain, menorrhagia, vaginal discharge, or infertility. Males may have an epididymal mass, sometimes seen in patients with miliary TB. TB can cause granulomatous uveitis.

DIAGNOSIS

Infection with *M. tuberculosis*

The diagnosis of LTBI is one of exclusion based on the finding of DTH and the absence of active TB. The TST has been used widely and there is strong epidemiologic evidence supporting its interpretation. Tuberculin purified protein derivative (PPD) derived from autoclaved culture filtrates of *M. tuberculosis* is used to elicit DTH. The response elicited by PPD is nonspecific because of broad cross-reactivity among tuberculous and nontuberculous mycobacteria and other organisms as well. The TST is performed by injecting 5 tuberculin units of PPD in 0.1 mL intradermally. The reaction is assessed as induration after 48 to 72 hours. Problems with the TST are legend. It is the only bioassay used in clinical medicine, and there is no quality control of the application or reading of the TST. The sensitivity of the TST is less in immunosuppressed patients, such as those with HIV infection, and also less in the presence of active TB. The TST may revert to negative over time, and it may be boosted by the application of PPD. This can result in a "pseudoconversion" that does not represent new infection with *M. tuberculosis*. Perhaps the greatest limitation of the TST is its nonspecificity. There has been uncertainty in its interpretation, particularly in the setting of previous vaccination with *M. bovis* bacille Calmette-Guérin (BCG). BCG administered once at birth has little effect on the TST beyond the first year. By 10 years of age, only 1% of positive TSTs can be ascribed to previous BCG administration.

The TST remains of value in the diagnosis of LTBI in at-risk individuals (see Table 332-1) who are candidates for treatment (preventive therapy). Interpretation of the TST is based on a "sliding scale" that takes into account an individual's a priori risk for *M. tuberculosis* infection and the risk for progressing to disease, if infected (Table 332-1). This, in effect, modifies the sensitivity and specificity of the TST. It should be noted that routine testing is not recommended for low-risk populations; however, testing may be performed because of employment. Certain populations should undergo annual testing, including staff or individuals living or working in congregate settings (incarcerated, homeless, HIV infected, correctional facility staff), injection drug users, and others at risk because of sociodemographic factors. For individuals who will undergo an annual TST, a true baseline should be established by two-step skin testing. After the initial negative TST, the test is repeated in 1 to 3 weeks (there is no need to repeat the test if the first TST is positive). An increased reaction size on the second TST is defined as boosting and may be due to previous infection with nontuberculous mycobacteria or *M. tuberculosis* or vaccination with BCG. TST conversion from negative to positive is the best indicator of intervening new infection with *M. tuberculosis* and is defined as an increase in reaction size of 6 mm or greater from less than 10 mm to 10 mm or greater. It also may be of value to perform a two-step TST on individuals older than 60 years and therefore at risk for TST reversion.

In HIV infection, the TST may be negative before the administration of antiretroviral therapy (ART) and convert to positive with treatment. For this reason it is recommended that the TST be repeated in TST-negative HIV-infected persons once their $CD4^+$ count reaches 200/μL and annually thereafter.

The sensitivity of the TST is decreased in individuals with TB, more so in certain forms of extrapulmonary TB. Though insensitive for the diagnosis of active TB, the TST has another application in low-prevalence areas. If the differential diagnosis of a clinical condition includes TB, establishment of previous *M. tuberculosis* infection increases the likelihood that the clinical findings represent TB. The TST is of particular value in the evaluation of smear-negative patients with pulmonary disease suggestive of PTB and in patients suspected of having extrapulmonary TB. Confirmatory findings such as positive culture or histology or response to therapy are necessary to establish the diagnosis of TB.

IGRAs have also been approved for the diagnosis of LTBI, and the CDC considers them interchangeable with the TST. The main advantage of IGRAs is specificity because the antigens used to stimulate the production of interferon-γ are relatively restricted to *M. tuberculosis* and not present in BCG and most nontuberculous mycobacteria. IGRAs also require only a single patient visit. The disadvantages of IGRAs are expense, technical requirements, and controversy over test sensitivity in certain situations such as HIV infection and in household contacts of patients with PTB. The main indication for performing an IGRA, therefore, is to diagnose LTBI in a person who had received BCG vaccination beyond the first year of age. There are several other situations in which IGRAs may be useful. One would be confirmation of a positive TST. Another might be HIV infection. Because treatment of LTBI is effective in TST-positive HIV-infected persons and the risk for progression of infection is inordinately high in such individuals, it is important to perform tests with high negative predictive value. Therefore, both a TST and IGRA should be performed in HIV-infected persons and others at high risk of progression from infectious diseases or poor outcome. If either is positive, the individual would become a candidate for treatment of LTBI.

Active Tuberculosis

In countries with a high TB burden, the diagnosis of TB is often based on clinical symptoms and sputum microscopy. Clinical diagnosis without the benefit of culture confirmation or radiography is the norm in endemic countries where access to diagnostics is limited. The diagnosis is also made on clinical grounds alone when smears are negative and suspicion for TB is high. Cultures, if available, require several weeks to months, and the decision to begin therapy must be made promptly. Clinical diagnosis is particularly important in HIV-infected persons because of the risk for rapid progression of the TB if left untreated and in those with forms of TB that are paucibacillary (pediatric, meningeal, miliary, abdominal, pleural, pericardial). The diagnosis of miliary, abdominal, pleural, and pericardial TB may be confirmed by the finding of AFBs in biopsied tissue or by culture. In the absence of bacteriologic confirmation, either because cultures are negative or because they are unavailable, the final diagnosis often relies on response to therapy or establishment of an alternative diagnosis. It should be noted that the empirical approach, taken of necessity in resource-limited settings, leads to overdiagnosis and overtreatment of TB, which expends TB program resources and delays treatment of other infections. It is therefore preferable to attempt to establish a definite diagnosis based on demonstration of *M. tuberculosis* by smears, cultures, or nucleic acid amplification tests of infected secretions or tissue specimens.

Sputum microscopy is the standard approach to the diagnosis of PTB. A smear requires 1000 to 10,000 bacilli per mL to be read as positive. Both hot and cold carbol fuchsin methods (Ziehl-Neelsen and Kinyoun) are used extensively. The use of fluorochrome stains such as auramine-rhodamine allows more rapid screening of sputum smears. Three specimens, preferably early morning samples, should be examined to establish the diagnosis. Yield is higher in the presence of cavitary lung disease. Approximately half of individuals with PTB are AFB sputum smear negative, and this proportion is higher in the HIV infected. The quantity of AFBs present in the sputum smear is a measure of the infectiousness of patients with PTB, and on this

basis a second important role as a tool to monitor the potential for transmission and response to therapy has evolved for the sputum smear.

HIV-infected persons with PTB carry a particular risk for transmission to health care workers and have been documented as sources of nosocomial outbreaks. Therefore, in the United States, depending on the prevalence of TB, HIV-infected persons with pulmonary symptoms may be placed into respiratory isolation until infectious TB can be reasonably excluded by three negative sputum smears for AFB on specimens separated by at least 8 hours.

The diagnosis of pediatric TB has always been problematic. Children do not produce sputum readily, and TB is often noncavitary, extrapulmonary, or both. Sputum samples may not be readily obtained from infants and children. Options in this case include sputum induction and gastric aspiration. The sensitivity of AFB smears of gastric aspirates and induced sputum is 25 to 30%. Therefore, the diagnosis often is based on clinical and epidemiologic features as well as response to therapy.

Bronchoscopy with bronchoalveolar lavage or transbronchial biopsy is another option for the diagnosis of TB and is useful in all severely ill individuals in whom the diagnosis of TB or an alternative infection must be made quickly if treatment is to have an impact on patient outcome.

AFB smears should be performed on normally sterile fluid obtained from all patients suspected of having TB. The yield of smears from pleural fluid, pericardial fluid, ascitic fluid, and cerebrospinal fluid (CSF) is low in patients with TB but may be higher in those with HIV coinfection, particularly if immunodeficiency is advanced. In TB meningitis, CSF may clot spontaneously and AFB stains of the clot have increased yield. Rapid diagnosis of some forms of extrapulmonary TB may be made by biopsy of tissue (pleural, pericardial, peritoneal, synovial, terminal ileum); the presence of granulomas, particularly if necrotizing, virtually confirms the diagnosis. Necrotizing granulomas are seen in TB and in fungal diseases (particularly histoplasmosis, blastomycosis, coccidioidomycosis, and sporotrichosis). AFBs may also be seen in tissue histology and *M. tuberculosis* cultured from the specimen.

The diagnosis of miliary TB can be suggested by CT of the chest and confirmed by transbronchial lung biopsy (highest yield), as well as biopsy of the liver, bone marrow, or abnormal lymph nodes. If TB meningitis is suspected and the patient is immunosuppressed, it is particularly important to exclude cryptococcal meningitis by performing a cryptococcal polysaccharide antigen test, as well as an India ink preparation on CSF sediment.

The diagnosis of TB from specimens of normally sterile fluid can be difficult and is increased by culturing relatively large volumes. In addition, the yield of biopsy and culture of tissue (pleura, pericardium) is additive. There are particular diagnostic features for various forms of extrapulmonary TB. In TB meningitis, the initial CSF examination may show neutrophil predominance, but this evolves into a lymphocytic meningitis (100 to 500 cells/μL) with high protein and depressed glucose. TB of the pleura, pericardium, and peritoneum is associated with an exudative effusion, often with a lymphocyte predominance. In the words of Maxwell Finland, "The more lymphocytes the more likely it is TB." Low glucose may be found in 20% of TB effusions but limits the differential diagnosis considerably. For example, malignancy, empyema, and rheumatoid arthritis are the other causes of pleural effusion with low glucose. Pericardial fluid in patients with TB pericarditis may be bloody. Eosinophilic meningitis and chylous pleural effusions or ascites may also be seen in TB.

Currently, the "gold standard" for the diagnosis of TB is culture on solid (Löwenstein-Jensen) or in liquid (BACTEC MGIT 960 system) media. The MGIT system, which has replaced BACTEC, is nonradiometric and based on oxygen quenching in the presence of replicating mycobacteria. When compared with solid media, culture with liquid media is more sensitive and growth is more rapid (1 to 3 weeks vs. 3 to 8 weeks for solid media). Once an isolate is available, drug susceptibility testing should be performed to guide therapy. This takes an additional 2 to 4 weeks on solid media, although INH and RIF susceptibility results are available in several days when the molecular line probe assay described later is used. Liquid medium can be inoculated with smear-positive specimens for direct drug susceptibility testing, which also accelerates the process. Once mycobacterial growth occurs, speciation is possible within hours with commercially available DNA probes. Nuclear acid amplification tests are approved and commercially available for use in TB diagnostics. Their sensitivity is somewhat higher than that of AFB smears and their specificity is excellent. Expense precludes routine use of such tests, however.

There has been renewed commitment to develop rapid diagnostics for the detection of *M. tuberculosis* that have a sensitivity and specificity better than smear and approaching that of culture. As an example, the Xpert MTB-RIF was developed by Cepheid and recently approved for use in Europe. Through in situ DNA amplification reaction, this test allows a specific diagnosis of TB and determination of susceptibility to RIF within 90 minutes. After minimal processing, sputum is added to a cartridge. Gene amplification is done with primers based on the *rpoB* gene, which encodes the target of RIF, and resistance-conferring mutations are detected. This method is capable of establishing the diagnosis of TB in 97% of patients with PTB, including 99% of AFB sputum smear–positive and 90% of smear-negative individuals, thus rivaling the sensitivity of culture. It does not require molecular expertise by the technician and is not subject to amplicon (DNA) contamination because it is a closed system. There are numerous other candidate new diagnostics in various phases of development, mostly based on gene amplification, detection of bacterial constituents and antibodies to them, and host immune and inflammatory responses.

The development of new diagnostics also targets rapid determination of drug susceptibility. The Xpert MTB-RIF test described earlier is promising in this regard. The commercially available molecular line probe assay (Hain Genotype MTBDR plus) has been approved in Europe and is recommended by the World Health Organization. This assay is based on electrophoresis of bacterial constituents and probing for mutations in the targets of INH and RIF. The assay requires that the sputum smear be positive and that the technician be trained in molecular methods, and the results are available in several days. As noted earlier, it is also useful for rapidly establishing drug susceptibility once cultures are positive.

TREATMENT Rx

Comprehensive reviews of TB treatment have been published and provide complete information on drugs for TB, monitoring of therapy, management of adverse events, and treatment of pregnant women, children, and other special populations:

- *http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5211a1.htm* (treatment)
- *http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5804a1.htm* (treatment and prevention in HIV-infected persons)

Treatment of TB is both a clinical and a public health issue. The goals are to cure the patient and to minimize transmission. For that reason, the treating physician has the obligation to ensure that treatment is completed with good adherence to medications. Because of the declining number of TB cases in the United States, with subsequent decline in expertise in TB management, treatment is more likely to occur in a public health clinic than in the private sector. The cornerstone of TB treatment is multidrug therapy. This is necessary because *M. tuberculosis* undergoes spontaneous mutation to drug resistance at a frequency such that most patients with cavitary lung disease—and therefore a high burden of organisms—are likely to harbor resistant mutants.

For the treatment of TB caused by drug-susceptible organisms, there is an intensive phase of therapy for the first 2 months aimed at the rapidly dividing and metabolizing organisms and usually resulting in sterilization of sputum in those with PTB. This is followed by a 4- to 6-month continuation phase that kills the slowly metabolizing, persisting organisms. The five first-line antituberculosis drugs, INH, RIF, ethambutol (EMB), PZA, and streptomycin (SM), form the foundation of chemotherapy for TB. The precepts of therapy have been largely defined by controlled clinical trials. Standard short-course therapy for PTB requires a 2-month intensive phase of four drugs (INH, RIF, EMB, and PZA), followed by a 4-month continuation phase with INH and RIF.

The use of intermittent dosing regimens increases the feasibility of directly observed therapy but is controversial. Recent papers from Hong Kong and the United States have shown, in fact, that intermittent regimens may be slightly less effective than daily 5/7 regimens (5 weekdays observed, 2 weekend days self-administered). For patients with extensive cavitary disease and the severely immunosuppressed, daily therapy should be administered throughout the entire course. For HIV-infected persons with TB who are not severely immunosuppressed, treatment should be daily during the intensive phase and at least three times weekly during the continuation phase. Non–HIV-infected persons without extensive cavitary disease can be treated with intermittent regimens throughout. Originally, EMB was perceived to be a "place holder" should the isolate prove to be resistant to INH, and the recommendation was to eliminate its use once drug susceptibility test results were available. There is recent evidence that EMB may be important because of its synergistic or additive activity with other "first-line" drugs, thereby providing an argument against its premature discontinuation before a full 2 months of therapy has been received.

The problem of nonadherence has led to the directive to provide directly observed therapy. The addition of PZA to the intensive phase allows for the so-called short-course chemotherapy; if PZA is not tolerated, comparable outcomes can be obtained with 9 months of INH-RIF. Treatment of

drug-susceptible TB with this standard regimen can be expected to cure approximately 90 to 95% of cases. Routine monitoring of liver function test results is not recommended unless there is preexisting liver disease. Patients should return to the clinic promptly with any signs of drug toxicity, particularly those of early hepatotoxicity (nausea, malaise, anorexia, upper abdominal discomfort). Visits should be scheduled monthly and include clinical assessment and sputum examinations. For those with PTB, sputum cultures are continued until two consecutive cultures are negative. About 20% of patients with cavitary PTB remain sputum culture positive after 2 months of therapy. In uncomplicated PTB, defervescence is expected within 2 weeks, and there should be weight gain and diminution of cough and chest pain. A positive sputum culture at 3 months or failure to improve on chest radiographs suggests nonadherence with therapy, drug-resistant TB, or an alternative or complicating diagnosis. Positive sputum culture at 4 months is defined as treatment failure.

Extrapulmonary TB is usually associated with a smaller bacterial burden than is the case with PTB and can be treated with standard short-course regimens of 6 to 9 months' duration. However, because of the serious ramifications of treatment failure, more prolonged treatment of at least 9 to 12 months is recommended for miliary, meningeal, and skeletal TB. Adjunctive surgical débridement and stabilization may be necessary for skeletal TB. Adjunctive corticosteroids are indicated for TB pericarditis and severe pleurisy, as well as extensive PTB with clinical toxicity or respiratory failure. In TB meningitis, dexamethasone has been shown to improve survival but has not had an impact on the proportion surviving with severe neurologic sequelae. Ventricular shunting may be necessary to relieve hydrocephalus.

HIV-TB coinfection creates additional management issues. Fortunately, the response to treatment of TB is comparable to that in HIV-uninfected individuals, except for higher early mortality. Intermittent regimens have a tendency to lead to RIF resistance; therefore, daily administration of drugs is recommended in the intensive phase, and drugs should be administered no less than three times weekly in the continuation phase. The administration of cotrimoxazole prophylaxis is associated with improved survival.■ A recent study demonstrated that integration of the treatment of TB and HIV rather than sequential treatment of first TB and then HIV is associated with a 56% reduction in mortality.■ The results of two randomized controlled trials indicate a survival benefit to starting ART within the first 2 weeks if CD4 <200/mm^3; most of the benefit may be in those with CD4 <50 mm^3.

Early initiation of ART also incurs a risk for paradoxical reaction, a form of immune reconstitution inflammatory syndrome (IRIS) (Chapter 402). TB-IRIS is more likely to occur when the CD4$^+$ count is low, the viral load is high, and the interval between starting TB drugs and ART is short. Immune reconstitution is associated with inflammation and transient exacerbation of disease mimicking progression of TB. There may, for example, be fever, lymphadenitis, and pleural or worsening parenchymal disease, including consolidation and nodular opacities on chest radiographs. In about a third of dually infected patients, IRIS will develop within the first 2 months of treatment and often within the first 2 to 3 weeks of starting ART. TB-IRIS is not usually an important cause of morbidity or mortality and can be managed with supportive care. More problematic is IRIS associated with respiratory failure or neurologic involvement. Initiation of ART in HIV-infected persons may also be associated with "unmasking TB," which occurs within 3 months. This may be due to a missed diagnosis of TB in screening, the development of inflammation at sites of mycobacterial replication in tissue, or progression of latent infection consequent to ART. Unmasking TB is common in countries endemic for TB (5 to 10% but about 25% in South Africa) and associated with morbidity, mortality, and risk for nosocomial transmission.

In general, TB does not affect the response of HIV to ART. A major issue, however, is the interactions between rifamycins that induce CYP3A hepatic microsomal enzymes and protease inhibitors and some non-nucleoside reverse transcriptase inhibitors. RIF can be used safely in efavirenz-based regimens, which are well tolerated and effective for the treatment of persons coinfected with TB and HIV. Where available and affordable, rifabutin can be substituted for RIF because it is less active as an inducer of microsomal enzymes and can be used with protease inhibitors.

Management of TB-HIV coinfection may be complicated for the clinician. For example, a new fever may be due to drug reaction, TB-IRIS, drug resistance, or a complicating opportunistic infection.

Drug-resistant TB is more difficult to cure and in some instances may be incurable. General issues concerning the management of drug-resistant TB are listed in Table 332-2. A major problem, however, is the lack of information on drug susceptibility at the time of initiation of treatment. In resource-limited settings, drug susceptibility testing may not be available at all. Drug resistance is more likely in retreatment cases, so standardized retreatment regimens are administered. The risk for drug resistance is greater if the initial regimen was not administered in a directly observed therapy program. For patients who relapse, did not receive directly observed therapy, were not treated with an RIF-containing regimen, were known or presumed to have irregular treatment, or have severe disease, an expanded regimen should be started, for example, INH, RIF, and PZA plus an injectable (SM if not previously used) and an FQ, with or without an additional oral agent (ethionamide, para-aminosalicylic acid [PAS], or cycloserine). Ideally, the retreatment regimen should contain at least three drugs to which the isolate is likely to be susceptible. In resource-poor environments, SM alone is often added to INH, RIF, EMB, and PZA. Although most retreatment cases remain drug susceptible, about 25% do not respond adequately to the standard regimen. It has therefore become clear that drug susceptibility testing should be performed for all patients being retreated to ensure success of treatment and to prevent the acquisition of additional resistance.

Monoresistance to INH or SM has little effect on the outcome of TB treatment. INH-resistant TB can be treated with RIF, PZA, and EMB for 6 months. Ofloxacin may be added for extensive or refractory disease. RIF-resistant TB can be treated with 12 to 18 months of INH, EMB, ofloxacin, and PZA (plus an injectable for the first 2 months if there is extensive disease). The acquisition of additional drug resistance is more likely if the initial isolate was resistant to one drug (6%) or more than one drug (14%) versus being pan-susceptible (0.8%).

MDR TB represents a problem of a different order of magnitude. Not only is cure difficult and extremely expensive, but unrecognized MDR TB can also lead to nosocomial outbreaks and rapid and high rates of fatality in the HIV infected. The World Health Organization has recommended a "DOTS-PLUS" strategy for the management of MDR TB in resource-limited settings. An empirical regimen is started based on the predominant drug susceptibility testing profile in the local setting. Unfortunately, this strategy may promote the acquisition of additional drug resistance and even the development of XDR TB if the MDR isolate is resistant to one or more drugs in the empirical regimen. There is no substitute for performing drug susceptibility testing that includes all first-line and available "second-line" drugs. MDR TB is not a homogeneous entity. Frequently, the first diagnosis of MDR TB occurs in the setting of residual susceptibility to most other drugs. However, after repeated treatments, the isolate usually acquires additional drug resistance and, regardless of whether it fulfills the definition, is essentially XDR.

The cornerstone of treatment of MDR TB is the administration of at least four drugs to which the isolate is susceptible (see Table 332-2). Typically, the regimen will include first-line drugs with retained activity, an FQ, an injectable (amikacin, kanamycin, or capreomycin), and a second-line drug if disease is extensive (ethionamide, cycloserine, PAS). The duration of treatment is set at 12 to 18 months (12 to 15 months after sterilization of sputum). Residual susceptibility to FQ treatment and to capreomycin has been shown to be determinants of treatment outcome. Surgical resection is a consideration if the disease is localized, sputum remains culture positive, medical therapy is not tolerated, or massive hemoptysis is present. Cure rates of 60 to 80% can be expected if therapy is targeted to drug susceptibility test results and MDR organisms remain sensitive to enough chemotherapeutic drugs that a reasonable regimen can be established.

The definition of XDR TB requires that an organism be MDR with additional resistance to an FQ plus at least one of three injectables (amikacin, kanamycin, capreomycin). The outcome of treatment of XDR TB has been variable. The best reported results have been obtained in Peru with a comprehensive approach that included therapeutic regimens that were tailored according to drug susceptibility testing. Effective regimens included cycloserine, capreomycin, and PAS. Moxifloxacin may be active even if the isolate is resistant to first-generation FQs. Adjunctive surgery should be considered.

The emergence of drug resistance has emphasized the need for new drugs and new drug regimens. A drug regimen that shortens the course of TB would lessen the emergence of drug resistance because adherence would increase and the administration of direct observed therapy would be simplified. Once MDR TB develops and particularly in the setting of XDR TB, new drugs are necessary to improve efficacy and shorten treatment.

There are promising developments with existing classes of drugs, as well with as new classes about to enter or already in clinical trials. Rifapentine, a rifamycin with a longer half-life than RIF, is effective when administered to non–HIV-infected TB patients once weekly in the continuation phase. The new FQs moxifloxacin and gatifloxacin have increased activity against *M. tuberculosis* and are being studied in 4-month regimens. There is early evidence that isolates resistant to first-generation FQs may retain susceptibility to moxifloxacin. TMC 207 is a diarylquinoline specific for *M. tuberculosis* ATP synthase. TMC 207 is therefore unlikely to be used to treat pneumonias and other infections and will be reserved for TB, which should slow the emergence of drug resistance. When TMC 207 is used to treat MDR TB, it accelerates sputum clearance of organisms and increases the proportion of patients who sterilize their sputum, very promising evidence of activity.■ Another approach of considerable interest is the combination of meropenem and clavulanate, a β-lactam and a β-lactamase inhibitor. This combination has activity against XDR TB organisms. Because the drugs are in clinical use for other indications, the time required for development as a TB indication will be considerably shorter. Linezolid has promising early bactericidal activity and may be useful to treat or prevent drug-resistant TB. PA-824 and OPC-67683 are nitroimidazole derivatives that are active against slowly replicating bacilli. Also in development are SQ-109 (ethylenediamine), an ethambutol derivative, and PNU-100480 (an oxazolidinone more active than linezolid).

TABLE 332-2 GUIDELINES FOR THE MANAGEMENT OF TUBERCULOSIS CAUSED BY DRUG-RESISTANT ORGANISMS

Do not add a single drug to a failing regimen.
When starting or modifying therapy, add three previously unused drugs (one an injectable) to which there is likely to be susceptibility.
In multidrug-resistant tuberculosis (MDR TB), when there is resistance to additional first-line drugs, treat with 4 to 6 drugs.
Patients with MDR TB have the highest priority for directly observed therapy because treatment failure may be associated with extensively drug-resistant TB.
Intermittent therapy should not be used (except for injectables after 2-3 mo).
Do not use drugs to which the *M. tuberculosis* isolate is resistant. Low-level resistance to isoniazid may be an exception.
There is cross-resistance among rifamycins but not between streptomycin and other aminoglycosides.
Drug susceptibility testing for pyrazinamide is complex technically and not performed in most laboratories. Monoresistance to pyrazinamide suggests *M. bovis*.
Moxifloxacin may be active in some cases resistant to first-generation fluoroquinolones.

PREVENTION

The issues surrounding prevention are presented in a comprehensive statement published in 2000, *http://www.cdc.gov/mmwr/preview/mmwrhtml/rr4906a1.htm*, and prevention in HIV-infected persons is presented at the website *http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5804a1.htm*.

The approach taken in a low-prevalence setting such as the United States is to target tuberculin skin testing to those at high risk for recent *M. tuberculosis* infection and to those with comorbid conditions that predispose to progression from infection to disease (see Table 332-1). In either category, a positive TST becomes an indication for treatment of LTBI.

LTBI can be treated with INH for 9 months, thereby decreasing the lifetime risk for development of TB by approximately 75 to 90%, depending on the level of adherence to treatment. Pyridoxine should be administered to prevent INH-induced peripheral neuropathy. Monitoring of liver function is indicated in older individuals (the risk for hepatotoxicity increases beyond the age of 35 years) and in those with significant alcohol intake or underlying liver disease (or both). INH should be discontinued if symptoms develop (see Treatment) or hepatic transaminase levels rise to more than three to five times the upper limit of normal. Alternative regimens for the treatment of LTBI are RIF for 4 months or INH and RIF for 3 months. In HIV-infected persons, treatment of LTBI confers short-term efficacy (about 1 year), but this may be extended if ART is administered. In a low-resource setting in the HIV infected, the absence of any cough, any fever, and night sweats for 3 of the preceding 4 weeks has a negative predictive value of 97% and may obviate the need for chest radiography if it is not routinely available. Furthermore, a recent preliminary report suggests that treatment for 3 years confers a survival advantage. Immunosuppression decreases the sensitivity of the diagnosis of LTBI in HIV-infected persons. This creates a quandary because efficacy of treatment has been established only for those with a positive TST. Unfortunately, treatment of LTBI has not been applied broadly. In fact, it is estimated that less than 1% of those who could benefit actually receive appropriate therapy. This is in part due to the concern that if screening is inadequate, patients with active TB will be treated with a single drug and thereby acquire drug resistance. INH can be administered safely if there is no history of cough, fever, or night sweats in the previous 4 weeks.

There are no data on how to treat LTBI caused by a known or probably drug-resistant isolate. PZA plus EMB or ofloxacin has been used after known exposure to MDR TB susceptible to the combination, but gastrointestinal intolerance is very common. Studies of linezolid are planned in this population.

Secondary preventive therapy after completion of TB treatment is indicated in HIV-infected persons in the setting of intense exposure to *M. tuberculosis*. Data demonstrating efficacy of secondary prevention largely result from studies of adults in Congo and gold miners in South Africa.

Tracing of household contacts is a critical element of TB programs. The household is a major site of TB transmission, particularly in an area of low endemicity, so treatment of TST converters is an important strategy for elimination of TB. It is essential that transmission be limited in hospitals and other settings in which infectious PTB patients may co-mingle with susceptible hosts. The risk of transmission to health care workers should be ascertained annually. The finding of excessive risk for new TB infection should lead to focused measures for reducing transmission. All TB suspects should be placed in respiratory isolation in negative-pressure rooms with at least six air exchanges per hour and high-efficiency particulate air (HEPA) filtration or ultraviolet irradiation. N-95 personnel respirator devices that are fit-tested are necessary for individuals entering areas with a known high risk for exposure.

BCG vaccine is widely used and relatively safe except in the setting of immunosuppression. Unfortunately, efficacy has been variable by age and by latitude. A meta-analysis indicated an overall efficacy of 50%. It is approximately 80% effective in preventing the severe forms of TB in childhood, miliary TB, and TB meningitis. However, its failure to prevent adult TB, particularly at low latitudes, which include the most endemic areas, means that BCG vaccine does not have an impact on the public health problem of TB. The development of a more effective protective vaccine has been hampered by the absence of good animal models and the lack of correlates of protective immunity in humans. The issue is further compounded by the natural history of TB such that large, lengthy, and expensive trials may be needed to establish protective efficacy. Nonetheless, several vaccine candidates have been developed and their potential efficacy supported by preclinical studies in animal models. Two of the 12 currently in clinical trials are MVA85A, a recombinant modified vaccinia virus expressing the 85A antigen, a major secretory product of *M. tuberculosis*, and Mtb72f, a combination of two immunogenic antigens, Mtb 32a and Mtb 39a, in two adjuvants, ASO2a and ASO1B.

PROGNOSIS

In the prechemotherapeutic era, minimal PTB stabilized in about 50% of cases. Pleural TB also self-cured with a risk for reactivation as noted previously. With treatment, the prognosis of patients with TB depends on the extent of PTB, the sites of extrapulmonary TB, drug susceptibility of the isolate, and the presence of HIV infection and other comorbid conditions. With extensive PTB, respiratory failure may supervene with a poor prognosis. There is also increased risk for serious, sometimes lethal hemoptysis and pneumothorax. Miliary TB is associated with a high case-fatality rate, in part related to delays in diagnosis. TB meningitis is associated with serious neurologic residua, as well as high mortality. MDR TB and XDR TB are accompanied by high rates of treatment failure, morbidity, and mortality. TB in HIV-infected persons is associated with high early mortality that is poorly characterized. In the absence of ART, there is increased risk for other opportunistic infections and progression of HIV disease. The addition of ART, however, results in the morbidities associated with the concurrent administration of TB and HIV medications and with TB-IRIS.

333 THE NONTUBERCULOUS MYCOBACTERIA

STEVEN M. HOLLAND

DEFINITION

Nontuberculous mycobacteria generally include the growing number of mycobacteria other than *Mycobacterium tuberculosis* and its close relatives (Chapter 332) and *Mycobacterium leprae* (Chapter 334). Other names that have been used include *atypical mycobacteria, mycobacteria other than tuberculosis,* and *environmental mycobacteria.* The number of nontuberculous mycobacteria is growing rapidly as a result of the advent of DNA sequence typing for determining criteria for speciation. Accordingly, the number of species of nontuberculous mycobacteria has increased to almost 150 and will continue to increase for the near future.

The Pathogens

Identification of any mycobacterium requires that the appropriate tests be thought of ahead of time and be performed because routine microbiologic testing does not identify mycobacteria. Nontuberculous mycobacteria are typically first detected on acid-fast smears of sputum or other body fluids. When levels of organisms are high, mycobacteria may be seen on Gram stain as gram-positive beaded rods, but this finding is unreliable. The first step in identification is to request the appropriate smear (acid-fast or fluorochrome) and culture. Nontuberculous mycobacteria are broadly differentiated into rapidly growing (<7 days) and slowly growing (>7 days) forms. *M. tuberculosis*, by contrast, typically takes 2 or more weeks to grow. Formation of pigment in light (photochromogens) or dark (scotochromogens) and lack of pigment (nonchromogens) have also been used to help categorize nontuberculous mycobacteria. Current diagnostics use biochemical, nucleic acid, or cell wall composition on high-performance liquid chromatography for speciation (Table 333-1). For purposes of diagnosis, prognosis, and therapy, identification of nontuberculous mycobacteria should be taken to the species level.

TABLE 333-1 COMMON NONTUBERCULOUS MYCOBACTERIA

ORGANISM	DISEASE
RAPIDLY GROWING NONTUBERCULOUS MYCOBACTERIA	
M. abscessus	Lung, disseminated, lymph node
M. chelonae	Skin
M. fortuitum	Line infections, lung
M. smegmatis	Almost never associated with disease
SLOWLY GROWING NONTUBERCULOUS MYCOBACTERIA	
M. avium complex	Lung, disseminated, lymph node
M. kansasii	Lung
M. marinum	Skin, tendons (fish tank granuloma)
M. xenopi	Lung
M. simiae	Lung
M. szulgai	Lung
M. malmoense	Lung
M. scrofulaceum	Lymph node
M. haemophilum	Disseminated, skin
M. genavense	Disseminated
M. ulcerans	Skin (Buruli ulcer; toxin producing)
M. neoarum	Disseminated
M. celatum	Disseminated
M. gordonae	Almost never causes disease
M. terrae complex	Disseminated

EPIDEMIOLOGY

As a group, the nontuberculous mycobacteria are ubiquitous in soil and water and are often found in certain animals, but they rarely cause disease in humans. There are no known instances of human-to-human transmission of nontuberculous mycobacteria. Because these infections are not reported to health agencies and their identification is sometimes problematic, reliable data on incidence and prevalence are lacking. In the United States, however, isolates of nontuberculous mycobacteria have exceeded those for *M. tuberculosis* for many years. In patients with cystic fibrosis (Chapter 89), for example, rates of clinical nontuberculous mycobacterial infection range from 3 to 15%, but even more patients harbor the organism. However, differentiating active disease from commensal harboring of the organism remains problematic. Other patient groups, such as those with bronchiectasis, also have elevated rates of nontuberculous mycobacterial infection, but the rates are undefined. The bulk of nontuberculous mycobacterial disease in North America is due to *Mycobacterium kansasii, Mycobacterium avium* complex (MAC), and *Mycobacterium abscessus.*

PATHOBIOLOGY

Because exposure is essentially universal and disease is rare, normal host defenses against nontuberculous mycobacteria must be highly effective. Therefore, otherwise healthy individuals in whom disease develops may have specific susceptibility factors that permit these infections to become established, multiply, and cause disease.

With the advent of human immunodeficiency virus (HIV) infection, $CD4^+$ T lymphocytes have been identified as key effectors against nontuberculous mycobacteria. Much of the genetic basis of susceptibility to disseminated nontuberculous mycobacterial infection outside HIV infection has been found to be due to specific mutations in the interferon-γ (IFN-γ)/interleukin-12 (IL-12) synthesis and response pathways. However, only about 50% of disseminated cases unassociated with HIV infection have a genetic diagnosis, and genetic causes of predisposition to nontuberculous mycobacterial lung disease are still very few.

Mycobacteria are typically phagocytosed by macrophages, which respond with the production of IL-12, a heterodimer composed of p35 and p40 moieties that together constitute IL-12p70 (Fig. 333-1). IL-12 activates T lymphocytes and natural killer cells through binding to its receptor (composed of IL-12Rβ1 and IL-12Rβ2/IL-23R) and results in phosphorylation of STAT4 (signal transducer and activator of transcription 4). IL-12 stimulation leads to secretion of IFN-γ, which activates neutrophils and macrophages to produce reactive oxidants and increase major histocompatibility complex and Fc receptors. IFN-γ signals through its receptor (composed of IFN-γR1 and IFN-γR2), thereby leading to phosphorylation of STAT1, which in turn regulates IFN-γ–responsive genes such as those for IL-12 and tumor necrosis factor-α (TNF-α). Therefore, the positive feedback loop between IFN-γ and IL-12/IL-23 is pivotal in the immune response to mycobacteria and other intracellular infections. The advent of potent TNF-α inhibitors, such as infliximab, adalimumab, certolizumab, and etanercept (Chapter 35), has provided the ability to neutralize this critical cytokine, which has occasionally resulted in mycobacterial and fungal infections.

CLINICAL MANIFESTATIONS

Disseminated Disease

Disseminated nontuberculous mycobacterial disease secondary to MAC infection used to occur commonly in the setting of advanced acquired immunodeficiency syndrome but is now uncommon in North America because of MAC prophylaxis and improved treatment of HIV infection. The portal of entry was the bowel, with spread to bone marrow and the blood stream. Rapidly growing mycobacteria such as *Mycobacterium fortuitum* sometimes infect deep indwelling lines. The severe disseminated infection seen with immune defects is typically associated with malaise, fever, and weight loss, and it is often accompanied by organomegaly and lymphadenopathy. Disseminated (two or more organ) involvement in a child without an underlying iatrogenic cause should prompt an investigation of the

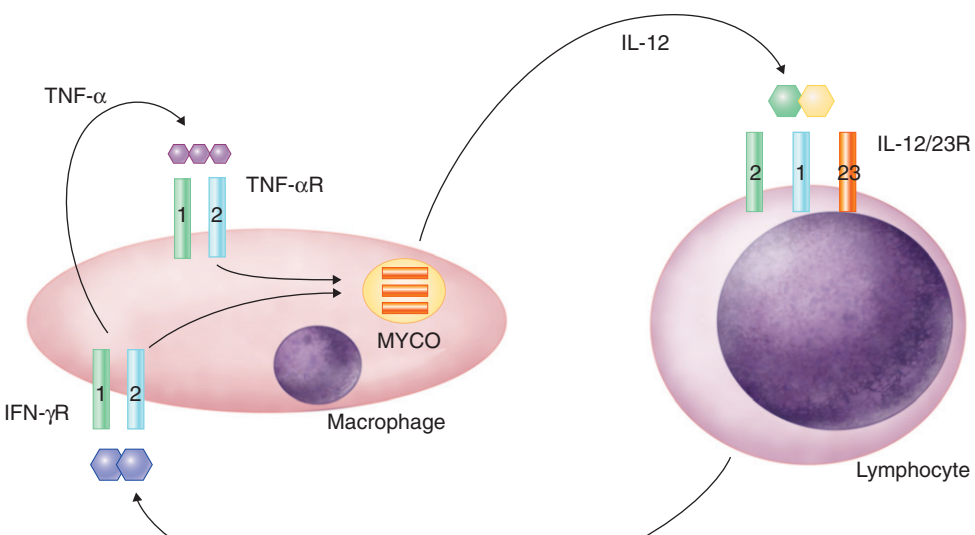

FIGURE 333-1. Schematization of the critical cytokine interactions between infected macrophages and T and natural killer lymphocytes. Organisms (MYCO) infect macrophages, which release heterodimeric interleukin-12 (IL-12). This acts on the IL-12/23 receptor complex and leads to the production of homodimeric interferon-γ (IFN-γ). IFN-γ acts on its receptor to stimulate the production of tumor necrosis factor-α (TNF-α) and kill intracellular organisms such as mycobacteria, salmonellae, and some fungi. Homotrimeric TNF-α acts on its own receptor and also contributes to killing of intracellular organisms. Both IFN-γ and TNF-α lead to upregulation of IL-12. TNF-α–blocking antibodies work either by blocking the ligand (infliximab, adalimumab, certolizumab) or by providing soluble receptor (etanercept). Mutations in both chains of IFN-γR, IL-12p40, and IL-12Rβ1 and signal elements for IFN-γR and TNF-αR have been identified through their predisposition to mycobacterial infections.

IFN-γ/IL-12 pathway. Nontuberculous mycobacterial osteomyelitis is especially common with dominant negative mutations in IFN-γR1. A male with conical or peg teeth or an abnormal hair pattern and disseminated nontuberculous mycobacterial infection should be evaluated for defects in the pathway that activates nuclear factor κB. Some patients with disseminated, rapidly growing infections (predominantly *M. abscessus*) have high-titer autoantibodies to IFN-γ.

Pulmonary Disease

Lung disease caused by nontuberculous mycobacteria is by far the most common form of the infection in North America. Predisposing factors include underlying lung disease, such as bronchiectasis (Chapter 90), pneumoconiosis (Chapter 93), chronic obstructive pulmonary disease (Chapter 88), primary ciliary dyskinesia, and cystic fibrosis. The manifestations of *M. kansasii* infection can be very similar to those of tuberculosis (Chapter 332) and consist of hemoptysis, chest pain, and cavitary lung disease. MAC infection most commonly occurs in women in their sixth or seventh decade who have had months to years of nagging intermittent cough and fatigue, with or without sputum production or chest pain. Bronchiectasis and nontuberculous mycobacterial infection often coexist and progress in tandem, thus making causality difficult to determine. When compared with male smokers with upper lobe cavitary disease, who tend to carry the very same single strain of MAC indefinitely, nonsmoking females with nodular bronchiectasis tend to have several strains simultaneously and change them over the course of their disease process. Patients with pulmonary alveolar proteinosis (Chapter 91) are prone to pulmonary nontuberculous mycobacterial and nocardial infections. Esophageal motility disorders, such as achalasia (Chapter 140), have been associated with pulmonary disease, especially that caused by rapidly growing nontuberculous mycobacteria such as *M. abscessus.*

Cervical Lymph Nodes

Isolated cervical lymphadenopathy, most frequently caused by MAC, is the most common form of nontuberculous mycobacterial infection in young children in North America. The organism is generally MAC, but other nontuberculous mycobacteria can also cause disease. The cervical swelling is often firm and relatively painless with a paucity of systemic signs. Because the differential diagnosis of painless adenopathy includes malignancy, many of these infections are inadvertently diagnosed at biopsy. Local fistulas usually resolve completely with resection or antibiotic therapy, or both.

Skin and Soft Tissue Disease

Mycobacterium marinum causes skin infections, usually papules or ulcers, associated with water exposure and is known as "fish tank granuloma." Numerous outbreaks of skin infections caused by rapidly growing mycobacteria (especially *M. abscessus, M. fortuitum,* and *Mycobacterium chelonae*) have been due to skin contamination from instruments used for surgical procedures (especially cosmetic surgery), injections, and other procedures. These infections are typically accompanied by painful, erythematous, draining subcutaneous nodules, usually without associated fever or systemic symptoms.

DIAGNOSIS

With the continued decline in cases of tuberculosis, nontuberculous mycobacteria are now the most common mycobacteria isolated from humans in North America. The conventional tuberculin skin test (purified protein derivative [PPD]) evokes a cell-mediated response to secreted mycobacterial antigens. Unfortunately, the PPD test does not differentiate well between nontuberculous mycobacterial and tuberculosis infection, although large PPD reactions (>15 mm) more commonly signify tuberculosis. With the progressive decline in active tuberculosis in the United States, nontuberculous mycobacteria are likely to account for significant proportions of PPD reactivity. Newer IFN-γ release assays (IGRAs) incubate blood with relatively tuberculosis-specific recombinant proteins and elicit T-cell secretion of IFN-γ, thereby helping clarify whether PPD reactivity is due to tuberculosis.

Isolation of nontuberculous mycobacteria from blood specimens is clear evidence of disease. However, because the slow-growing nontuberculous mycobacteria typically do not grow well in routine blood culture media, the diagnosis must be suspected. Isolation of nontuberculous mycobacteria from a biopsy specimen is strong evidence of infection, but cases of laboratory contamination do occur. Identification of organisms on stained sections of biopsy material confirms the authenticity of the culture. Some unusual nontuberculous mycobacteria require lower incubation temperatures or special additives for growth.

The radiographic appearance of nontuberculous mycobacterial disease in the lung ranges from normal to nodules, bronchiectasis, air space disease, and extensive cavity formation, similar to that seen in tuberculosis (Fig. 333-2). Isolation of nontuberculous mycobacteria from respiratory samples presents special problems in both sensitivity and specificity. *Mycobacterium gordonae* is often recovered from respiratory samples and is almost never thought to be a real pathogen. Many patients, especially those with bronchiectasis, will occasionally have nontuberculous mycobacteria recovered from sputum culture without such mycobacteria being seen on smear. Specific criteria for definitive diagnosis of nontuberculous mycobacterial lung disease exist for MAC, *M. abscessus*, and *M. kansasii*, but they are probably good guidelines for other nontuberculous mycobacteria as well. A positive diagnosis requires that two of three sputum samples grow nontuberculous mycobacteria, regardless of smear findings; a positive bronchoscopic alveolar sample, regardless of smear findings; or a biopsy specimen of pulmonary parenchyma with granulomatous inflammation or mycobacteria found on section and nontuberculous mycobacteria on culture.

Once isolated, identification of nontuberculous mycobacteria is important because it will determine the broad class of antimycobacterial therapy to be used. Many laboratories now use DNA probes to identify MAC, *M. gordonae*, and *M. kansasii*. Drug susceptibility testing is of limited and largely unproven

FIGURE 333-2. Chest computed tomography in a patient with severe pulmonary *Mycobacterium abscessus* infection. Arrows indicate bronchiectasis. Note the extensive left upper lobe destruction and diffuse pleural reaction. In addition, the left lung is smaller than the right as a result of extensive loss of lung parenchyma.

value, although clarithromycin susceptibility testing for MAC and rifampin susceptibility testing for *M. kansasii* are indicated. Initial isolates of MAC that have not been exposed to macrolides are almost always susceptible to macrolides. Any nontuberculous mycobacteria that have resisted a course of antimicrobials should probably be tested for antibiotic susceptibility as well.

PREVENTION

Prophylaxis of MAC disease in patients infected with HIV is started when the $CD4^+$ T-lymphocyte count is less than 50 cells/μL. Azithromycin, 1200 mg weekly, clarithromycin, 1000 mg daily, and rifabutin, 300 mg daily, are effective.

TREATMENT

Rx

It is rarely an emergency to initiate treatment of nontuberculous mycobacterial infections, which are relatively slow-growing, chronic infections that evolve over a period of weeks to years, not hours to days. Therefore, empirical therapy is not usually needed, and identification of the species is advisable before starting complex, often poorly tolerated, and potentially toxic regimens. Similar to the case with tuberculosis, single-drug therapy is almost always associated with the emergence of antimicrobial resistance and is strongly discouraged.

MAC infection frequently requires complex multidrug therapy, the foundation of which is a macrolide (clarithromycin or azithromycin), ethambutol, and a rifamycin (rifampin or rifabutin). For disseminated nontuberculous mycobacterial disease in HIV-infected patients, the use of rifamycins poses special problems of drug interactions with protease inhibitors. For pulmonary MAC disease, three-times-weekly administration of drugs has been used successfully. The duration of therapy is prolonged, generally for 12 months after culture conversion and typically for a total of at least 18 months. Other drugs with activity against MAC include aminoglycosides, fluoroquinolones, and clofazimine.

M. kansasii lung disease is similar to tuberculosis in many ways and is also effectively treated with isoniazid (300 mg/day), rifampin (600 mg/day), and ethambutol (15 mg/kg/day). Treatment should continue until cultures have been negative for at least 1 year. Other drugs with very high activity against *M. kansasii* include clarithromycin, fluoroquinolones, and aminoglycosides.

Rapidly growing mycobacteria pose special therapeutic problems. Extrapulmonary disease in an immunocompetent host is usually due to inoculation (e.g., surgery, injection, trauma) or line infection and is often treated successfully with a macrolide and another drug (based on in vitro susceptibility), along with removal of the offending focus. By comparison, pulmonary disease, especially that caused by *M. abscessus*, is extremely difficult to cure, although repeated courses of treatment are usually effective in reducing the infectious burden and symptoms. Therapy generally includes a macrolide along with an intravenous agent such as amikacin, a carbapenem, cefoxitin, or tigecycline. Other oral agents used according to in vitro susceptibility testing and tolerance include fluoroquinolones, doxycycline, and linezolid.

Treatment of the other nontuberculous mycobacteria is less well defined, but macrolides and aminoglycosides are usually effective, with other agents added as indicated. Expert consultation is strongly encouraged for difficult or unusual nontuberculous mycobacterial infections.

PROGNOSIS

The effect of nontuberculous mycobacterial infection on longevity is closely tied to the underlying condition (e.g., IFN-γ/IL-12 pathway defect, cystic fibrosis). With no or inadequate treatment, symptoms are intrusive, and the infections can lead to fatal complications, including overwhelming infection or severe lung destruction.

334 LEPROSY (HANSEN'S DISEASE)

JOEL D. ERNST

DEFINITION

Leprosy (Hansen's disease) is a chronic infection caused by *Mycobacterium leprae,* an acid-fast, slowly growing bacterium that cannot yet be cultured in vitro. Leprosy is found worldwide, although seven countries of high prevalence currently account for more than 80% of reported cases. The primary manifestations of infection with *M. leprae* occur in the skin and peripheral nerves. The skin lesions of leprosy are classically hypopigmented, hypoesthetic or anesthetic, and nonpruritic. Peripheral nerves can be damaged by direct infection with *M. leprae* or by the immune response to the infection; the result is loss of sensation and motor function. Additional morbidity is due to the peripheral nerve dysfunction, including painless traumatic and burn injuries, secondary bacterial infections, and muscle atrophy and contractures. Leprosy per se is not a cause of death, but the debility associated with leprosy contributes to the severity of poverty and the likelihood of death from malnutrition or other infections. Despite the low transmissibility of *M. leprae* and the ability of multiple-drug therapy to cure leprosy, it remains a stigmatized disease that can pose a challenge to diagnosis and therapy.

The Pathogen

M. leprae is an acid-fast bacillus that contains a mycolic acid–rich cell wall and a single membrane. Despite nearly 150 years of effort, *M. leprae* remains uncultivatible in vitro. For biochemical and structural characterization, *M. leprae* can be grown in large quantities in nine-banded armadillos *(Dasypus novemcinctus),* and inoculation of the footpads of athymic mice allows semi-quantitation of viable bacilli.

The genome of *M. leprae* consists of 3,268,203 base pairs (bp), compared with the *Mycobacterium tuberculosis* genome of 4,411,529 bp, and the number of expressed genes of *M. leprae* is approximately 60% fewer than that of *M. tuberculosis.* Because *M. leprae* and *M. tuberculosis* probably evolved from a common mycobacterial ancestor, *M. leprae* appears to have lost approximately 2000 genes since this divergence, leaving it dependent on specialized ecologic niches for its survival. Among the genes lacking in *M. leprae* are those of the *mbt* complex, whose products are involved in bacterial acquisition of iron. *M. leprae* also lacks many of the genes for lipid biosynthesis and modification that are characteristic of *M. tuberculosis.* The genome sequence has also allowed a directed approach to identification of 16 "strains" of *M. leprae* from geographically diverse sources.

EPIDEMIOLOGY

Leprosy is found worldwide, although endemic leprosy is absent from northern Europe, where it was present in epidemic form as recently as the 19th century. The global prevalence of leprosy is about 213,000 known cases, and the current incidence is about 250,000. By definition of the World Health Organization (WHO) Strategic Plan for the Elimination of Leprosy, a newly diagnosed patient who has been treated with multidrug therapy is removed from the prevalence registry, which explains the lower prevalence than incidence of this chronic infection. Since initiation of the WHO Strategic Plan (whose goal is to eliminate leprosy as a public health problem, that is, a prevalence of <1 in 10,000 in all regions), an estimated 14 million people have been cured of leprosy.

The success of multidrug therapy notwithstanding, leprosy remains a public health problem in four countries in Africa, two in Southeast Asia (India and Nepal), and one in the Americas (Brazil). India and Brazil currently have the largest number of cases. Although domestic transmission of leprosy is extremely rare in the United States, 137 cases of leprosy were diagnosed in 2006, including cases in immigrants from India, Brazil, the Philippines, the Dominican Republic, and Mexico. Because leprosy is not highly transmissible, it is not considered a disease of travelers other than immigrants.

The inability to culture *M. leprae* in vitro has been a major hindrance to understanding of the modes of transmission and reservoirs of the organism. Observational studies reveal a low frequency of leprosy in casual travelers or temporary residents of high-incidence regions, thus indicating that *M. leprae* is not highly transmissible. Even in areas of high incidence, clusters of leprosy are rare outside families or others with prolonged close contact. It is believed that transmission of *M. leprae* commonly occurs through the respiratory route because nasal secretions of people with lepromatous leprosy may contain 10^7 viable bacilli per milliliter. In addition, transmission of *M. leprae* is thought to occur through contact with contaminated soil, although soil has not been found to be a reservoir for the bacilli.

PATHOBIOLOGY

Immunology

There is an inverse correlation between the number of lymphocytes and the number of acid-fast bacteria present in skin lesions. "Tuberculoid" lesions have abundant lymphocytes, well-formed granulomas, and few bacteria (hence this form of leprosy is also termed paucibacillary). In contrast, "lepromatous" lesions have very few lymphocytes, poorly organized or no granulomas, and large numbers of bacteria (also termed multibacillary leprosy). Between these polar extremes are intermediate forms that represent a continuum of the histopathologic and bacteriologic findings, termed borderline tuberculoid, borderline, and borderline lepromatous (Fig. 334-1). In addition to correlating with the number of bacteria in individual lesions, the polar forms of leprosy correlate with the total number of skin lesions in an individual patient: tuberculoid leprosy exhibits few (fewer than five) lesions, whereas lepromatous leprosy is characterized by multiple lesions (five or more, up to hundreds).

Leprosy provides a paradigm for the effect of the cellular immune response to a bacterial pathogen on the clinical manifestations of the infection. Individuals in whom a T helper 1 (T_H1) immune response (characterized by antigen-specific T cells that produce interferon-γ, lymphotoxin [LTA], or interleukin [IL]-2 and no IL-4 or IL-5) develops to *M. leprae* exhibit few skin lesions and few bacteria within the lesions (paucibacillary leprosy). In contrast, people in whom a T_H2 immune response develops (T cells that produce little interferon-γ, lymphotoxin, or IL-2 but produce IL-4, IL-5, and IL-13) have larger numbers of skin lesions and large numbers of bacteria within their lesions (multibacillary leprosy). The primary determinant of the differential immune response to *M. leprae* is incompletely understood, although substantial evidence indicates that host genetic polymorphisms contribute to the likelihood of paucibacillary versus multibacillary leprosy.

Pathogenesis of Nerve Damage

Peripheral nerve damage, the most important consequence of infection with *M. leprae,* occurs in all forms of leprosy and underlies the complications of the infection. *M. leprae* invades Schwann cells, the glial cells of peripheral nerves. Schwann cells form a functional unit with peripheral nerve axons and are surrounded by laminin-2, a neural-specific extracellular matrix protein. The G domain of laminin-2 can bind simultaneously to *M. leprae* and to the Schwann cell laminin receptor α-dystroglycan, which promotes binding of *M. leprae* to Schwann cells by use of laminin-2 as a bridging molecule. Laminin-2 interacts with two distinct molecules on the surface of *M. leprae,* a 21-kD protein and phenolic glycolipid-1 (PGL-1); either can mediate internalization by Schwann cells. Once *M. leprae* is bound and internalized by Schwann cells, it can cause direct demyelination of peripheral nerves in the absence of an immune response, apparently by signaling through ErbB2 and Erk1/2. *M. leprae*–mediated demyelination occurs without early cell death or toxicity, although Schwann cells and neurons can die by apoptosis later after infection. In addition, dead *M. leprae* or PGL-1 shed from live or dying *M. leprae* can mediate peripheral nerve demyelination and may contribute to the ongoing nerve damage that can follow initiation of chemotherapy. In addition to PGL-1–mediated demyelination, an *M. leprae* 19-kD lipoprotein can mediate Schwann cell apoptosis in vitro, and apoptotic Schwann cells can be found in human leprosy lesions. These mechanisms are probably responsible for the nerve damage in multibacillary leprosy.

In addition to direct damage to peripheral nerves by *M. leprae,* the immune response in leprosy also contributes to nerve damage, especially in paucibacillary (tuberculoid) leprosy, in which the bacteria or PGL-1 or both are present in insufficient quantity to cause widespread nerve damage, and in reversal reactions, in which inflammation is particularly prominent. Several distinct immunologic mechanisms probably contribute to the nerve damage in leprosy. Pro-inflammatory cytokines such as tumor necrosis factor-α (TNF-α), IL-1β, and interferon-γ are especially prominent in lesions during reversal reactions, when irreversible nerve damage can occur. Because these molecules can contribute to inflammatory tissue damage and can induce apoptosis of Schwann cells in vitro, it is likely that these mediators play an active role in nerve damage. Reversal reactions are also characterized by an increase in the number of $CD4^+$ T lymphocytes in lesions, and at least some of these $CD4^+$ cells exhibit a cytotoxic phenotype and kill *M. leprae*–infected Schwann cells through antigen- and major histocompatibility complex class II–dependent secretion of cytotoxic granule contents. Whether these mechanisms of nerve damage occur in chronic tuberculoid leprosy is not established, but similar cytokines and T lymphocytes are found in tuberculoid lesions.

Genetics

Cases of leprosy cluster in families, partly because of shared environments and similar exposure but also probably because of genetic determinants of susceptibility. Genetic loci whose allelic variants are related to altered susceptibility to infection with *M. leprae* include *NRAMP1, TNF, TLR1, FCN2, LTA, NOD2,* and *RIPK2.* NRAMP1, NOD2, RIPK2, and TNF are expressed by macrophages, and quantitative or temporal differences in their expression may account for differences in innate susceptibility to infection. TLR1 and ficolin-2 are pattern recognition molecules that recognize bacterial

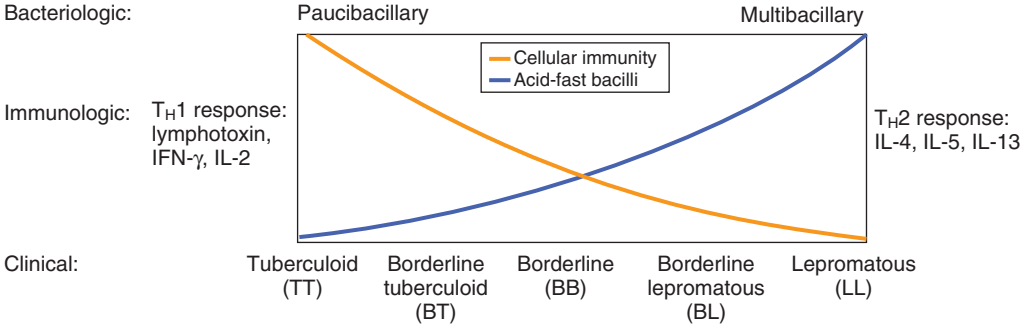

FIGURE 334-1. Bacteriologic, immunologic, and clinical spectrum of leprosy. Tuberculoid (paucibacillary) leprosy is characterized by a T_H1 immune response and few or no detectable bacilli in biopsy specimens of skin lesions or smears of skin slits. At the opposite pole of the spectrum, lepromatous (multibacillary) leprosy is accompanied by a T_H2 immune response, numerous skin lesions, and numerous acid-fast bacilli on skin biopsy specimens or smears. The intermediate forms can be classified according to their resemblance to tuberculoid or lepromatous leprosy. IFN = interferon; IL = interleukin.

FIGURE 334-2. Tuberculoid leprosy. A single large lesion with irregular, raised, erythematous borders and a depressed, hypopigmented center is shown. (From Hansen's disease [leprosy]. In: James WD, Berger TG, Elston DM, eds. *Andrews' Diseases of the Skin,* 10th ed. Philadelphia: Elsevier; 2006.)

FIGURE 334-3. Lepromatous leprosy. Numerous papules and nodules are apparent. Lepromatous macules have ill-defined borders, with normal sensation usually maintained. (From Hansen's disease [leprosy]. In: James WD, Berger TG, Elston DM, eds. *Andrews' Diseases of the Skin,* 10th ed. Philadelphia: Elsevier; 2006.)

lipopeptides and polysaccharides, respectively, whereas NOD2 and its downstream kinase RIPK2 are involved in responses to bacterial peptidoglycan. Genes with polymorphisms associated with a predisposition to distinct clinical forms of leprosy (i.e., lepromatous vs. tuberculoid) include HLA-DRB1*1501 and HLA-DRB1*1502, NRAMP1, TNF, IL-10, and TAP2.

CLINICAL MANIFESTATIONS

The most common manifestations of leprosy involve the skin and peripheral nerves and are determined by the polarity of the disease: paucibacillary (tuberculoid) or multibacillary (lepromatous). The onset of leprosy is usually insidious. Depending on the form of leprosy, numbness may be an initial complaint or finding, and skin lesions may become apparent only months or years later. The classification of leprosy as tuberculoid, lepromatous, or one of the borderline forms is based on the combination of clinical examination, the number of bacteria seen on skin slit smears or skin biopsy specimens, and the histologic appearance. Because the nature of the potential complications and the specific course of chemotherapy are determined by the form of leprosy, accurate diagnosis and classification are essential.

Tuberculoid Leprosy

Tuberculoid leprosy is characterized by the presence of fewer than five skin lesions, which are typically hypopigmented or erythematous macules with raised erythematous borders and an atrophic center (Fig. 334-2). The skin lesions in tuberculoid leprosy are usually hypoesthetic or anesthetic; when multiple lesions are present, their distribution is asymmetrical. The skin lesions may be large and are most commonly found on the face, trunk, or extremities; however, they are not found in the axillae, groin, or perineum or on the scalp, presumably because of the preference of *M. leprae* for lower temperatures.

Local peripheral nerve involvement is common in tuberculoid leprosy and is asymmetrical. In addition to hypoesthesia or anesthesia of the skin lesions, nerve involvement in tuberculoid leprosy is manifested as enlargement or tenderness (or both) of the peripheral nerves that serve the region of the skin lesions. Superficial nerves such as the ulnar, superficial peroneal, or greater auricular nerves may be visibly enlarged, depending on the location of the skin lesions. Functional complications of nerve involvement, such as muscle atrophy and contractures, may be present at the time of diagnosis of tuberculoid leprosy. Tuberculoid leprosy is a stable form; it does not convert to borderline or lepromatous forms.

Lepromatous Leprosy

Lepromatous leprosy is characterized by multiple skin lesions that are smaller than those observed in tuberculoid leprosy (Fig. 334-3). Although the sites of skin lesions are similar to those of tuberculoid leprosy, the multiple lesions of lepromatous leprosy are often symmetrically distributed. Lepromatous macules may have poorly defined borders and no loss of sensation; local nerve enlargement is not characteristic. In addition to macules, lepromatous skin lesions may be nodules or plaques, or they may diffusely infiltrate the skin, especially on the face (which may cause loss of eyebrows and "leonine facies").

Nerve involvement in lepromatous leprosy is characteristically symmetrical and exhibits a stocking-glove distribution, unrelated to the location of skin lesions. Peripheral nerve involvement may initially be manifested as loss of temperature sensation, followed by loss of light touch, pain, and deep pressure sense. In addition, dysesthesia is common. Motor complications, including muscle weakness and atrophy of the muscles of the hands, feet, and face, develop in the absence of effective antileprosy chemotherapy. Involvement of the facial nerve may result in corneal exposure, ulceration, and blindness. People with lepromatous leprosy may also have prominent rhinorrhea as a result of nasal mucosal involvement, and they may shed large numbers of *M. leprae* in their nasal secretions—one of the major sources of bacilli for transmission to other individuals. Like tuberculoid leprosy, lepromatous leprosy is stable; conversion to other forms does not occur.

Borderline Forms of Leprosy

Borderline tuberculoid leprosy is characterized by skin lesions similar to those of tuberculoid leprosy, but they are more numerous and may be accompanied by satellite lesions around large lesions. In borderline leprosy, skin lesions are numerous but remain asymmetrical. The lesions are usually plaques rather than macules and exhibit satellite lesions. Nerve involvement in borderline leprosy is manifested as thickening or tenderness of local nerves, but the skin lesions retain sensation. Borderline lepromatous leprosy is characterized by numerous symmetrical small macules, papules, plaques, and nodules but not the diffuse skin infiltration found in full-blown lepromatous leprosy. Unlike tuberculoid and lepromatous leprosy, the borderline forms are unstable and progress to the lepromatous form over time unless effective treatment is provided. Reactional states, including both reversal reactions and downgrading reactions, occur in people with borderline forms of leprosy.

Reactional States

People with leprosy who may otherwise avoid care may exhibit acute reactional symptoms and signs. Physicians in developed countries may encounter patients with reactional states in acute care settings.

Type 1 reactions, which are mediated by cellular immune responses to *M. leprae* antigens in skin lesions and nerves, occur in people with borderline tuberculoid, borderline, and borderline lepromatous leprosy. Type 1 reactions are frequently accompanied by worsening of peripheral nerve manifestations and may result in permanent nerve damage; they should be considered medical emergencies. Reversal reactions, which are type 1 reactions that occur after initiation of chemotherapy for leprosy or human immunodeficiency virus (HIV) infection, are associated with enhanced T_H1 immune responses that develop in people with a large burden of *M. leprae;* they are most severe in those with borderline lepromatous leprosy. Downgrading reactions occur in association with the transition of borderline disease toward the lepromatous form. Although the immune mechanisms that underlie reversal reactions and downgrading reactions are believed to be distinct, their clinical manifestations are indistinguishable. Type 1 reactions may have an acute or insidious onset, and they are characterized by inflammation of preexisting skin and nerve lesions. Skin lesions, which become erythematous and edematous, may also become tender and thereby resemble cellulitis, but type 1 reactions are not accompanied by fever or other systemic symptoms or signs. Increased expression of TNF has been found in lesions during type 1 reactions and may contribute to the clinical and functional consequences. Moreover, type 1 reactions have been reported when TNF antagonist therapy has been withdrawn after diagnosis of borderline lepromatous leprosy.

Type 2 reactions, also known as erythema nodosum leprosum (ENL), occur in people with borderline lepromatous and lepromatous leprosy; they may be mediated by immune complexes rather than cellular immune responses. Type 2 reactions, which occur most often after initiation of antileprosy chemotherapy or during pregnancy, are generally accompanied by fever and arthralgias. Additional signs of systemic inflammatory disease may appear, including hepatosplenomegaly, lymphadenopathy, arthritis, nephritis, keratitis, and iritis. The skin lesions of ENL resemble those of classic erythema nodosum (Chapter 448), with widely distributed erythematous dermal and subcutaneous nodules whose location is unrelated to the leprosy lesions. Biopsy of ENL lesions shows leukocytoclastic vasculitis.

Leprosy and Human Immunodeficiency Virus

$CD4^+$ T-cell-mediated immunity is essential for control of *M. leprae,* and the extent of T_H1 immunity determines whether an individual will have tuberculoid or lepromatous leprosy. However, coinfection with HIV and depletion of $CD4^+$ T lymphocytes does not affect the rate of progression of leprosy, nor does it cause conversion of tuberculoid leprosy to the lepromatous form. In contrast, type 1 reversal reactions may accompany immune reconstitution subsequent to initiation of effective combination antiretroviral therapy for HIV infection. The manifestations of these reversal reactions are similar to those observed in people who are not infected with HIV.

DIAGNOSIS

The diagnosis of leprosy should be considered in any patient with skin and peripheral nerve manifestations, especially those who have lived in countries where leprosy is endemic. Although leprosy is a chronic infection, its acute complications require prompt diagnosis and therapy to prevent irreversible peripheral nerve damage. It is also important to classify a patient's disease as tuberculoid, lepromatous, or one of the specific borderline forms because correct classification is necessary for selecting optimal therapy and anticipating potential reactional states. Because *M. leprae* cannot be cultured in vitro and there is currently no reliable serologic test or other diagnostic biomarker for leprosy, diagnosis and classification of leprosy depend on the combination of clinical examination, histopathologic evaluation, and acid-fast staining of skin slit or biopsy specimens.

Clinical Examination

Examination of an individual with possible or confirmed leprosy must include evaluation and documentation of the number, location, and characteristics of skin lesions. In addition to descriptions of the skin lesions, accurate classification of leprosy depends on whether the lesions are distributed symmetrically and whether they are hypoesthetic or anesthetic. The examination must also include a search for enlarged and tender peripheral nerves; for the presence of sensory deficits (especially temperature sensation and pain) and skin ulcerations; and for the nature and distribution of motor deficits, muscle atrophy, and contractures. Because some medications used for the treatment of leprosy are contraindicated in pregnancy, women of childbearing age should be evaluated for pregnancy.

Skin Smears and Biopsies

In developing countries, classification of multibacillary or paucibacillary leprosy is made by the combination of clinical examination findings and bacterial counts as determined on acid-fast–stained smears made from skin slits of lesions and skin from cool areas of the body, such as the earlobes. In developed countries, skin biopsies are usually performed instead of skin slits. Skin specimens should be obtained from the active borders of lesions and should include subcutaneous tissue. On hematoxylin-eosin staining, tuberculoid leprosy is characterized by granulomas with giant cells, aggregates of epithelioid macrophages that are neither vacuolated nor foamy, and lymphocytes at the periphery. Although granulomas may be found in other skin diseases, selective destruction of nerve trunks and perineural fibrosis are specific features of leprosy. Acid-fast stains (preferably done with the Fite procedure) show rare or undetectable bacilli in tuberculoid leprosy. Lesions of lepromatous leprosy show poorly organized granulomas without giant cells or lymphocytes; macrophages are foamy and lipid laden. Acid-fast staining of lepromatous leprosy lesions reveals abundant bacilli that usually appear in large clumps ("globi"). The borderline forms of leprosy exhibit less well organized granulomas, with fewer giant cells and lymphocytes but more foamy macrophages and acid-fast bacilli as the spectrum varies from borderline tuberculoid to borderline lepromatous.

Specialized immunohistochemistry stains, such as for $CD4^+$ T lymphocytes or cytokine expression, are useful in research studies but are not currently used for the diagnosis or classification of leprosy. Polymerase chain reaction amplification of *M. leprae* genomic DNA from skin slits or skin biopsy specimens has not yet contributed to enhanced sensitivity or specificity of diagnosis or classification.

Diagnosis of Reactional States

The diagnosis of type 1 reactions is based on clinical findings in a patient with borderline tuberculoid, borderline, or borderline lepromatous leprosy and acute inflammation of preexisting skin lesions, with or without worsening of nerve lesions. Type 1 reactions are not accompanied by systemic findings such as fever or arthritis. At highest risk for type 1 reactions are patients who have recently initiated antileprosy chemotherapy, although type 1 reactions can occur spontaneously. Diagnosis of a type 2 reaction (ENL) is also based on clinical findings of new erythematous subcutaneous or dermal nodules in a patient with borderline lepromatous or lepromatous leprosy. There are currently no diagnostic tests or biomarkers for ENL, and skin biopsy will not distinguish ENL from classic erythema nodosum.

TREATMENT Rx

Agents to Treat Leprosy

The first-line antimicrobial agents for leprosy are dapsone and rifampin. Clofazimine, minocycline, certain fluoroquinolones, and clarithromycin are also useful in specific contexts, including drug intolerance or resistance.

Dapsone is inexpensive and well tolerated, has a long serum half-life (~28 hours), and is safe for use during pregnancy. Glucose-6-phosphate dehydrogenase (G6PD)–deficient individuals (Chapter 164) are susceptible to dapsone-induced methemoglobinemia and hemolysis, and all patients should be screened for G6PD deficiency before starting dapsone. Patients with mild G6PD deficiency (the African type, caused by mutations that lead to instability of the enzyme) can begin dapsone at 25 mg/day but require close monitoring for anemia. Dapsone can also cause bone marrow suppression and profound neutropenia. Other rare adverse effects of dapsone include hepatitis, cholestatic jaundice, and a syndrome characterized by exfoliative dermatitis, generalized lymphadenopathy, fever, and hepatosplenomegaly.

Rifampin, the most bactericidal drug against *M. leprae,* is well absorbed after oral administration and has a serum half-life of approximately 3 hours. Rifampin should never be used as monotherapy because resistance can develop with single point mutations in its target, RNA polymerase II. Because rifampin is bactericidal and rapid release of components from dead bacteria can have pro-inflammatory effects, some experts withhold rifampin during reversal reactions. Adverse effects of rifampin include maculopapular rash, hepatotoxicity, an influenza-like syndrome (most frequent with intermittent therapy), and orange discoloration of tears, urine, saliva, and sweat. Thrombocytopenia occurs occasionally but is not usually severe. Rifampin also induces metabolism and decreases serum concentrations of other drugs, including antiretroviral protease inhibitors and non-nucleoside reverse transcriptase inhibitors, methadone, and oral contraceptives. Rifampin decreases serum concentrations of dapsone, but this effect is not clinically significant with a dapsone dose of 100 mg/day.

Clofazimine is a lipophilic dye that is bacteriostatic against *M. leprae*. It has a very long (~70 days) half-life and appears to have anti-inflammatory activity as well as direct bacteriostatic activity. Because of its anti-inflammatory activity, clofazimine is useful in the treatment of type 1 reactional states. Clofazimine is generally well tolerated; its major side effect is discoloration of the skin, which occurs in nearly all clofazimine-treated patients. The skin discoloration can range from reddish tan to bluish black and can be blotchy, but it is reversible within 6 to 12 months of discontinuation of the drug. In chronic reactional patients maintained with high doses of clofazimine (200 to 300 mg/day), enteropathy with crampy abdominal pain, mild nausea or diarrhea (or both), and even bowel obstruction can develop.

Regimens to Treat Leprosy

Chemotherapy for leprosy involves the use of multiple drugs to optimize the rate of cure and to prevent emergence of drug resistance. The regimen currently recommended in the United States for paucibacillary leprosy consists of dapsone, 100 mg, and rifampin, 600 mg, both given daily for 12 months. The recommended regimen for multibacillary leprosy is dapsone, 100 mg, plus rifampin, 600 mg, and clofazimine, 50 mg, each given daily for 24 months (available at *http://www.hrsa.gov/hansens/clinical/regimens.htm*). In resource-limited countries, where the burden of leprosy is highest, the WHO regimen for paucibacillary leprosy is dapsone, 100 mg daily, plus rifampin, 600 mg once a month, for 6 months. The WHO regimen for multibacillary leprosy is dapsone, 100 mg daily, plus rifampin, 600 mg once a month, plus clofazimine, 50 mg daily, plus an additional dose of clofazimine, 300 mg once a month (available at *http://www.who.int/lep/resources/pubs/en/index.html*). The monthly doses of rifampin and clofazimine should be administered under supervision.

Response to Therapy

Response to effective therapy for leprosy is seen clinically as flattening and resolution of the papules, nodules, or plaques, with or without improvement in nerve function. Clinical improvement may begin within the first months of therapy, but resolution of skin lesions is often delayed as long as 1 to 2 years after completion of therapy. Quantitation of the bacillary load to assess response to treatment is cumbersome, semiquantitative, and not recommended.

Patients who have been adequately treated may experience worsening of nerve and skin symptoms, perhaps because of a late reversal reaction or relapsed leprosy. If skin specimens do not reveal acid-fast organisms, a therapeutic trial of corticosteroids, which will ameliorate the symptoms of reversal reactions but not those of relapsed leprosy, can help make the distinction and assist in choosing subsequent therapy. Patients who experience relapse after treatment of paucibacillary disease should be treated for multibacillary disease because the most likely cause of relapse is previous multibacillary disease that was misclassified. Patients with multibacillary disease who relapse should be retreated with a regimen containing dapsone and rifampin, with the addition of at least two drugs that were not used in the initial treatment regimen, unless susceptibility testing is available and confirms that the organisms remain susceptible to dapsone and rifampin. The choices among additional drugs include minocycline, moxifloxacin, and clarithromycin. Relapsed multibacillary patients may benefit from lifelong maintenance therapy after completing 2 years of a salvage regimen. Because susceptibility testing cannot be performed with in vitro assays, the mouse footpad assay has been used, but it is becoming less available. The alternative approach to determination of susceptibility by sequencing the targets of dapsone and rifampin (*folP1* and *rpoB,* respectively) offers promise.

Treatment of Reactional States

Type 1 reactions may develop before, during, or years after completion of antileprosy chemotherapy. Type 1 reactions that involve worsening of nerve symptoms and findings are medical emergencies because permanent nerve damage can occur. Type 1 reactions usually respond to prednisone at a daily dose of 60 to 80 mg, which can be tapered slowly once symptoms are controlled. Type 1 reactions can also respond to high-dose clofazimine (200 to 300 mg/day), although reactions with worsening nerve symptoms should be treated initially with prednisone. Patients who have type 1 reactions that occur before or during antileprosy chemotherapy and whose reactions include nerve involvement should have rifampin withheld until the worsened nerve symptoms resolve because release of pro-inflammatory components from dying bacteria may contribute to inflammation and nerve damage. Dapsone and clofazimine should be continued during treatment of type 1 reactions.

The treatment of choice for severe type 2 reactions (ENL) is thalidomide, except in pregnant or potentially pregnant women. Thalidomide requires that patients and the prescribing physician be enrolled in the System for Thalidomide Education and Prescribing Safety (STEPS) program to avoid the drug's teratogenic effects. The mechanism of action of thalidomide is incompletely understood but is likely to include inhibition of TNF. The dose of thalidomide for ENL varies, depending on the severity of the reaction. In patients with ENL and high fever, frank arthritis, and large subcutaneous plaques, up to 100 mg four times daily may be required to achieve a clinical response. Once a clinical response is achieved, the dose of thalidomide may be tapered to a maintenance dose of 50 to 100 mg given once daily at night (because thalidomide is sedating). For milder cases of ENL, 50 to 100 mg per night may be sufficient to achieve and to maintain control. ENL in women of childbearing age and thalidomide-unresponsive cases may respond to corticosteroids. Antileprosy chemotherapy, including rifampin, should be continued in patients with ENL.

Other Therapy

Nerve damage in leprosy, which can result in muscle atrophy, contractures, and autoamputation, is the major cause of debility. Supportive care, reconstructive surgery, physical and occupational therapy, and rehabilitation can be extremely valuable in allowing patients to achieve and to maintain optimal function.

PREVENTION

There is currently no effective specific vaccine for leprosy, but several trials have observed a partial protective effect of bacille Calmette-Guérin vaccination. It is likely that improved understanding of transmission of *M. leprae* will be generated by the use of DNA-based strain typing, so better preventive measures are likely to become available in the near future.

PROGNOSIS

Multidrug chemotherapy cures a high proportion of people with paucibacillary and multibacillary leprosy. The currently recommended regimens provide high rates of response, with relapse rates of approximately 0.1% per year in paucibacillary cases and up to 5% per year in multibacillary cases. Some cases of paucibacillary leprosy may enter remission or even self-cure, but all cases of multibacillary leprosy are progressive. Because of its efficacy and low toxicity, multidrug chemotherapy should be used in all people in whom leprosy is diagnosed to minimize long-term morbidity.

RICKETTSIAL INFECTIONS

DIDIER RAOULT

DEFINITION

Rickettsioses are emerging infectious diseases. Because of better diagnostic tools and changes in tick exposure, many new rickettsial diseases have been described in the past 20 years. Three families of diseases are grouped under this name: rickettsioses, ehrlichioses and anaplasmoses, and Q fever.

The Pathogens

The agents of rickettsial diseases (formerly grouped in the order Rickettsiales) are small gram-negative bacteria that grow within eukaryotic cells. They have never been grown in axenic media thus far and for culture require living hosts such as cell cultures, embryonated eggs, or susceptible animals. With the exception of *Rickettsia prowazekii,* the agent of epidemic typhus, these bacteria infect humans incidentally and are mainly animal pathogens. On the basis of molecular phylogeny, the bacteria causing rickettsial diseases have been reclassified into three phyla (Table 335-1).

Because of their difficult growth in vitro, the main diagnostic tool for rickettsioses is serology. Serologic evaluation is frequently hampered by late positivity and cross-reactivity. The development of direct staining in blood

smears or skin biopsy samples as well as polymerase chain reaction (PCR) amplification of DNA in blood samples or biopsy specimens has considerably helped identification at the species level and led to the description of emerging pathogens.

RICKETTSIOSES (DISEASES CAUSED BY *RICKETTSIA* SPECIES AND *ORIENTIA TSUTSUGAMUSHI*)

DEFINITION

Rickettsia spp are small gram-negative bacteria that multiply free in the cytoplasm of their host cells. The target cells in humans are endothelial cells or monocytes, and vasculitis is the most prominent clinical manifestation. These bacteria invade cells by phagocytosis and escape the phagosome vacuole.

The genome of *Rickettsia* is small, between 1.1 and 1.6 Mb; some have plasmids and potential for conjugation. These bacteria have a family of outer membrane proteins of the surface cell antigen family, including rOmpA (lacking in typhus group) and rOmpB. These proteins are major antigens that help identify the rickettsial species, and their encoding genes are used for amplification and sequencing for diagnostic or taxonomic purposes. Among rickettsiae, two subgroups, the typhus group and the spotted fever group, were identified on the basis of growth conditions and antigenicity. A specific group antigen, determined to be lipopolysaccharide, has been identified. The optimal growth temperature is 37° C for the typhus group and 32° to 35° C for the spotted fever group. The complete genome sequencing of *R. prowazekii* (from the typhus group) showed that it is mainly a subset of *Rickettsia conorii* (a member of the spotted fever group).

Tick-Borne Rickettsioses

ROCKY MOUNTAIN SPOTTED FEVER

EPIDEMIOLOGY

Rocky Mountain spotted fever (RMSF), the most severe of the rickettsioses, is caused by *Rickettsia rickettsii* (Table 335-2). It is the major tick-transmitted rickettsiosis (Chapter 367) recognized in America, with *Rickettsia africae* in the West Indies, *Rickettsia parkeri* in the southern states of the United States, and, perhaps, *Rickettsia amblyommii*. It was described first in the 19th century in the western United States. RMSF is prevalent in at least 44 states in the United States (Fig. 335-1) and in Central and South America (Argentina, Brazil, Colombia, Costa Rica, Mexico, and Panama).

Rickettsia is transmitted transovarially to tick progeny from one generation to the next. The infecting ticks are mainly *Dermacentor andersoni* (a wood tick) in the western United States; *Dermacentor variabilis* (the American dog tick) in the East, the Midwest, and the South; and *Rhipicephalus sanguineus* in Arizona. In Central and South America, *Amblyomma cajennense* is the major vector. Humans are infected through infected saliva after a tick bite. The duration of attachment is critical in any tick-borne rickettsiosis, and transmission is unlikely when the tick feeds for less than 20 hours. The tick bite is painless and frequently unnoticed. Rarely, an eschar at the site of the tick bite is observed in RMSF. The epidemiology of RMSF undergoes largely unexplained yearly variations. This temporal repartition is determined by tick activity and human encounter. More than 500 cases occur each year, and more than 90% are reported from April to September. The disease is more prevalent in children younger than 10 years. A recent increase has been reported, but the current

diagnostic tools do not allow discrimination between RMSF and other rickettsioses.

CLINICAL MANIFESTATIONS

Two to 14 days after the tick bite, fever and headaches appear. The fever is high (temperature >102° F) and associated with nonspecific symptoms, including malaise, myalgias, nausea, vomiting, anorexia, and diarrhea. At this stage, RMSF is not frequently diagnosed, but during the "tick season," patients with high fever who live in or have a history of travel to an endemic location and, possibly, a history of tick bite should be considered as possibly having RMSF.

The most characteristic feature is a rash. However, the classic triad of fever, headache, and rash is present in only 44% of confirmed cases. Rash is found in 14% of cases on the first day of disease and in less than 50% in the first 3 days. The rash is macular; it appears first on the ankles and wrists and then generalizes. Spots are 1 to 5 mm in diameter and can evolve from pink to purpuric. A rash can appear later or even not at all; Rocky Mountain "spotless" fever represented 34% of cases in a series from the Centers for Disease

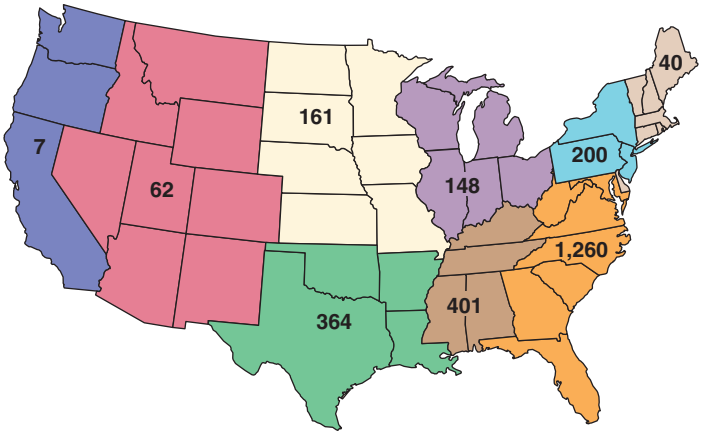

FIGURE 335-1. Number of reported cases of Rocky Mountain spotted fever by region, 1994 to 1998.

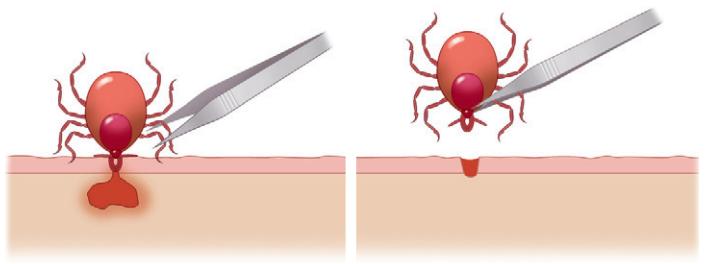

FIGURE 335-2. Tick removal technique.

Control and Prevention (CDC). Involvement of the palms and soles theoretically differentiates the typhus diseases (in which it is absent) from the spotted fevers.

Untreated patients worsen progressively. The disease is associated in various degrees with general manifestations related to vascular inflammation and increased vascular permeability and with multiple organ involvement that can lead to multiple organ dysfunction syndrome (MODS). In severe forms, patients suffer from edema, hypovolemia, hypoalbuminemia, and hypotension leading to shock. In very severe cases, necrosis and gangrene of the extremities occur. In some instances, noncardiogenic pulmonary edema develops; pulmonary involvement leading to respiratory distress can cause death. Renal failure can result either from hypovolemia and shock and be reversible or from acute tubular necrosis and require hemodialysis. The usual neurologic symptoms are confusion, lethargy, and stupor. In severe cases, delirium, coma, and seizures are observed. Cerebrospinal fluid (CSF) sampling exhibits meningitis in a third of cases; in general, a few monocyte cells (10 to 100) are observed, along with increased protein but normal glucose levels. Heart involvement can cause arrhythmia. Liver involvement is manifested as an increase in transaminases in a third of patients and jaundice in 8%. Jaundice can also reflect hemolysis. Intestinal tract involvement is manifested as abdominal pain, diarrhea, vomiting, and severe bleeding (upper gastrointestinal hemorrhage can cause death). Ocular involvement consists of conjunctivitis and retinal abnormalities, including hemorrhages, papilledema, and arterial occlusion.

The blood cell count shows a normal number of white blood cells but often immature myeloid cells. Thrombocytopenia is observed in 30 to 50% of cases and may be marked in severe cases. Anemia develops in 30% of patients. Coagulopathy with decreases in clotting factors (including fibrinogen) and prolonged coagulation times may contribute to bleeding; albuminemia may be low and proteins of the acute phase response increased (C-reactive protein, ferritin, fibrinogen). Hyponatremia and hypocalcemia may be noted and correlate with severity, as with an increase in creatininemia. Increased concentrations of serum enzymes such as aminotransferases (aspartate [AST] and alanine [ALT] aminotransferase), lactate dehydrogenase (LDH), and creatine kinase usually reflect the severity of organ involvement, including the lung, heart, and liver and multifocal rhabdomyolysis.

DIAGNOSIS

The diagnosis of RMSF should be based on clinical and epidemiologic findings and lead to early use of doxycycline. The most important clue is unexplained fever in a patient with a history of tick exposure in an endemic area. When a rash is present, RMSF should be suspected and the patient treated accordingly unless another cause is demonstrated. The differential diagnosis includes other rickettsioses (such as those caused by *R. parkeri* in southeastern states), meningococcemia, enterovirus infections, typhoid, leptospirosis, ehrlichiosis, gonococcemia, toxic shock syndrome, syphilis, rubella, measles, and the Kawasaki syndrome. Drug hypersensitivity, especially after antimicrobial use for febrile illness, is sometimes confused with RMSF.

The main diagnostic test relies on serology, and treatment should never be delayed to obtain diagnostic confirmation. Criteria for laboratory confirmation include a fourfold or greater change in antibody titer determined by serology (measured by immunofluorescence assay [IFA], complement fixation, or latex agglutination) and direct detection of the bacterium by demonstration of specific antigens by immunodetection, genomic amplification by PCR, or culture. A biopsy specimen of a skin lesion is the best sample for this purpose. Culture of *Rickettsia* takes 3 to 7 days and is restricted to specialized laboratories. It is performed on cell lines such as Vero, L929, or HEL cells. Immunodetection by IFA or immunohistochemistry is sensitive and specific. It can be performed with frozen or fixed and paraffin-embedded material and allows retrospective diagnosis. PCR amplification and identification give promising results in rickettsioses in general but have not been properly evaluated for diagnosis of RMSF. Skin biopsy and direct detection in removed ticks yield the best results because blood contains inhibitors and only few copies of rickettsial DNA.

Two serum samples should be tested (early and convalescent). The early serum is usually negative because patients seroconvert between the 7th and 15th days. IFA is highly sensitive and specific. A cutoff value of 1/64 for total immunoglobulin and 1/32 for IgM antibodies is required for diagnosis. The latex agglutination cutoff is 1/64 or 1/128. Cross-reactive antibodies have been reported with infections caused by other rickettsioses, *Ehrlichia, Bartonella, Legionella,* and *Proteus.* False-positives, including IgM, may be observed when rheumatoid factor is present in serum and in patients with viral infection generating nonspecific B-lymphocyte proliferation (cytomegalovirus, Epstein-Barr virus). Complement fixation (which lacks sensitivity) and the Weil-Felix test (using antibodies that cross-react with *Proteus* strains) should not be used.

TREATMENT

Rx

The prognosis for patients with RMSF depends on the timing of antimicrobial treatment. Doxycycline saves patients with RMSF. The recommended dose is 100 mg two times a day, and treatment should be continued for at least 3 days after the fever resolves. Oral treatment is effective, but in patients with gastric intolerance or coma, the intravenous route is advised. Several antimicrobials are effective in vitro against *R. rickettsii,* including fluoroquinolones, rifampin, and new macrolide antimicrobials (but not erythromycin), but lack of clinical experience precludes their use for RMSF. β-Lactam antimicrobials, aminoglycosides, and cotrimoxazole are not effective.

Severely ill patients should be treated in intensive care units and fluid administration carefully monitored. Mechanical ventilation is used in case of respiratory distress, hemodialysis in patients with renal insufficiency, and antiseizure drugs in patients with seizures. Anemia and coagulation abnormalities may also be corrected. For patients with gangrene of the extremities, amputation may be necessary. Glucocorticoids have not proved useful.

PREVENTION

Prevention is based on avoidance of tick bites (Chapter 367) by use of repellents, protective garments, or both. To discourage tick attachment, repellents containing permethrin can be sprayed on boots and clothing and will last for several days. Repellents containing DEET (*N,N*-diethyl-*m*-toluamide) can be applied to the skin but will last only a few hours before reapplication is necessary. It is also useful to check for ticks after exposure. Careful examination of the scalp, groin, and axillae is recommended. The tick can be removed by forceps, and the skin should be disinfected (Fig. 335-2).

PROGNOSIS

The evolution of RMSF depends strongly on the timing of diagnosis and antimicrobial treatment. The current fatality rate is 2.4% on the basis of a 4-year national survey in the United States (27 deaths were attributable to

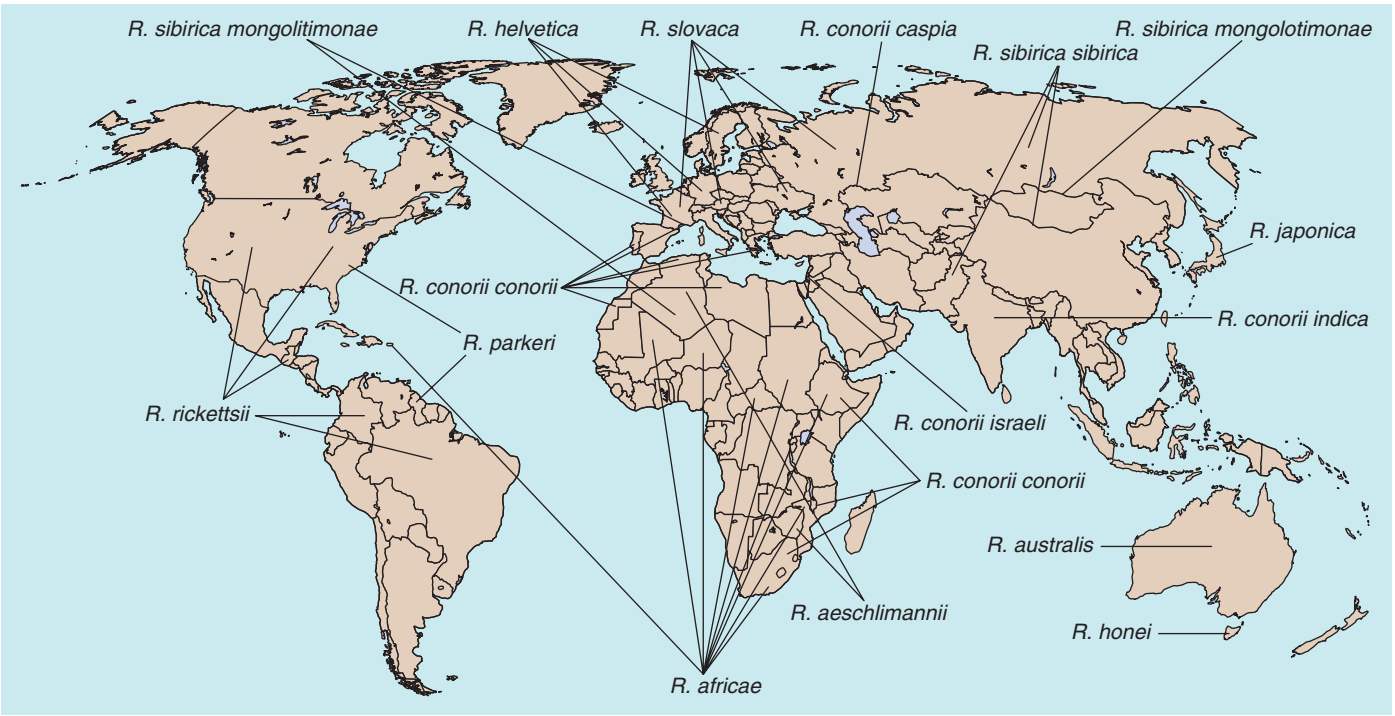

FIGURE 335-3. Geographic distribution of tick-borne rickettsioses.

RMSF during this period). This rate is currently lowering, but this may result from reporting of confounding rickettsial diseases. No significant difference in outcome was observed between blacks and whites, but the case-fatality rate was highest in people older than 70 years (9%). Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency were more susceptible to severe infection. Chloramphenicol was associated with a poorer outcome than treatment with doxycycline. Recovery from RMSF is usually complete, but neurologic sequelae can remain, and amputation of extremities may be necessary after gangrene.

OTHER TICK-BORNE RICKETTSIOSES

EPIDEMIOLOGY

Like other tick-transmitted diseases (Chapter 367), rickettsioses have a limited geographic distribution that is determined mainly by the tick vector ecology (Fig. 335-3). *R. parkeri* has recently been identified in the United States and South America. *R. conorii* is found in Europe around the Mediterranean and Caspian seas (*caspia* subspecies); *Rickettsia slovaca, Rickettsia raoultii,* and possibly *Rickettsia helvetica* in western and central Europe; and *Rickettsia sibirica mongolotimonae* in France and Greece. Elsewhere, a number of specific agents of rickettsial disease have been identified (see Table 335-2).

CLINICAL MANIFESTATIONS

R. conorii comprises different but closely related subspecies. Many names are given to the infection caused by *R. conorii:* Mediterranean spotted fever (MSF), boutonneuse fever, Marseilles fever, Kenya tick typhus (caused by the subspecies *R. conorii conorii*), Astrakhan fever (caused by *R. conorii caspia*), Israeli spotted fever (caused by *R. conorii israeli*), and Indian tick typhus (caused by *R. conorii indica*). *R. conorii* is closely related to *R. rickettsii,* with which it shares many common antigens that generate cross-reactive antibodies. MSF resembles RMSF but has several specificities. The spontaneous evolution is milder, but a fatality rate of 1.5 to 2.5% in hospitalized patients is still observed. A malignant form of the disease that includes purpuric rash, shock, and MODS has been described in alcoholic, diabetic, human immunodeficiency virus (HIV)–infected, and old or debilitated patients. The typical clinical manifestation is that of a patient with fever, a rash, and a tache noire (i.e., a black eschar at the site of the tick bite). A tache noire is found in 50 to 80% of cases. Multiple lesions do not occur because the dog tick vector, *R. sanguineus,* seldom bites humans. The rash is frequently clearly papular, which led to one of the names of the disease, boutonneuse fever. Israeli tick bite fever and Astrakhan fever appear to be milder than typical MSF, and tache noire is usually lacking.

R. africae, which causes African tick bite fever, may be responsible for most of the rickettsioses worldwide. It is extremely common in travelers visiting southern Africa. It is transmitted by African ticks, *Amblyomma hebraeum* and *Amblyomma africanum.* These ticks are often infected; as many as 60% can harbor *R. africae.* They usually feed on ungulates but attack human beings in groups and cause a high prevalence of infection in rural Africa (60% of tested patients exhibit antibodies) and in travelers. The tick attacks typically generate clusters of cases in Safari tourists. The disease differs from MSF in that it is much milder, fever is frequently absent, a rash is observed in only half the patients, and the rash may be vesicular (which has never been reported in confirmed MSF). Moreover, several taches noires are frequently observed. They are prevalently found on the lower limbs and often associated with draining lymphadenopathy in the groin.

Japanese spotted fever (caused by *Rickettsia japonica*) and Siberian tick typhus (caused by *R. sibirica*) resemble MSF. Infections caused by *R. sibirica mongolitimonae* resemble MSF but in some cases exhibit specific clinical features, including a tache noire, groin lymphadenopathy, and lymphangitis joining these two lesions. The disease has recently been named lymphangitis-associated rickettsiosis. *Rickettsia australis* (Queensland tick typhus) and *Rickettsia honei* (Flinders Island spotted fever) cause diseases resembling MSF, but their rash can be vesicular.

R. slovaca and *R. raoultii* cause a disease apparently common in Europe named scalp eschar and neck lymphadenopathy transmitted by ticks (Hungary, Germany, France, Spain). Its tick vectors, *Dermacentor marginatus* and *Dermacentor reticulatus,* preferentially bite in cold months and bite the scalp because they prefer hairy prey. In contrast to other tick-borne rickettsioses, the disease is more prevalent in children and women. It is rarely exanthematic; the typical clinical picture consists of an erythematous skin lesion at the site of the tick bite on the scalp that ranges from 2 to 8 cm in diameter and a draining neck lymphadenopathy (which may be painful). Rarely, patients may exhibit fever and a rash. Deep postinfectious asthenia and residual alopecia at the site of the tick bite can be observed. The occurrence of this rickettsiosis without rash may stimulate research on other new rickettsial diseases with only localized manifestations.

DIAGNOSIS

The diagnosis of other tick-borne rickettsioses is similar to that of RMSF, mainly by serology (IFA; see earlier). An exception is *R. slovaca* infection, in which the serologic response is weak, possibly because of its lack of general

infection; in this case, PCR of a skin lesion sample by a swab or a lymph node aspirate is the best solution. In *R. africae* infection, the serologic response occurs later than in RMSF and MSF, and late serum samples are therefore recommended.

TREATMENT Rx

Doxycycline (100 mg twice daily for adults or 4.4 mg/kg body weight per day in two divided doses for children under 45.4 kg [100 lb]) is the drug of choice for treatment. A single day of therapy usually suffices, but in adults with more severe disease, it should be administered until the patient is afebrile for 24 hours. In pregnant women, josamycin, a macrolide antimicrobial, has proved efficient at a dose of 3 g daily for 7 days for MSF; quinolones and newer macrolide antimicrobials give results comparable to those of doxycycline but with longer regimens.

Flea-Transmitted Diseases

Fleas (Chapter 367) can harbor two rickettsial species: *Rickettsia typhi,* the agent of murine typhus; and *Rickettsia felis,* the agent of flea-borne spotted fever. Both rickettsiae can be transmitted transovarially in the flea. Vectors are *Xenopsylla cheopis* and *Pulex irritans* but also *Ctenocephalides felis,* a cat flea. Rats, cats, opossums, and dogs can propagate infected fleas. These reservoirs and vectors are distributed worldwide, and thus these diseases have a global distribution. Fleas can be infected by both species at the same time.

MURINE TYPHUS

DEFINITION

Fleas are usually infected by *R. typhi* when feeding on apparently healthy rats that have blood-borne infection. Humans and other mammals are infected through autoinoculation by scratching a fleabite that is contaminated with feces from an infected flea. Murine typhus, because of its cycle, is more prevalent in hot and humid areas, when rats proliferate.

EPIDEMIOLOGY

In the United States, 50 to 100 cases are reported yearly, mainly in southern California and southern Texas. In California, a transmission cycle involving opossums and cat fleas has been demonstrated. Murine typhus is extremely common in Southeast Asia and North Africa and is a common cause of fever in travelers.

CLINICAL MANIFESTATIONS

On the basis of studies of infected volunteers, the incubation period is generally 8 to 16 days. The disease begins with abrupt fever, nausea, vomiting, myalgias, arthralgias, and headache. A rash is observed in 40 to 50% of patients about 6 days after the onset. It is detected even less frequently in patients with dark skin. The rash begins as pink maculae that can evolve to be maculopapular. It is often discrete, starting in the axilla; it generalizes to the trunk but does not usually involve the face, palms, and soles. In severe cases, it can become purpuric. The most frequently involved organ is the lung. A third of patients have a cough, and in a fourth, a nonspecific interstitial pneumonia develops that is sometimes associated with a pleural effusion. In severe forms, respiratory failure occurs. In patients with severe disease, neurologic symptoms range from confusion and stupor to coma and seizures. Cerebral hemorrhages may occur. Digestive involvement can be manifested as vomiting, abdominal pain, jaundice, and, in severe cases, hematemesis.

The white blood cell count shows leukopenia and then leukocytosis. Thrombocytopenia can be noted as well as anemia, specifically when hemolysis is observed (frequently in patients with G6PD deficiency). A moderate increase in serum liver enzymes is common. In patients with severe disease, hyponatremia and hypoalbuminemia are observed.

DIAGNOSIS

The diagnosis of murine typhus is based mainly on serology (IFA) with titers similar to those of RMSF. On serologic evaluation, *R. typhi* cross-reacts with *R. prowazekii;* it can be differentiated either by comparing titers (two dilutions or more if IgG and IgM titers are discriminative) or by cross-adsorption. In this technique, the serum is absorbed with either antigen and then retested, and the causative agent is that removing antibodies to both bacteria. Skin biopsies and blood samples for culture and PCR may be valuable.

TREATMENT Rx

Treatment is the same as that for RMSF.

PROGNOSIS

The prognosis is usually favorable, but 10% of patients require intensive care and 1% die. Older patients and those with G6PD deficiency (Chapter 164) or chronic debilitating conditions are at higher risk.

FLEA-BORNE SPOTTED FEVER CAUSED BY *RICKETTSIA FELIS*

R. felis is mainly transmitted transovarially. Its genome comprises one or two plasmids, one being apparently conjugative. This is a new, incompletely defined disease. The bacterium is found in fleas in the Americas, Asia, Europe, Africa, and New Zealand. Isolated cases have been reported from Texas, Mexico, Brazil, France, and Germany. Reported cases all exhibited fever, a rash in six of seven cases, and inoculation eschar in some cases. The diagnosis can be based on serologic evaluation using specific *R. felis* antigen or PCR of blood or skin biopsy samples. Treatment has not been established, but the bacterium is highly susceptible to doxycycline and resistant to erythromycin.

Louse and Mite Infections

EPIDEMIC LOUSE-BORNE TYPHUS

EPIDEMIOLOGY

The human body louse (Chapter 367) lives in clothes and multiplies rapidly when cold weather and lack of hygiene allow it to. The body louse transmits three bacterial diseases: trench fever (caused by *Bartonella quintana*), relapsing fever (caused by *Borrelia recurrentis*), and exanthematic typhus (caused by *R. prowazekii*). The name *typhus* is derived from the Greek *tuphos,* which describes the neurologic condition associated with this disease and with typhoid. The body louse is prevalent during war, in poor countries, and in the homeless population of rich countries, including the United States and Europe. A 100,000-person outbreak of typhus was reported during the civil war in Burundi in 1997, and cases were reported in Russia, Peru, the United States, Algeria, and France in the 1990s. Louse-transmitted diseases killed more people than weapons did during central and eastern European wars in the 19th and 20th centuries.

The epidemiology of *R. prowazekii* is mainly related to humans as reservoirs and lice as vectors. In the United States, the eastern flying squirrel *(Glaucomys volans volans)* is also a reservoir, and its fleas, lice, and mites can be infected.

R. prowazekii has also been found in *Amblyomma* ticks, but their role is not known. The louse is infected when feeding on blood, which it does five times a day. *R. prowazekii* multiplies in the gut of the louse and is released in feces; after a few days, it destroys intestinal epithelium, which causes bright red blood to spread from the gut (typhus was also named the red louse disease). The patient is usually contaminated by infected feces (in which *R. prowazekii* survives for weeks), through aerosols, or by skin autoinoculation after scratching. Patients who recover from typhus may harbor the bacterium in a dormant form and suffer relapses under stressful conditions years later; this relapsing form is called Brill-Zinsser disease. During the relapse, a bacteremia occurs that may allow the start of a new outbreak if lice bite the patient.

CLINICAL MANIFESTATIONS

Typhus begins abruptly with fever, headaches, and myalgias, which may have led to the crouched posture termed sutama in the largest recent outbreak in Burundi. Cough and neurologic signs (stupor, confusion, or coma) are common. A rash is observed in 20 to 80% of patients, depending on the population studied; it is probably commonly underobserved on dark skin. It generally starts in the axilla and then spreads. The rash is usually macular but can be papular or purpuric in severe cases. In some cases, diarrhea and jaundice are reported. Splenomegaly is infrequently found. In severe cases, shock occurs and the fatality rate is 20 to 30%. Leukopenia, thrombocytopenia, and anemia as well as an increase in serum hepatic enzymes may be noted.

Sylvatic typhus in the United States is caused by an *R. prowazekii* variant and is a milder disease. The most prominent clinical features are neurologic. Few cases have been described, and nearly all occurred in areas where the eastern flying squirrel is found, east of the Mississippi.

Brill-Zinsser disease is difficult to diagnose because rash is rare and recent exposure to lice can be lacking. Interviewing the patient may reveal prior exposure to lice, associated or not with a diagnosis of typhus in previous years. The disease is mild and the prognosis is good.

DIAGNOSIS

The diagnosis of typhus should be considered when grouped cases of high fever with confusion are observed in patients exposed to lice. The most common diagnostic error is to attribute the findings to typhoid, which can have fatal consequences because the antimicrobials typically prescribed for that condition (β-lactams, cotrimoxazole, and quinolones) are ineffective treatment of typhus. In tropical countries, typhus is frequently confused with malaria, hemorrhagic fever, and dengue. In people with lice, it can be confused with trench fever and relapsing fever, but treatment for both can be prescribed.

The diagnosis of typhus should be clinical because the fatality rate is high and the treatment safe and efficient. Any outbreak of unexplained fever in unhygienic environments may suggest typhus, including outbreaks during civil wars (such as in Algeria, Rwanda, and Burundi), during social collapses (such as in Russia and Ukraine), in jails (such as in Rwanda and Burundi), and in chronically poor and cold countries. The diagnosis is based mainly on serology, in which there is cross-reaction with *R. typhi* (see earlier). When the investigation is performed under difficult field conditions, a drop of blood applied on filter paper and sent to a reference laboratory is valuable for serologic testing. Culture and PCR are helpful and can be performed with a skin biopsy sample or blood. Lice are good diagnostic tools because they can be tested even when dry and can be sent in closed containers without specific temperature conditions.

TREATMENT Rx

Treatment of typhus is extremely simple, cheap, and effective; 200 mg of doxycycline orally in two divided doses is life-saving. Comatose patients should be treated parenterally. In allergic patients, chloramphenicol is the only known alternative, prescribed at a dose of 2 g/day for 10 days. There is no current vaccination, and the fight against lice is the major prevention strategy. Because lice are fragile, changing and boiling clothes are efficient. When this is not possible, insecticide (primarily permethrin) or ivermectin orally should be used.

SCRUB TYPHUS *(ORIENTIA TSUTSUGAMUSHI)*

EPIDEMIOLOGY

Scrub typhus is transmitted by the bite of trombiculid mite (Chapter 367) larvae infected by *O. tsutsugamushi.* These mites, also named chiggers, are vertically infected through their mother. Scrub typhus distribution is limited to a triangle extending between northern Japan, eastern Australia, and eastern Russia and includes the Far East, China, and the Indian subcontinent. All together, 1 billion people may be exposed. Seasonality is determined by the emergence of larvae. It is one of the three most common causes of prolonged fever in rural Asia; in temperate zones, it occurs mainly in autumn and to a lesser extent in spring. *O. tsutsugamushi* species have a wide heterogenicity that may allow the definition of several species, but a single species is currently recognized with many serotypes. The more frequent are Kato, Karp, Gilliam, and Kawasaki.

CLINICAL MANIFESTATIONS

The disease occurs in patients exposed to rural or urban foci of scrub typhus after a delay of 10 or more days. The onset is usually sudden and includes fever, headache, and myalgias. Attentive examination may reveal an inoculation eschar at the site of the mite bite and tender draining lymph nodes. Generalized lymphadenopathy and rash may be observed. The symptoms vary according to organ involvement. Neuromeningeal symptoms are relatively common. Severe forms can be manifested as septic shock. Abortion commonly occurs in pregnant women.

Leukopenia, thrombocytopenia, and increased levels of hepatic enzymes can occur. Evolution depends on the hosts and strains, and the fatality rate ranges from 0 to 30%. Scrub typhus is not more severe in HIV-infected patients, and surprisingly, HIV suppressive factors appear to be produced during infection. Relapses may occur in this disease.

DIAGNOSIS

Diagnosis may be difficult. Because the clinical features are frequently not specific, epidemiologic factors are critical. A diagnosis of infectious mononucleosis has erroneously been made in patients with scrub typhus. The bacterium can be detected by culture (in cells or mice) or by PCR in blood and biopsy specimens. The serologic technique first used was agglutination of *Proteus mirabilis* serotype OXK in the Weil-Felix reaction. This test lacks sensitivity and specificity and should be replaced by IFA or enzyme-linked immunosorbent assay tests using the three or four major serotypes.

TREATMENT Rx

Chloramphenicol was the mainstay of treatment for many years, but now doxycycline is recommended. Single-day treatment with doxycycline is followed by relapses, and even repeated treatment for 2 days at a 7-day interval does not prevent all relapses. Hence, the currently recommended regimen is doxycycline, 100 mg orally twice a day, for 7 days. Cases resistant to doxycycline have been reported, and rifampin (600 mg orally daily) is a reasonable alternative. Quinolones should be avoided. Prophylaxis is based on the use of repellents.

RICKETTSIALPOX *(RICKETTSIA AKARI)*

EPIDEMIOLOGY

Rickettsialpox was first described in New York City, where it is still prevalent, by a general practitioner in 1946. *R. akari,* the causal agent, is transmitted by the bite of the mouse mite *(Liponyssoides sanguineus)*. Its prevalence is probably underestimated; an active search revealed 13 cases in a New York hospital in the 1980s. Cases have been reported in Arizona, Utah, and Ohio. After the terrorist attacks of 9/11/01, cases of black skin eschars were investigated as possible anthrax in New York but were in fact rickettsialpox. High seroprevalence was reported among intravenous drug users in Baltimore. Cases have also been reported from Russia, Ukraine, Slovenia, and Korea.

CLINICAL MANIFESTATIONS

Ten days after the mite bite, the beginning of the illness is marked by fever, headache, and myalgia. Careful examination reveals an inoculation eschar and a draining lymphadenopathy that could be mistaken for cutaneous anthrax. Two to 6 days later, a rash appears and comprises 5 to 40 macular, then papular and vesicular spots. This aspect led to the name of the disease. It is frequently mistaken for chickenpox. The disease is usually mild.

DIAGNOSIS

The diagnosis can be made by serologic testing with IFA. Specific antigens react with high titer, but antibodies to other *Rickettsia* may be detected. The diagnosis may also be made on skin specimens by culture, immunodetection, or PCR.

TREATMENT Rx

Doxycycline is highly efficient in these patients. Prevention is based on the control of mice.

EHRLICHIOSES AND ANAPLASMOSES

DEFINITION

The index case of modern ehrlichiosis was reported in the United States in 1987. The patient died of fever, presumably acquired after a tick bite in Arkansas, despite receiving chloramphenicol. The patient had several initially confusing diagnostic features; on blood smears, morulae in polymorphonuclear (PMN) cells were seen, and antibodies to *Ehrlichia canis,* a pathogen of dogs but not humans, were detected. He was then thought to have *Ehrlichia chaffeensis,* but this bacterium infects monocytes, not PMN cells. A diagnosis of *Anaplasma phagocytophilum* infection (or human granulocytic ehrlichiosis [HGE]) was considered, but the tick vector of this disease is absent in Arkansas. The most likely diagnosis is currently believed to be

infection with *Ehrlichia ewingii,* an agent transmitted by *Amblyomma americanum* that is prevalent in Arkansas, infects PMN cells, and cross-reacts with *E. canis,* although it typically affects immunocompromised hosts. This case illustrates the progress in knowledge on ehrlichioses and how difficult it is to conclude the etiology of an atypical infection definitively on the basis of serology alone.

All *Ehrlichia* pathogenic for humans except *E. ewingii* can be cultured. The ehrlichiae have been reclassified into four genera, mainly on the basis of 16S ribosomal RNA–derived phylogenetic analysis. Two are the tick-associated genera *Ehrlichia* and *Anaplasma* (*A. phagocytophilum,* or the HGE agent that was formerly named *Ehrlichia phagocytophila*). One is a helminth-associated genus, *Neorickettsia,* including *Neorickettsia sennetsu* (formerly *Rickettsia sennetsu,* then *Ehrlichia sennetsu*). The fourth is *Wolbachia pipientis,* a bacterium associated with arthropods (insects, crustaceans, and acarids) and helminth worms (mainly filaria). These organisms elicit cross-reactive antibodies.

Ehrlichiae multiply exclusively in vacuoles of their eukaryotic cell host, where they form clusters known as morulae. The vacuoles are derived from phagosomes and help the organism escape bactericidal lysosomal fusion. In humans, ehrlichiae are associated with monocytes *(E. chaffeensis, E. canis, N. sennetsu)* or PMN cells *(A. phagocytophilum, E. ewingii).*

Ehrlichioses can be acquired through tick bites, by ingestion of nematodes through contaminated water or animals (fish, snails), or as a consequence of filariasis.

American Human Monocytic Ehrlichiosis *(Ehrlichia chaffeensis)*

EPIDEMIOLOGY

Human monocytic ehrlichiosis (HME) is caused by *E. chaffeensis.* This organism has been isolated or identified by PCR mainly in the United States, in the southeastern, south central, and mid-Atlantic states and California (Table 335-3). In the United States, *A. americanum* (Lone Star tick) is the vector (Chapter 367) and the white-tailed deer is the main mammalian reservoir. Immature ticks are infected by blood while feeding on persistently bacteremic reservoirs. *E. chaffeensis* is transmitted transstadially in the tick and infects its next host (deer or human) during its next blood meal. The disease epidemiology reflects the tick habitat and activity, with most cases being contracted in the southern United States, in rural areas, and from April to September. In highly endemic areas, the incidence can reach 100 cases per 100,000 inhabitants. The severity is age dependent, which may explain the lower incidence reported in children. Males are more often affected than females, with a sex ratio of 4:1.

CLINICAL MANIFESTATIONS

The incubation lasts for 7 to 10 days after an identified tick exposure in 80% of cases. Patients have fever, headache, malaise, nausea, and anorexia. Untreated patients worsen and may require intensive care. Digestive tract involvement consisting of nausea, vomiting, diarrhea, and abdominal pain is common. Central nervous system infection is manifested in many forms from confusion to coma. A rash is observed in a third of cases and lymphadenopathy in a fourth. In severe forms, sepsis syndrome and MODS may occur.

The white blood cell count typically shows leukopenia, caused by both lymphopenia and neutropenia. Thrombocytopenia is also frequently noticed; anemia may appear later. Coagulopathy may be observed in severe forms. Increases in serum enzymes, including AST, ALT, and LDH, may reflect organ involvement, as does creatininemia. CSF examination in patients with neurologic symptoms reveals pleocytosis and increased protein levels. Cells may be monocytic or PMN. The prognosis depends on early antimicrobial treatment, but the fatality rate is still high at 2.5%. In persons coinfected with HIV, it may be most severe; in one series, 6 of 13 patients died.

TABLE 335-3 EHRLICHIOSES AND ANAPLASMOSES

DISEASE	AGENT	VECTOR	GEOGRAPHIC REPARTITION
American monocytic ehrlichiosis	*Ehrlichia chaffeensis*	*Amblyomma americanum*	South central, southeastern, mid-Atlantic coastal states
Human granulocytic ehrlichiosis	*Anaplasma phagocytophilum*	*Ixodes ricinus*	Europe, China
		Ixodes scapularis	Northeast, upper Midwest, northern California
E. ewingii	*Ehrlichia ewingii*	*Amblyomma americanum*	South central, southeastern, mid-Atlantic coastal states
Japanese monocytic ehrlichiosis	*Neorickettsia sennetsu*	Helminth of the gray mullet?	Japan
E. canis	*Ehrlichia canis*	*Rhipicephalus sanguineus*	Venezuela

DIAGNOSIS

The diagnosis of HME should be considered in patients with a history of tick exposure and unexplained fever. HME resembles RMSF, but rash is less frequent. Later in the disease, it can be misdiagnosed as anything that causes severe sepsis.

Leukopenia associated with thrombocytopenia and an increase in liver enzyme levels may establish the etiology. Careful examination of blood and CSF smears may help identify typical morulae. Treatment should be started in any suspected case. The diagnosis can be confirmed by culture in specialized laboratories using a canine cell line, DH82. However, PCR is more practical; confirmatory PCR using a second target gene is useful. Most cases are currently diagnosed serologically by a fourfold or greater increase in antibody titer or by seroconversion. The reference technique is IFA. A single titer of 25 is indicative of the diagnosis. There are cross-reactive antibodies among *Ehrlichia* species and with *A. phagocytophilum.* Western blotting may be valuable to distinguish among these bacteria.

TREATMENT Rx

Doxycycline (100 mg twice daily for adults) is the drug of choice for patients with ehrlichiosis. The optimal duration of therapy has not been established, but current regimens recommend continuation of treatment for at least 3 days after the fever subsides and until evidence of clinical improvement, for a minimum total course of 5 to 7 days. Severe or complicated disease may require longer treatment courses. Because tetracyclines are contraindicated in pregnancy, rifampin has been used successfully in a limited number of pregnant women with documented HME.

Human Granulocytic Ehrlichiosis *(Anaplasma phagocytophilum)*

EPIDEMIOLOGY

The first human case of *A. phagocytophilum* infection was recognized in 1990. The disease is found in America, Asia, and Europe (Fig. 335-4). It is transmitted by *Ixodes scapularis* (eastern North America), *Ixodes pacificus* (western North America), *Ixodes ricinus* (Europe), and *Ixodes persulcatus* (Asia), the vectors of Lyme disease (Chapter 329), and its epidemiology is similar. Coinfection with the two diseases may occur. The temporal distribution of the disease parallels that of nymph tick activity, with two peaks in spring and autumn. Ticks are born free of *Ehrlichia* and are infected while feeding on bacteremic small mammals. Deer play a major role as hosts of adult ticks and reservoirs. In highly endemic areas, the incidence can reach 50 per 100,000 inhabitants per year. The mean age of diagnosed patients is high, and males are more frequently infected than females, with a sex ratio of 3:1.

CLINICAL MANIFESTATIONS

The incubation time is usually between 7 and 10 days, and 80% of patients report a history of tick exposure. Many infections may be asymptomatic or too mild to require a diagnostic procedure. The disease frequently begins abruptly, with fever, headache, malaise, and myalgias that may be particularly severe. Rash is found in less than 10% of cases. Visceral involvement may be observed and includes digestive symptoms such as nausea, vomiting, and diarrhea. Neurologic symptoms may include confusion, meningitis, and meningoencephalitis.

The evolution of the disease is favorable in most cases, even without specific therapy, but the disease may evolve to septic shock in some patients. Patients with underlying diseases are more at risk of dying. Most deaths are the consequence of *Ehrlichia*-induced immunosuppression, and patients may experience invasive aspergillosis, candidiasis, cryptococcosis, and herpes esophagitis.

DIAGNOSIS

Laboratory findings consist of the association of thrombocytopenia and leukopenia (lymphopenia or neutropenia). An increase in serum transaminases is also frequent. The diagnosis can be made by careful examination of blood smears for morulae within PMN cells. Culture from blood is possible in appropriate cells (HL-60), and PCR is useful as for HME. Most cases are diagnosed by serologic testing with IFA, which is comparable to that in HME (see earlier).

TREATMENT Rx

Treatment is also similar to that of HME except that *A. phagocytophilum* is susceptible to fluoroquinolones in vitro, but these drugs have not been tested in patients.

Ehrlichia ewingii

Canine granulocytic ehrlichiosis, reported in the United States in 1972, is caused by *E. ewingii.* This bacterium was characterized by amplification and sequencing of the 16S ribosomal RNA gene. The vector of *E. ewingii* is *A. americanum* (Chapter 367), which also transmits *E. chaffeensis.* Among 60 cases of ehrlichiosis in Missouri in 1999, 4 were caused by *E. ewingii;* 4 other cases have been reported since by the CDC. The disease was prevalent in immunocompromised hosts (seven of eight) coinfected with HIV or receiving immunosuppressive drugs. Patients who report tick exposure are noted to have fever, thrombocytopenia, leukopenia, and various symptoms, including meningitis. Morulae may be seen on blood smears in PMN cells. The evolution in reported cases was good; patients responded dramatically to doxycycline. Patients have antibodies to *E. chaffeensis,* and PCR has been shown to be useful when it is applied to blood samples. This diagnosis should be considered when ehrlichiosis is suspected in immunocompromised patients exposed to *A. americanum* ticks.

Ehrlichia canis

Canine monocytic ehrlichiosis was reported first in Algeria in the 1930s. It is caused by *E. canis* and transmitted by the dog tick *R. sanguineus* (Chapter 367). This tick is found worldwide and is prevalent in temperate and hot areas. In 1996, a single case of infection was reported in an asymptomatic man from Venezuela who owned an infected dog. Recently, cases have been reported in patients in South America.

Wolbachia Species

Wolbachia bacteria are endosymbionts of arthropods and nematodes. They were known to be present in filarial worms, but it was later shown that they may play a role in human disease. These bacteria manipulate the fertility of their host. Eradication of *Wolbachia* in filariae may lead to infertility and stop the microfilariae from spreading. This effect was demonstrated by field treatment with doxycycline in patients with onchocerciasis. The patients improved when treated with this drug, which is effective on *Wolbachia* and subsequently on the worm's fertility but not on the worm itself. In 2001, it was shown that the adverse reactions observed after treatment of lymphatic filariasis may be caused by the release of *Wolbachia* from destroyed worms. Some authors suggested that eradicating *Wolbachia* before the anthelmintic prescription would avoid these reactions. For some reason, *Loa loa* (Chapter 366) do not harbor *Wolbachia,* and the genome of *Wolbachia* integrated in the *Brugia malayi* genome makes it inaccessible to therapy.

Q FEVER

DEFINITION

Q fever is a worldwide zoonosis caused by *Coxiella burnetii.* The name Q fever is derived from "query" to emphasize the surprising aspect of the disease first described in Queensland, Australia, in 1935 by Derrick. The infection in humans is variable in its severity, clinical expression, and natural course (i.e., acute or chronic). It is considered by the CDC to be a potential agent of bioterrorism. Ungulates and pets are the major sources of human infection.

The Pathogen

C. burnetii is a gram-negative bacterium that naturally infects its host's monocytes. It multiplies in an acidic vacuole. Strains are heterogeneous genetically and antigenically and are associated with acute infections of variable severity. *C. burnetii* in vitro generates a deleted, avirulent mutant also named phase II.

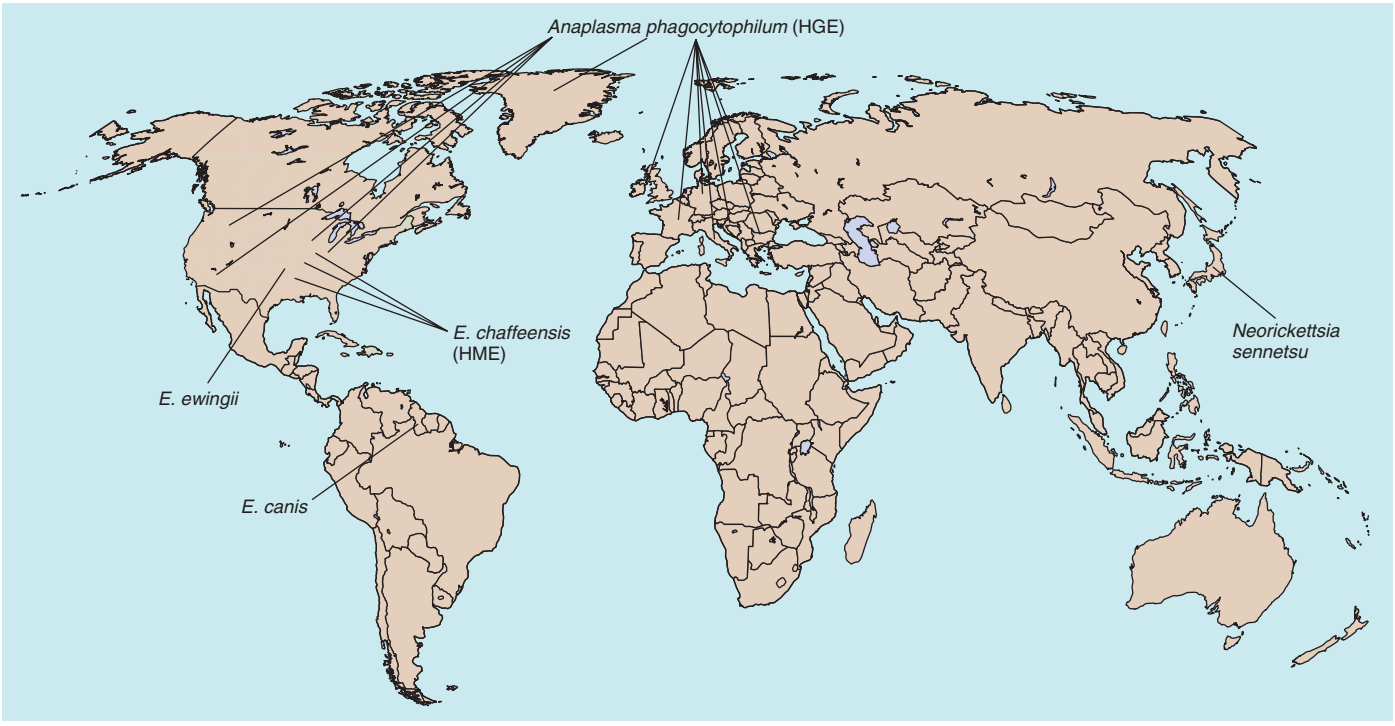

FIGURE 335-4. Geographic distribution of ehrlichioses. HGE = human granulocytic ehrlichiosis; HME = human monocytic ehrlichiosis.

This mutant exhibits diagnostic antigens that are useful because they are more reactive during acute infection.

C. burnetii is incompletely eliminated after acute infection. In immunocompromised hosts and patients with cardiac valve lesions, *C. burnetii* continues to multiply despite high levels of antibodies and causes chronic infection. Control of the disease in acute Q fever is associated with the formation of a granuloma.

EPIDEMIOLOGY

C. burnetii infects a wide range of animals, including mammals, birds, and ticks. Ungulates and pets (cats and dogs) are the most common source of the disease. Mammals are infected through aerosols and may shed *Coxiella* in feces, urine, milk, and birth products. Humans are usually infected by aerosols or less frequently by exposure to milk products. Interhuman infections through sexual intercourse, during delivery, or by blood transfusion have been reported. *Coxiella* survives in the environment and can be spread far by the wind. In the past few years, major outbreaks were related to sheep and goats. The disease is partly seasonal and related to lambing time. The current geographic repartition is largely unknown. Males have more severe disease but are not more often exposed to Q fever, and middle-aged people are more frequently affected and hospitalized. The number of reported cases recently increased dramatically in Europe and Asia. Many American soldiers were infected in Iraq.

CLINICAL MANIFESTATIONS

After contamination by *C. burnetii,* 60% of patients seroconvert without apparent disease, 38% experience a self-limited disease, and only 2% require diagnostic evaluation. Months to years after the primary infection, a chronic infection associated with an immunocompromised situation, a cardiac valve lesion, or a vascular prosthesis or aneurysm develops in 0.2 to 0.5% of patients.

Patients with diagnosed acute infection may have a variety of symptoms (Table 335-4). Isolated prolonged fever was observed in 14% of more than 1000 patients. Pneumonia was found in 37% and was the only symptom in 17%. This percentage may vary according to the place of study and reach 90% of diagnosed cases. Some cases may be associated with respiratory distress. Hepatitis is found in 60% of patients and is the sole manifestation in 40%. The association of fever and a moderate increase in transaminases is an important clue. Some hepatitides, specifically in middle-aged men, are associated with an inflammatory syndrome and autoantibodies and may be resistant to antimicrobial treatment. Liver biopsy, when it is performed, exhibits granulomas that may be typified by a lipid vacuole and surrounded by a fibrinoid ring in the form of a doughnut. Less frequently, in 1.5% of cases, patients exhibit a rash. Patients can have specific neurologic manifestations such as meningitis, encephalitis, meningoencephalitis, or peripheral neuropathy. In 1 to 2% of cases, patients have cardiovascular manifestations, such as pericarditis or more rarely myocarditis.

Evolution is usually favorable even without treatment, except in special hosts. In pregnant women, symptomatic or not, Q fever compromises the pregnancy. When infected during the first trimester, the patient usually aborts spontaneously. When the patient is infected later, the disease can result in fetal death or prematurity, or the outcome may be normal. Chronic uterine infection may develop in half the patients infected during pregnancy, and they may later experience multiple spontaneous abortions. Thirty percent to 50% of patients with heart valve or vascular lesions may experience chronic endocarditis within 2 years. This evolution is not prevented by regular treatment.

Patients with Q fever endocarditis have a chronic infection with low-grade fever, progressive degradation of valve function, and progressive heart failure. Fever is intermittent, and vegetations are frequently absent on cardiac echocardiography. Endocarditis is therefore not frequently considered in the initial differential diagnosis. If it is not diagnosed, the disease progressively worsens, and emboli (mainly cerebral) as well as renal insufficiency, splenomegaly, and hepatomegaly may be observed. Digital clubbing may also be seen. The main clue to the diagnosis in a patient with a valvulopathy is unexplained sickness (unexplained fatigue, weight loss, fever), a biologic abnormality (leukopenia, increased erythrocyte sedimentation rate, thrombocytopenia, increase in hepatic enzymes), or rapid degradation of a prosthetic valve. Chronic osteomyelitis, hepatitis, and infection of an aneurysm and vascular prosthesis have been reported.

Leukopenia may be observed; thrombocytopenia is frequent, as are increases in hepatic enzymes. Circulating anticoagulant associated with antiphospholipid antibodies may be observed (Chapter 177), as may anti–smooth muscle antibodies. During endocarditis, antinuclear antibodies, microhematuria, and rheumatoid factor are frequently found.

TABLE 335-4 SITUATIONS THAT SHOULD PROMPT SEROLOGIC TESTING FOR Q FEVER

ACUTE Q FEVER (PHASE II ANTIGEN AND IgG ≥ 200 AND IgM ≥ 50)
Fever in a patient in contact with ungulates
Unexplained prolonged fever (>7 days)
Granulomatous hepatitis
Fever and thrombocytopenia
Meningoencephalitis
Myocarditis
Erythema nodosum
Fever during pregnancy
Fever in a patient in contact with a parturient pet
Unexplained atypical pneumonia
Fever and an increase in transaminases (2-5 times the normal level)
Aseptic meningitis
Guillain-Barré syndrome
Pericarditis
Spontaneous abortion
CHRONIC Q FEVER (PHASE I ANTIGEN AND IgG ≥ 800 AND IgA ≥ 100)
Blood culture–negative endocarditis
Patient with a valvulopathy and unexplained
Fever
Weight loss
Fatigue
Increased erythrocyte sedimentation rate
Increased transaminases
Thrombocytopenia
Patient with unusually rapid degradation of a prosthetic valve
Fever in a patient with a vascular aneurysm or prosthesis
Aseptic osteomyelitis
Chronic pericarditis
Multiple spontaneous abortions

DIAGNOSIS

The diagnosis is based mainly on serology (see Table 335-4). Direct detection by culture and PCR or immunochemistry in valve, liver, or blood samples is also useful, but serologic evaluation by IFA is the best method. Two antigens (phase I and phase II) can be tested. Acute Q fever is diagnosed when seroconversion or a fourfold increase is obtained with phase II antigen. A single serum test exhibiting IgG antibodies of 200 or greater and IgM of 50 or greater against phase II is also diagnostic. During chronic Q fever, antibodies are at higher titer and directed against both phase I and phase II. IgG against phase I at a titer of 800 or 1600 is diagnostic of chronic infection, as is IgA at 100 or greater. Serology is useful for follow-up of patients with acute Q fever and underlying disease and those with treated chronic Q fever.

TREATMENT

Rx

Treatment is easy during acute Q fever. Doxycycline is the most efficient antimicrobial, and it should be prescribed for 2 weeks. Some patients with hepatitis do not respond well because of an excessive immune response. They rapidly improve with a short course of glucocorticoids. In pregnant women, cotrimoxazole during the entire pregnancy may decrease the chance of an unfavorable outcome. As for endocarditis, bactericidal treatment is necessary. In vitro, antimicrobial efficacy is impaired by the low pH of the vacuole in which *C. burnetii* resides. Hydroxychloroquine increases the pH of this vacuole and restores the bactericidal effect of doxycycline. In patients with endocarditis, the recommended treatment is a combination of doxycycline (200 mg daily) and hydroxychloroquine (600 mg/day, then adjusted to reach a 1-mg/mL plasma concentration). This regimen is prescribed for 18 to 36 months according to serologic results. We recently observed that a more rapid favorable outcome was obtained with doxycycline serum levels higher than 5 µg/mL. Some strains may be resistant to doxycycline, and new macrolides may be an alternative. The major problem with this treatment is photosensitivity; sun exposure should be avoided. An alternative treatment is a combination of doxycycline and ofloxacin for 3 years or more.

PREVENTION

Prevention is based on veterinary control in animals. A vaccine is currently available in Australia.

ZOONOSES

STUART LEVIN

DEFINITION

Zoonoses are classically, though not without controversy, defined as infections or diseases naturally transmitted between humans and vertebrate animals. There are approximately 1400 human pathogens, of which about 800 species are zoonotic. Of the approximate 180 emerging or reemerging pathogens in the past 3 decades, 130 are known to be zoonotic, with a disproportionate number of the new zoonoses being caused by RNA viruses. As a recent editorial states, this is a microbial world that humans are barely allowed to live in, and nothing microbes do or become should surprise us. We have little ability to predict how an emerging zoonotic pathogen will act. Most zoonotic pathogens, like rabies, enter a human and cause disease, but in these cases, humans are dead-end hosts and are unlikely to transmit the disease to others. Less commonly, pathogens such as human immunodeficiency virus (HIV) or recombinant swine H1N1 enter the human population with great difficulty but are then successfully transmitted to cause global epidemics solely from human-to-human transfer. The recent emphasis on emerging infections, which are predominantly zoonoses, and the potential for new pandemics markedly enhance the need for human medicine to be integrated with veterinary medicine and veterinary research.

EPIDEMIOLOGY

During the course of evolution, humans have sought the company of vertebrates for many reasons, including their companionship as pets. The more than 100 million dogs and cats in the United States facilitate the transmission of more than 250 different infectious species and cause more than 1 million bite injuries each year.

Almost all arthropod-transmitted infectious agents acquired from vertebrates in the United States are due to either ticks or mosquitoes. Ticks are the more common villain, and Lyme disease is the most common arthropod-transmitted infectious disease in the United States. Not all arthropod-transmitted diseases are zoonotic. For instance, arthropod-transmitted infections such as West Nile fever, *Schistosoma japonicum,* and *Trypanosoma rhodesiense* are zoonoses, whereas *Schistosoma mansoni, Trypanosoma gambiense, Wuchereria bancrofti, Onchocerca volvulus,* and vivax malaria are not; these non-zoonoses cause more than a billion infections per year, are transferred from human to human, and do not depend on vertebrate reservoirs. Human infestations with ectoparasites are not considered zoonoses.

The risk of contracting a zoonosis is increased by direct animal contact; in meat handlers, poachers, hunters, exotic animal smugglers, and international travelers; by exposure to and inhalation of infectious air particles; by insect bites, contact with previously infected human blood products, and contact with and ingestion of infectious agents transmitted by animal-contaminated water; and by insufficiently cooked meat, eggs, dairy products, and fish. Raw shellfish, which are the "garbage filters" of the ocean, can transmit at least 25 different infectious or toxic diseases to humans, but shellfish are invertebrates, and such diseases are not zoonoses. Ticks can introduce more than one pathogen while feeding; Lyme disease, ehrlichiosis, and babesiosis can all be transmitted by a single tick bite. Threats from mosquito bites include St. Louis encephalitis and West Nile virus. Patrons of petting zoos, pet owners, farmers, hunters, laboratory researchers, cave explorers, hikers, and veterinarians, among others, are at higher risk for a zoonosis than is the general population. Infectious agents transmitted by these routes from animal sources essentially include members of all microbial classes: viruses and prions, bacteria and rickettsia, fungi, helminths, and protozoa. Immunocompromised hosts, such as splenectomized patients, transplant recipients, patients with acquired immunodeficiency syndrome (AIDS), and pregnant women and their fetuses, are at higher risk for clinical disease when exposed to these various infectious agents. Chagas' disease, a protozoal infection, is a zoonosis in South America but is not endemic to the United States; however, immigration from Latin America has led to an estimated 300,000 persons with *Trypanosoma cruzi* infection, usually subclinical, in the United States and the potential for transmission of the infection through blood or organ donations. *Leishmania donovani* is almost always a small-animal reservoir zoonosis, but in India, it has set up shop with just human-to-human insect transfer.

As the world shrinks, warms, flattens, and remains in conflict, new infectious diseases seem inevitable, and previously rare ones are seen in unexpected places (Table 336-1) because of global warming, human intrusion into previously underexplored or never-explored sites, world travel, deforestation, and the increasing threat of biologic terrorism or warfare. Increasing urbanization, intermingling of humans and domestic animals, and lack of adequate sanitation can dramatically increase the incidence and severity of epidemic infectious disease.

CLINICAL MANIFESTATIONS

Zoonoses can manifest as a variety of clinical syndromes, including respiratory disease (Table 336-2), central nervous system disease (Table 336-3), and rash or skin lesions (Table 336-4). Other zoonotic clinical syndromes may present as sepsis, polyarthritis, jaundice, acute renal failure, endocarditis, or diarrhea (Table 336-5).

Emerging zoonotic infectious diseases include Nipah virus and Hendra virus encephalitis, *Hantavirus* pneumonia and *Hantavirus* fever with renal failure, the coronavirus that causes severe acute respiratory syndrome (SARS), West Nile encephalitis (which spread coast to coast in the United States over 3 years and is now apparently a permanent resident), monkeypox (an outbreak in the upper Midwest was caused by pet prairie dogs), *Leishmania mexicana* in Texas, and at least 8 to 10 newly identified tick-borne rickettsial spotted fevers worldwide, including the flea-borne *Rickettsia felis* in California. Avian or "bird flu" (H5N1), SARS, monkeypox, H1N1 (swine) influenza, and West Nile fever have recently exposed the fragility of our world village. Nevertheless, exotic zoonoses remain a less frequent cause of fever in travelers than the well-known, ordinary gastrointestinal and pulmonary pathogens.

DIAGNOSIS

Non–animal-associated environment- or travel-related infectious diseases can be confused with zoonoses. The vast majority of clinical diseases caused by *Legionella pneumophila, Entamoeba histolytica, Giardia lamblia, Burkholderia pseudomallei, Chromobacterium violaceum, Aeromonas hydrophila,* and airborne fungi such as *Blastomyces dermatitidis, Coccidioides immitis,* and *Histoplasma capsulatum* are acquired through environmental exposure and are only rarely related to animal hosts. *Sporothrix schenckii,* almost always an environmentally acquired pathogen stemming from vegetation-related injuries, has also been transmitted from cats with draining cutaneous ulcers to owners and animal handlers. Histoplasmosis has been acquired by explorers (spelunkers) in caves contaminated by bat guano. Other noninfectious toxin-induced diseases acquired from animals and insects, such as tick paralysis and the fish toxin illnesses, do not represent zoonoses.

Unfortunately, some descriptive disease titles can be misleading to clinicians and interfere with reaching the correct diagnosis. The transmission of tick-borne Rocky Mountain spotted fever actually occurs much more commonly in the southeastern United States than in the Rocky Mountains and has even occurred in the middle of New York City. Urban New York City continues to be a major source of rickettsialpox, where it was first described 60 years ago. Vegetarians and other strict non–pork-eating persons have been seriously infected with the pig tapeworm *Taenia solium* as a result of fecal contamination of food from infected human food-handlers.

Until recently, human influenza A was not well recognized as a zoonosis; however, interspecies spread and mixing of swine, avian (H5N1 virus), and human influenza viruses can occur in unique geographic areas, such

TABLE 336-1 NEWER ZOONOSES IN THE UNITED STATES (EMERGING INFECTIONS)

DISEASE*	INFECTIOUS AGENT	CLINICAL FINDINGS	VECTOR/ACQUISITION
Ehrlichiosis, monocytic	*Ehrlichia chaffeensis*	Fever, myalgia, leukopenia, monocyte inclusions not often seen, maculopapular rash in a minority	*Amblyomma* (Lone Star) tick bite
Human granulocytic anaplasmosis (HGE)	*Anaplasma phagocytophilium*	Fever, myalgia, leukopenia, granulocyte inclusions often seen on blood smear	*Ixodes* (deer) tick bite
"Flu syndrome"	*Ehrlichia ewingii*	Immunocompromised host—fever, myalgia	*Amblyomma*
Cat-scratch disease	*Bartonella* spp (there are 8 identified zoonotic *Bartonella* spp)	Cervical lymphadenopathy in normal hosts and cutaneous and hepatic angiomatosis in AIDS patients	Cat scratch or bite
Hemorrhagic diarrhea	Enterohemorrhagic *Escherichia coli* O157:H7 (other species)	Rectal bleeding, dysentery, hemolytic-uremic syndrome	Contaminated, undercooked meat
Hantavirus pulmonary syndrome	*Hantavirus*—Sin Nombre	Noncardiac pulmonary edema, elevated hematocrit	Fomites of wild rodents
Cryptosporidium diarrhea	*Cryptosporidium parvum*	Prolonged watery diarrhea	Contaminated water—cattle and sheep
Dysentery	*Campylobacter jejuni*	Dysentery, reactive arthritis, Guillain-Barré syndrome	Contaminated chicken
Pyogenic skin ulcer	*Capnocytophaga canimorsus*	Sepsis, skin infection	Dog bites
West Nile fever encephalitis	West Nile virus	Encephalitis, myelitis, Guillain-Barré syndrome	Mosquito bite, birds
SARS	Coronavirus	Severe lower respiratory tract infection	Masked palm civet (presumed)
Cutaneous leishmaniasis	*Leishmania mexicana*	Skin nodules and ulcers	Wood rat

*See table of contents and index to locate a more detailed discussion of each disease.
AIDS = acquired immunodeficiency syndrome; SARS = severe acute respiratory syndrome.

TABLE 336-2 RESPIRATORY TRACT ZOONOSES

DISEASE*	MICROORGANISM†	CLINICAL FINDINGS	RESERVOIR AND/OR VECTOR
Psittacosis‡	*Chlamydophila psittaci*	Pneumonia, often severe	Aerosols from parrots, ducks, turkeys
Q fever	*Coxiella burnetii*	Pneumonia, hepatitis, myocarditis	Airborne from soil contaminated by sheep, goats, and cats, particularly if parturient
Tularemia	*Francisella tularensis*	Cutaneous ulcer and regional node, pneumonia and hilar node; pleural effusion	Rabbit contact (winter) and tick bites
Plague	*Yersinia pestis*	Inguinal nodes, bubonic plague (basilar pneumonia develops in 10%); hilar node enlargement	Fleas from prairie dogs, rock squirrels, rats
Hantavirus syndrome	*Hantavirus*	Upper respiratory to lower respiratory to adult respiratory distress syndrome (ARDS) to death	Deer mouse fomites: urine, feces, saliva
Rhodococcus pneumonia	*Rhodococcus equi*	Pneumonia often cavitates in those with AIDS and other immunosuppressed patients	Horse manure, soil
Mycoplasma arginini pneumonia	*Mycoplasma arginini*	Pneumonia, sepsis, neutropenia	Sheep, goats
Foot-and-mouth disease	*Aphthovirus*	Nonspecific upper respiratory tract infection, oral vesicles	Cloven-footed mammals
Whooping cough	*Bordetella bronchiseptica*	Pneumonia, bronchitis, whooping cough	Dogs
Histoplasmosis	*Histoplasma capsulatum*	Pneumonia or fever of unknown origin	Bats
Anthrax	*Bacillus anthracis*	Mediastinal widening with CT scan; pneumonia often absent	Herbivore mammals
Glanders	*Burkholderia mallei*	Pneumonia, erosive tracheobronchitis	Horses, mules

*See table of contents and index to locate a more detailed discussion of each disease.
†Because of the fastidious nature of some organisms, the rapid development of diagnostic tools, and the risk some agents pose to laboratory workers, a clinical microbiologist should be consulted if these agents are considered in a patient's differential diagnosis.
‡Occurs in more than 1000 animal species.
AIDS = acquired immunodeficiency syndrome; CT = computed tomography.

as southern China or Mexico (2009 novel H1N1 virus), where dense concentrations of ducks, pigs, and people cohabit. Viral incubation of the three influenza species in the pig, with a reassortment of antigens and subsequent spread of virulent "new" influenza strains to humans, can lead to massive influenza pandemics that in sheer numbers (billions) surpass any past epidemics of smallpox or plague. Initially, HIV-1 and HIV-2 were transmitted as simian immunodeficiency viruses from chimpanzees and mangabey primates, respectively, to humans. As with influenza, the subsequent 33 million (and counting) cases of HIV no longer require an animal reservoir for continuing transmission. Because these pandemics of AIDS and influenza now spread human to human without the help of the initiating animal host, the World Health Organization no longer considers them zoonoses.

Leprosy, an illness of biblical notoriety transmitted from human to human, is endemic in at least three animal species, including the armadillo. This animal has rarely been implicated in the transmission of leprosy to humans in the United States.

Despite the large number of zoonoses described, clinicians evaluating an individual patient usually need to consider only a limited number of historical details to arrive at an appropriate differential diagnosis:

1. A history of direct contact with animals or animal products, animal bites, arthropod exposure, and food ingestion may offer clues to the correct cause.
2. The patient's travel history must be considered because a number of zoonoses are still quite limited in geographic distribution.
3. Occupational and recreational high-risk activities must be ascertained.

TABLE 336-3 CENTRAL NERVOUS SYSTEM ZOONOSES

DISEASE*	ORGANISM	CLINICAL FINDINGS	ACQUISITION
Listeriosis	*Listeria monocytogenes*	Purulent meningitis during pregnancy, in patients older than 65 yr, in neonates, and in immunosuppressed	Unpasteurized cheese and other dairy products; cattle, goats
Leptospirosis	*Leptospira interrogans*	Aseptic meningitis, hepatorenal syndrome	Asymptomatic dogs, cattle; common water source
Herpes B encephalitis	Cercopithecine herpesvirus (herpes B virus)	Diffuse, progressive encephalitis	*Macaca* monkey bites or scratches
Lyme disease	*Borrelia burgdorferi*	Lymphocytic meningitis, motor-sensory neuropathy, facial palsy	Tick bite
Lymphocytic choriomeningitis	Lymphocytic choriomeningitis virus	Lymphocytic meningitis, occasionally with pneumonia	Inhalation of mouse secretions: urine, feces, saliva
Mosquito-borne encephalitis (U.S.)	Eastern, western equine, St. Louis, California encephalitis; West Nile virus	Diffuse encephalitis, least severe; California encephalitis, most severe; eastern equine encephalitis, myelitis, meningitis	Mosquito-borne from horses, birds
Rabies encephalitis	Rabies virus	Encephalitis; almost always fatal	Bites from dogs, skunks, bats, raccoons, foxes
Toxoplasmosis	*Toxoplasma gondii*	Multiple brain masses in AIDS patient	Cat feces or ingestion of undercooked lamb or pork
Cerebral cysticercosis	*Taenia solium*	Epilepsy, CNS cysts, eosinophilic meningitis, hydrocephalus	Fecal-oral; contamination of food with pork tapeworm eggs
New-variant Creutzfeldt-Jakob disease	Prion (proteinaceous infectious particle)	Dementia, ataxia, myoclonus	Beef from cattle fed scraps from contaminated sheep carcasses
Nipah virus	Paramyxovirus	Acute encephalitis, death	Pig contact
Hendra virus	Paramyxovirus	Pneumonitis, encephalitis	Horses, fruit bats

AIDS = acquired immunodeficiency syndrome; CNS = central nervous system.

TABLE 336-4 ZOONOSES CAUSING RASH OR SKIN NODULE-ULCER

DISEASE*	MICROORGANISM†	CLINICAL FINDINGS	RESERVOIR AND/OR VECTOR
Ehrlichiosis (monocytic)	*Ehrlichia chaffeensis*	Macular rash (seen in < ⅓ of patients) with a central distribution; prevalent in south-central U.S.	Tick bite
Leptospirosis	*Leptospira interrogans*	Central macular rash in 20%, with occasional enanthem, conjunctival suffusion, hepatorenal syndrome	Urine-contaminated water; dogs, cattle
Lyme disease	*Borrelia burgdorferi*	Erythema migrans; 20% have multiple lesions	Mouse reservoir—tick bite
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Acral or peripheral distribution of maculopapular to hemorrhagic rash to gangrenous lesions—no eschar	Tick bite
Typhus (epidemic)	*Rickettsia prowazekii*	Macular rash with a central distribution (can be hemorrhagic)	Flying squirrel fleas or fomites
Cat-scratch disease	*Bartonella* spp	Bacillary angiomatosis, peliosis hepatis in HIV patients, cervical adenopathy, subacute bacterial endocarditis, fever of unknown origin	Cat scratch or bite
Tularemia	*Francisella tularensis*	Ulcer and node, typhoidal syndrome, pneumonia	Rabbit contact and tick bite
Anthrax	*Bacillus anthracis*	Painless, edematous, nonpurulent ulcer that becomes black and necrotic over days; mediastinitis	Herbivore animal products, including animal hides
Rickettsialpox (spotted fever *Rickettsia*)	*Rickettsia akari, Rickettsia conorii, Rickettsia africae* (8 others found on all continents)	Fever, rash, eschar (multiple), tache noire (*R. africae,* often multiple)	Mouse mite, tick
Monkeypox	Orthopoxvirus	Multiple maculopustular lesions with lymphadenopathy	Prairie dog (U.S.), African rodents
Erysipeloid	*Erysipelothrix rhusiopathiae*	Red, tender, swollen finger; subacute bacterial endocarditis	Skin pricked while cleaning fish, domestic meat animals
Seal finger	?	Tender, swollen fingertip	Seal bite?

*See table of contents and index to locate a more detailed discussion of each disease.
†Because of the fastidious nature of some organisms, the rapid development of diagnostic tools, and the risk some agents pose to laboratory workers, a clinical microbiologist should be consulted if these agents are considered in a patient's differential diagnosis.

4. The patient's clinical manifestations (course and organ involvement) are used to focus on the most likely cause (see Tables 336-2 through 336-5).
5. Though neither specific nor sensitive, the inoculation nodule (eschar, tache noire, chancre, necrotic ulcer), with or without fever, rash, or local lymphadenopathy, is the only general clue from the physical examination that might alert the physician to a zoonosis when the history does not.
6. Significant unilateral hilar adenopathy in the presence of acute pneumonia can be a clue to anthrax, plague, or tularemia.

TREATMENT

Rx

The approach to treatment of the various zoonoses is presented in their respective chapters.

337

ACTINOMYCOSIS

ITZHAK BROOK

DEFINITION

Actinomycosis is an uncommon, subacute to chronic bacterial infection that induces both suppurative and granulomatous inflammation. Localized swelling with suppuration, abscess formation, tissue fibrosis, and draining sinuses characterize this disease. The infection spreads contiguously and often forms draining sinuses that extrude characteristic but not pathognomonic "sulfur granules." Infections of the oral and cervicofacial regions are most common, but any site in the body can be infected, including the thoracic region, the abdominopelvic region, and the central nervous system (CNS). Musculoskeletal or disseminated disease is rare but does occur.

The Pathogen

Actinomycetes of the genera *Actinomyces, Propionibacterium,* and *Bifidobacterium* act as the principal pathogens. However, 98 to 99% of actinomycoses are caused by non–spore-forming anaerobic or microaerophilic bacterial species of the genus *Actinomyces,* family Actinomycetaceae, order Actinomycetales. Of the 30 *Actinomyces* species, 8 may cause disease in humans: the strictly anaerobic *A. israelii, A. gerencseriae* (formerly known as *A. israelii* serotype II), *A. odontolyticus, A. naeslundii, A. meyeri, A. viscosus, A. pyogenes,* and *A. georgiae. A. israelii* is the most common species causing human disease. *Propionibacterium propionicum* (formerly known as *Arachnia propionica*) and *Bifidobacterium dentium* (formerly known as *Actinomyces eriksonii*) are also associated with clinically indistinguishable infection. The organisms are filamentous, branching, gram-positive, pleomorphic, non–spore-forming, non–acid-fast anaerobic or microaerophilic bacilli. *Actinomyces* organisms are fastidious bacteria that require enriched culture media; 6 to 10% ambient CO_2 may aid in their growth, which takes 3 to 10 days or more in culture. Most actinomycotic infections are polymicrobial and involve other aerobic and anaerobic bacteria. The most common co-isolates depend on the infection site and are *Actinobacillus actinomycetemcomitans, Aggregatibacter aphrophilus, Eikenella corrodens, Bacteroides, Fusobacterium, Capnocytophaga,* aerobic and anaerobic streptococci, *Staphylococcus,* and Enterobacteriaceae.

EPIDEMIOLOGY

Actinomyces species are members of the endogenous mucous membrane flora in the oral cavity, lower gastrointestinal tract, bronchi, and female genital tract. No external environmental reservoir, such as soil or straw, has been documented, nor has person-to-person transmission of pathogenic *Actinomyces* species been demonstrated. Although infection can occur in all age groups, it is rarely seen in children or patients older than 60 years. Most cases are encountered in individuals in the middle decades of life. A male-to-female infection ratio of 3:1 is reported in most series. The explanation for this ratio is the higher prevalence of poor oral hygiene and oral trauma in men. The annual reported incidence in the United States is fewer than 100 cases. However, because of the fastidious nature of the organism, many cases are undiagnosed, and the true incidence is probably much higher.

PATHOBIOLOGY

Actinomyces species are agents of low pathogenicity and require mucosal barrier disruption to cause disease. Actinomycosis usually occurs in immunocompetent persons but may afflict those with diminished host defenses. Oral and cervicofacial diseases are commonly associated with dental caries and extractions, gingivitis and gingival trauma, infection in erupting secondary teeth, chronic tonsillitis, otitis or mastoiditis, diabetes mellitus,

immunosuppression, malnutrition, and local tissue damage caused by surgery, neoplastic disease, or irradiation. Pulmonary infections generally arise after aspiration of oropharyngeal or gastrointestinal secretions. Gastrointestinal infection frequently follows loss of mucosal integrity, such as with surgery, appendicitis, diverticulitis, trauma, or foreign bodies. The use of intrauterine contraceptive devices (IUDs) increases risk for the development of actinomycosis of the female genital tract. Other predisposing factors are steroid use, immunosuppression, and human immunodeficiency virus infection.

Other bacterial species that are frequently copathogens with *Actinomyces* species may assist in the spread of infection by inhibiting host defenses and reducing local oxygen tension. Once the organism is established locally, it may spread progressively to surrounding tissues. The infection tends to spread without regard for anatomic barriers, including fascial planes and lymphatic channels. The end result is a chronic, indurated, suppurative infection (usually with draining sinuses and fibrosis, especially in pelvic and abdominal infection). The fibrotic walls of the mass before suppuration are "wooden" in nature and may be confused with a neoplasm. Hematogenous spread can be fulminant but is rare.

Actinomyces species grow in microscopic or macroscopic clusters of tangled filaments surrounded by neutrophils. Plasma cells and multinucleated giant cells are often observed with lesions, as are large macrophages with foamy cytoplasm around purulent centers. When visible, these clusters are pale yellow and exude through sinus tracks; they are called sulfur granules (originally called drusen). These granules (1 to 2 mm in diameter) are made of aggregates of organisms and contain calcium phosphate. A central purulent loculation surrounds the granules. Their centers have a basophilic staining property, with eosinophilic rays terminating in pear-shaped "clubs." One to six granules can be present per loculation, and up to 50 loculations can be present in a lesion. Multicenter giant cells can be seen as well.

CLINICAL MANIFESTATIONS

Cervicofacial

Cervicofacial infection is the most common manifestation of actinomycosis (Fig. 337-1). This infection is generally odontogenic in origin and evolves as a chronic or subacute painless or painful soft tissue swelling or mass involving the submandibular or paramandibular region. However, the submental and retromandibular spaces, temporomandibular joint, and cheek can be involved. The swelling may have a ligneous consistency caused by tissue fibrosis. Depending on the composition of the concomitant synergistic flora, the onset of actinomycosis may be acute, subacute, or chronic. When *Staphylococcus aureus* or β-hemolytic streptococci are involved, an acute painful abscess or a phlegmatous cellulitis may be the initial manifestation. The chronic form of the disease is the most common form and is characterized by painless infiltration and bluish or reddish induration that generally progress to form multiple abscesses and draining sinus tracks discharging pus that may contain sulfur granules in up to 25% of instances. Periapical infection, trismus, fever, pain, and leukocytosis may be present. The infection can extend to the carotid artery, tongue, sinuses, ears, mastoid, orbit, salivary glands, pharynx, masseter muscle, thyroid, larynx, trachea, or thorax. Bone (most commonly the mandible) may be invaded from the adjacent soft tissue and result in periostitis or osteomyelitis. Cervical spine or cranial bone infection may lead to subdural empyema and invasion of the CNS. The differential diagnosis includes tuberculosis (scrofula), fungal infections, nocardiosis, suppurative infections by other organisms, and neoplasms.

Thoracic

Thoracic actinomycosis is an indolent, slowly progressive process involving the pulmonary parenchyma and pleural space. This form accounts for 15 to 30% of actinomycosis cases and is caused by aspiration of infective material from the oropharynx as well as rarely after esophageal perforation, by extension into the mediastinum from the neck, by spread from an abdominal site, or by hematogenous spread to the lung. Infection can spread from a pneumonic focus across lung fissures to involve the pleura and the chest wall, with eventual fistula formation and drainage containing sulfur granules (Fig. 337-2). The mediastinum, pericardium, and myocardium can also rarely be affected. Granules are seldom present in sputum. The incidence of this complication, as well as the destruction of thoracic vertebrae and adjacent ribs, has declined in the antimicrobial era.

The complaints of patients with thoracic actinomycosis are nonspecific. The most common are chest pain, productive cough, dyspnea, weight loss, and fever. Anemia, mild leukocytosis, and elevated sedimentation rate are relatively common. There is often a history of underlying lung disease, and patients are rarely initially seen in an early stage of infection. The pulmonary lesion is either a mass lesion or pneumonitis and may resemble tuberculosis,

FIGURE 337-1. Actinomycosis of the jaw, observed at Letterman General Hospital, San Francisco, Calif., in a sergeant who had punctured the floor of his mouth while picking his teeth. (Office of Medical History, Office of the Surgeon General, U.S. Army.)

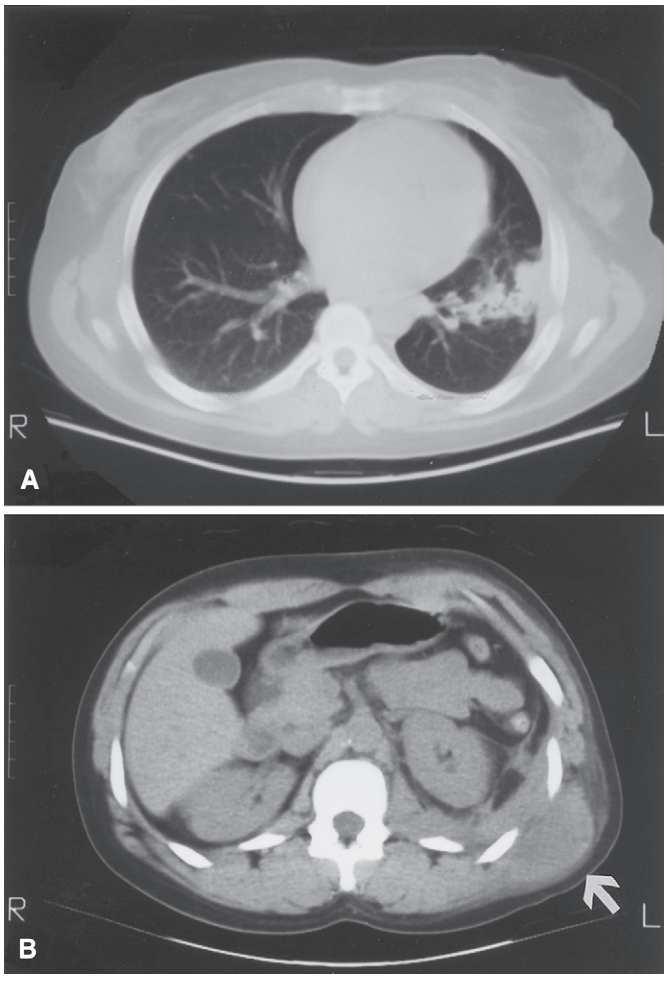

FIGURE 337-2. Thoracic computed tomography scan of a 43-year-old woman with pulmonary actinomycosis. There is consolidation of the lung with pleural thickening adjacent to the parenchymal disease (**A**). Abscess extended into the left breast and inferiorly to the costophrenic sulcus, to the retroperitoneum, and into the lateral abdominal wall (**B**, *arrow*).

especially when cavity formation occurs, or blastomycosis, which may destroy ribs posteriorly but rarely forms sinuses. Nocardiosis, bronchogenic carcinoma, cryptococcosis, aspiration pneumonia, pulmonary infection, and lymphoma can also mimic thoracic actinomycosis. Pleural thickening, effusion, or emphysema is common.

Abdominal

Abdominal actinomycosis is a chronic, localized inflammatory process that can occur weeks, months, or years after the integrity of the gastrointestinal mucosa is breached by surgery or trauma. Acute appendicitis with perforation, perforated colonic diverticulitis, and emergency surgery for trauma to the lower intestinal tract are among the predisposing factors. Extension from the thorax or pelvis or through hematogenous dissemination can also occur. The ileocecal region is involved most frequently (usually after appendicitis with perforation) with the formation of a mass lesion. The infection extends slowly to contiguous organs, especially the liver, and may involve retroperitoneal tissues, the spine, or the abdominal wall. Hepatic, renal, or splenic dissemination is an uncommon complication. Persistent draining sinuses may form, and those involving the perianal region can simulate Crohn's disease (Chapter 143) or tuberculosis. The extensive fibrosis of actinomycotic lesions, recognized by the examiner as a mass, often suggests tumor. A frequent finding on computed tomography (CT) is an infiltrative mass with dense inhomogeneous contrast medium enhancement. Constitutional symptoms and signs are nonspecific, the most common being fever, diarrhea or constipation, weight loss, nausea, vomiting, pain, and sensation of a mass.

Pelvic

Pelvic infection is observed in patients with prolonged use of IUDs, usually for longer than 2 years. Pelvic actinomycosis may also occur from extension of intestinal infection, commonly from indolent ileocecal disease. Manifestations of infection may range from a chronic vaginal discharge to pelvic inflammatory disease with tubo-ovarian abscesses or pseudomalignant masses. Patients generally have abnormal vaginal bleeding or discharge, abdominal or pelvic pain, menorrhagia, fever, and weight loss.

Endometritis is the earlier form of the infection, followed by tubo-ovarian abscesses. Extension to the uterus, bladder, rectal area, abdominal wall, peritoneum, pelvic bones, thorax, and systemic circulation can also occur.

Central Nervous System

Infections of the CNS are very rare and generally manifested as single or multiple encapsulated brain abscesses that appear as ring-enhancing lesions with a thick wall that may be irregular or nodular on contrast-enhanced CT scans. There are no features that readily distinguish actinomycosis from other causes of brain abscesses. Rarely, solid nodular or mass lesions termed actinomycetomas or actinomycotic granulomas are found. Headache and focal neurologic signs are the most common finding. Most actinomycotic infections of the CNS are seeded hematogenously from a distant primary site, but direct extension of cervicofacial disease also occurs. Sinus formation is not a characteristic of CNS disease. The rare meningitis caused by *Actinomyces* is chronic and basilar in location, and the cerebrospinal fluid pleocytosis is usually lymphocytic. Thus, it may be misdiagnosed as tuberculous meningitis. Extension to the cranial epidural or subdural space and spinal epidural space can also occur from adjacent foci.

DIAGNOSIS

Appropriate microbiologic and pathologic studies are essential for diagnosis. A high index of suspicion should be communicated to the microbiology laboratory, along with material from draining sinuses, from deep-needle aspiration, or from biopsy specimens. CT or ultrasound needle aspiration can be used to obtain a biopsy specimen. It is important to avoid contamination of the specimen by "normal flora" and administration of antimicrobial therapy before a specimen is obtained. Anaerobic culture is required, and no selective media are available to restrict overgrowth of the slow-growing *Actinomyces* by associated microflora. The presence, in pus or tissue specimens, of non–acid-fast, gram-positive organisms with filamentous branching is suggestive of the diagnosis. The characteristic morphologic features of sulfur granules within are helpful. In tissue sections stained with hematoxylin-eosin, sulfur granules are round or oval basophilic masses with a radiating arrangement of eosinophilic terminal clubs. However, *Actinomyces* species are infrequently visible in sections stained with hematoxylin-eosin; visualization is facilitated by special stains such as Gomori methenamine silver, *p*-aminosalicylic acid, McCallen-Goodpasture, and Brown-Brenn. Multiple biopsy sections from different tissue levels are recommended to improve the histopathologic diagnosis. The granules must be distinguished from similar structures that are sometimes produced in infections caused by *Nocardia, Monosporium, Cephalosporium, Staphylococcus* (botryomycosis), and others. *Actinomyces* and *Arachnia* can generally be differentiated from other gram-positive anaerobes by means of their growth rate (slow), by catalase production (negative, except for *A. viscosus*), and by gas-liquid chromatographic detection of the acetic, lactic, and succinic acids produced in peptone-yeast-glucose broth. Direct fluorescent antibody conjugates and immunofluorescence testing can be used but are not readily available to clinical microbiology laboratories.

Imaging methods such as conventional radiography, CT, and magnetic resonance imaging do not provide a specific diagnosis but allow more accurate definition of the dimensions and extension of the infection.

TREATMENT Rx

Prolonged antimicrobial therapy (i.e., 6 to 12 months) has typically been recommended for patients with all clinical forms of actinomycosis to prevent disease recrudescence. However, individualization of courses of therapy is recommended because the duration of treatment depends on the initial burden of disease, the site of infection, and the clinical and radiologic response. Adequate drainage is indicated if abscesses are present.

Penicillin G is the drug of choice for treatment of an infection caused by any of the *Actinomyces.* It is given in high dosage during a prolonged period because the infection has a tendency to recur. Most deep-seated infections can be expected to respond to intravenous penicillin G, 18 to 24 million units/day given for 2 to 6 weeks, followed by an oral phenoxypenicillin in a dosage of 2 to 4 g/day. A few additional weeks of oral penicillin therapy may suffice for uncomplicated cervicofacial disease; complicated cases and extensive pulmonary or abdominal disease may require treatment for 12 to 18 months. Little evidence exists of acquired resistance to penicillin G by *Actinomyces* during prolonged therapy. The combination of a penicillin (i.e., amoxicillin, piperacillin) and a β-lactamase inhibitor (i.e., clavulanate, tazobactam) offers the advantage of coverage against penicillin-resistant aerobic and anaerobic copathogens. Alternative first-line antibiotics include tetracycline, erythromycin, cephalexin, oxacillin, and clindamycin. Ceftriaxone, imipenem, and fluoroquinolones have also been used successfully. Metronidazole, aminoglycosides, and antifungal drugs are not effective. In vitro antimicrobial susceptibility testing of *Actinomyces* is difficult, and the results may not be predictive of antimicrobial effect in vivo.

The need to use combination antimicrobial therapy to attack microorganisms that are isolated in association with *Actinomyces* has not been established. However, because many of these organisms are known pathogens, treatment is usually appropriate, especially with lower abdominal infections. Surgical removal of infected tissue may also be necessary in some cases, especially if extensive necrotic tissue or fistulas are present, if malignant disease cannot be excluded, and if large abscesses cannot be drained by percutaneous aspiration. When well-defined IUD-related symptoms and Papanicolaou smears demonstrate *Actinomyces* by specific fluorescent-labeled antibody, the IUD should be removed. Antimicrobial administration for a 2-week period may be indicated. More serious infections require prolonged therapy.

PROGNOSIS

The availability of antimicrobial treatment has greatly improved the prognosis for all forms of actinomycosis. At present, cure rates are high, and neither deformity nor death is common.

NOCARDIOSIS

FREDERICK S. SOUTHWICK

DEFINITION

Nocardiosis refers to infections caused by *Nocardia* species. *Nocardia* most commonly causes pneumonia but can also infect the central nervous system (CNS) and skin. Less commonly, this organism can disseminate throughout the body. These infections usually occur in patients with defective immunity.

The Pathogen

Nocardia species are thin, aerobic, gram-positive bacilli that form branching filaments. The bacteria stain irregularly and appear beaded on Gram stain. The speciation of *Nocardia* has been problematic. The original classification was based on the ability to use specific nutrients and to decompose substrates such as adenine, casein, urea, gelatin, and xanthine. However, gene sequencing and DNA-DNA hybridization have now defined the true taxonomy. The species called *Nocardia asteroides* was previously reported to be the most common cause of human disease. However, the majority of these bacteria were misidentified by today's standards. The number of species causing human disease is large and includes *Nocardia abscessus*, *Nocardia brevicatena/paucivorans* complex, *Nocardia nova* complex, *Nocardia transvalensis* complex, *Nocardia farcinica*, *Nocardia cyriacigeorgica*, *Nocardia otitidis-caviarum*, *Nocardia veterana*, *Nocardia brasiliensis,* and *Nocardia pseudobrasiliensis*.

EPIDEMIOLOGY

Nocardia species are ubiquitous and originate primarily in soil. Despite being found throughout the environment, they rarely cause symptomatic infection in humans. Because nocardiosis is not a reportable disease, its frequency is unknown. However, the annual incidence is estimated to be 0.4 cases per 100,000 persons. The risk of symptomatic *Nocardia* infection is greatly increased in individuals who are immunocompromised (incidence estimated to be >1000-fold higher), including patients receiving immunosuppressive agents following bone marrow or solid organ transplants and patients with acquired immunodeficiency syndrome (AIDS). Corticosteroids are the most frequent immunosuppressants associated with nocardiosis; however, cases have also been reported in patients receiving anti–tumor necrosis factor-α antibody (infliximab) and other immunosuppressants. It is important to keep in mind that trimethoprim-sulfamethoxazole prophylaxis does not always protect against *Nocardia*. Other risk groups include patients with cancer, Cushing's disease, chronic granulomatous disease, and dysgammaglobulinemia. Patients with chronic pulmonary disorders, particularly alveolar proteinosis, are also more susceptible to this infection. In approximately one third of patients with nocardiosis, no predisposing condition can be identified.

PATHOBIOLOGY

Most *Nocardia* species gain entry to the host via the respiratory tract or, less commonly, by skin inoculation. Invading bacteria elicit a neutrophil response that inhibits but does not kill the organism. The bacteria are phagocytosed by neutrophils and macrophages and become enclosed in a membrane-bound phagolysosome. In this closed environment, neutrophils and macrophages are able to kill many species of bacteria by synthesizing superoxide and hydrogen peroxide. However, *Nocardia* are able to survive in this hostile environment by producing superoxide dismutase, an enzyme that inactivates these toxic oxygen byproducts. In addition, *Nocardia* species produce a mycolic acid called cord factor that inhibits the fusion of lysosomes with the phagolysosomal compartment, preventing toxic proteases and other antibacterial products from reaching the intracellular bacteria. In addition to neutrophils and macrophages, cell-mediated and humoral immunity plays a role in protecting the host against *Nocardia* invasion, explaining the wide range of immunocompromised patients at increased risk for contracting nocardiosis.

CLINICAL MANIFESTATIONS

Nocardiosis has no pathognomonic characteristics, and delays in diagnosis are common. Failure of a pulmonary or skin infection to respond to conventional antibiotic therapy should raise the possibility of a *Nocardia* species infection. Nocardiosis should always be considered in an immunocompromised patient.

Pulmonary Nocardiosis

Approximately two thirds of patients with nocardiosis present with pulmonary infection. Pulmonary disease is usually subacute in onset, mimicking a fungal or mycobacterial infection, and it is most commonly misdiagnosed as tuberculosis. The most common complaints are a persistent cough producing purulent sputum, fever, anorexia, and weight loss. Less commonly, patients may report pleuritic chest pain and dyspnea. Hemoptysis is rare, but it can develop in patients with large cavitary lesions. An acute onset of pneumonia has occasionally been reported in immunocompromised hosts.

Central Nervous System Infection

Approximately 5% of patients with a *Nocardia* infection have CNS involvement. Multilocular brain abscess is the most common CNS manifestation and is usually the consequence of transient bacterial dissemination from the lung. Lesions can occur in any region of the brain, and symptoms depend on location. Headache is the usual initial complaint and is frequently localized to the site of the abscess. Patients may also present with neurologic deficits as well as seizures. In AIDS patients, brain abscess is often accompanied by an abnormal chest x-ray, whereas in other patients, such abnormalities are not always present. The combined findings of a lung nodule on chest x-ray and a ring-enhancing CNS lesion are often mistaken for metastatic lung carcinoma. Other diagnoses that should be considered when an immunocompromised host presents with both lung and CNS foci are disseminated aspergillosis and toxoplasmosis. Meningitis is a less common CNS manifestation and is often associated with brain abscess (40% of meningitis cases). Cerebrospinal fluid cultures are often negative, and patients fail to fully respond to empirical antibiotic therapy.

Cutaneous Infection

Skin infection is usually caused by *N. brasiliensis* and usually follows a break in the skin that is contaminated by soil. Cutaneous disease has been reported in association with trauma, postoperative wounds, insect bites, thorn bush scratches, or even a cat scratch. Initially, a pustule or a moderately erythematous, nonfluctuant nodule develops at the site of inoculation. Erythema can extend along the lymphatic system and is associated with tender lymphadenopathy. This form of cutaneous infection has been termed *lymphocutaneous* or *sporotrichoid* disease. Similar skin manifestations are seen with cat-scratch disease, tularemia, *Mycobacterium marinum* infection, and sporotrichosis. In an immunocompromised host, disseminated infection may manifest as multiple erythematous, raised nodules, which is an ominous finding. In tropical regions of South and Central America, *Nocardia* species can cause ulcerations and large tumor-like lesions called mycetomas that are usually found on the lower legs.

DIAGNOSIS

Radiology

In pulmonary disease, chest x-ray findings are variable, with pulmonary nodules or mass lesions seen most often (Fig. 338-1). Less frequently, consolidation, cavitary lesions with air-fluid levels, interstitial infiltrates, and pleural effusions are found. Chest computed tomography (CT) often demonstrates areas of low attenuation within consolidations, multiple nodules, and extension of the infection to the chest wall. AIDS patients are more likely to have multiple pulmonary nodules, cavitary lesions, and upper lobe infiltrates. In some patients, particularly those with normal immune function, the infiltrate may resolve. However, the patient may present with brain abscess several months later as a consequence of transient dissemination. In CNS infection, CT or magnetic resonance imaging with contrast usually demonstrates one or more ring-enhancing lesions (Fig. 338-2). *Nocardia* brain abscess is more commonly multiloculated, but otherwise, the radiologic findings are similar to those of brain abscess caused by other bacteria. Positron emission tomography is not helpful in differentiating *Nocardia* brain abscess from tumor because both demonstrate increased uptake.

Histopathology

Invasive procedures are generally required for specific diagnosis. For pulmonary infection, bronchoscopy with transbronchial biopsy or skinny needle

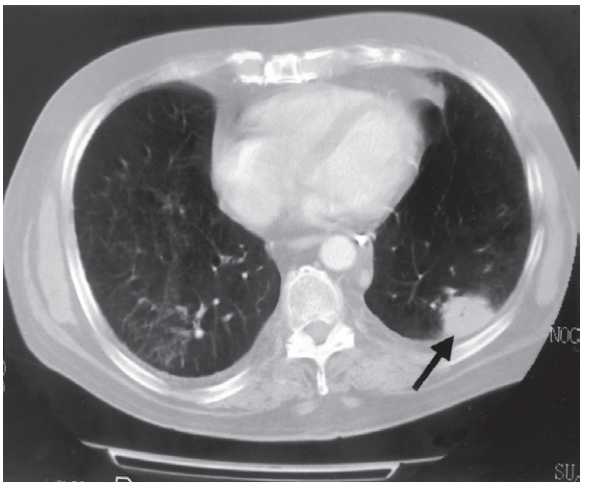

FIGURE 338-1. Chest computed tomography showing a peripheral nodular lung lesion *(arrow)* caused by *Nocardia* infection.

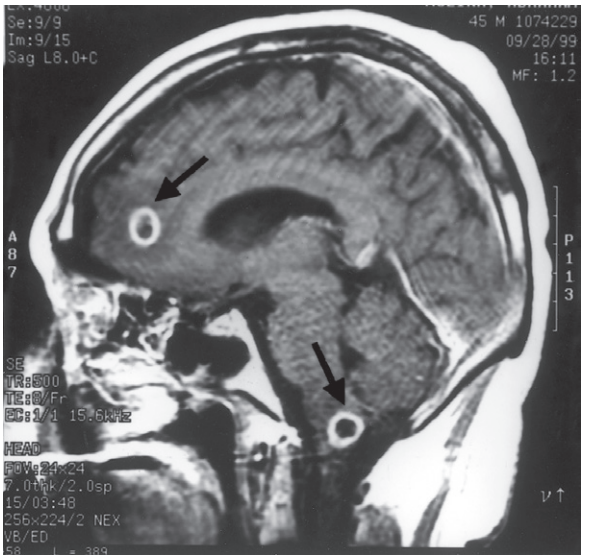

FIGURE 338-2. Multiple gadolinium-enhanced brain lesions *(arrows)* caused by *Nocardia* infection.

biopsy is recommended. For brain abscess, CT-guided needle aspirate is the diagnostic procedure of choice. Histopathology usually reveals an acute inflammatory response with a predominance of neutrophils. Micronodular abscesses with minimal capsular formation are usually found. Gram stain or Brown-Brenn stains reveal gram-positive beaded, branching forms. The morphology is identical to *Actinomyces;* however, the high lipid content of its cell wall often renders *Nocardia* modified acid-fast positive, whereas *Actinomyces* species are modified acid-fast negative. Acid fastness may be variable when staining *Nocardia* colonies from cultures, however, and it is unreliable for direct clinical samples.

Culture

Isolation of the organism on culture provides a definitive diagnosis for needle aspirate samples from brain abscess and a presumptive diagnosis when grown from respiratory and cutaneous samples. *Nocardia* species grow best under aerobic conditions with 5 to 10% carbon dioxide. Because the organisms grow slowly on blood agar, taking 3 to 5 days to form colonies, other organisms can overgrow. When *Nocardia* is suspected, the clinical laboratory should be notified to ensure the use of selective media and prolonged incubation. 16S Ribosomal RNA gene sequencing allows the rapid speciation of isolates. Increasing numbers of *Nocardia* have been shown to be resistant to sulfonamides. Therefore, antibiotic susceptibility testing should always be performed to guide the choice of treatment.

TREATMENT

Rx

Sulfonamides remain the treatment of choice for pulmonary and cutaneous disease. Trimethoprim-sulfamethoxazole given orally at a dose of 160/800 mg (one double-strength tablet) three times a day is the most common adult regimen. When patients with disseminated and/or CNS *Nocardia* are treated with sulfonamides alone, survival is less than 50%. One of the most common species to cause disseminated diseases, *N. farcinica*, is also one of the most common *Nocardia* species to be resistant to sulfonamides. In these more serious conditions, combination therapy is generally recommended, and the exact regimen is guided by antibiotic susceptibility testing. One recommended empirical regimen is trimethoprim-sulfamethoxazole at the doses stated earlier, amikacin (10 mg/kg/day in divided doses), and either ceftriaxone (2 g twice daily) or imipenem (500 mg every 6 hours). In a retrospective study, patients failing trimethoprim-sulfamethoxazole treatment responded to imipenem with or without amikacin. Linezolid 600 mg twice a day has been used successfully in a small number of CNS infections. However, prolonged therapy with this agent can lead to bone marrow toxicity and warrants weekly monitoring of the peripheral cell counts. Recently, the newer fluoroquinolones moxifloxacin and gatifloxacin (400 mg/day orally for both agents) were shown to have activity against several strains of *Nocardia,* including *N. farcinica* and *N. brasiliensis*, and these agents may be useful in patients who cannot tolerate sulfonamides; however, relapse has been reported. Minocycline (100 mg orally twice daily) and amoxicillin/clavulanate (875/125 mg orally twice daily) are other potentially effective alternative treatments for *Nocardia*. Because of the intracellular nature of *Nocardia* and the slow rates of bacterial growth, antibiotic treatment for 6 to 12 months in an immunocompromised host and 4 to 6 months in a normal host is usually required to prevent relapse.

For patients with brain abscess or subcutaneous abscesses, surgical drainage is required for cure, in addition to antibiotics.

PROGNOSIS

The overall mortality for nocardiosis is approximately 25%. In otherwise healthy individuals, pulmonary nocardiosis has a better prognosis (15% mortality). The survival rate is worse in patients with bacteremia, acute infection (symptoms for <3 weeks), disseminated disease involving two or more noncontiguous organs, and meningitis and in those receiving corticosteroids or cytotoxic agents.

SYSTEMIC ANTIFUNGAL AGENTS

DAVID A. STEVENS

Methods for in vitro susceptibility testing are available as standardized tools. A variety of assays are available for therapeutic drug monitoring of serum and other body fluids. As more common mutations inducing resistance are uncovered, it becomes possible to develop molecular screening methods that can detect the resistance genes in clinical isolates, in advance of susceptibility test results.

AMPHOTERICIN B–BASED PREPARATIONS

Mechanism of Action

Amphotericin B is a lipophilic molecule that exerts its antifungal effect by insertion into the fungal cytoplasmic membrane. Amphotericin B causes

membrane permeability to increase. Loss of intracellular molecules impairs fungal viability. The onset of action is rapid. Amphotericin B also has effects on oxidation that may enhance antifungal activity.

Spectrum of Activity and Mechanisms of Resistance

Amphotericin B is active against most fungi, and its spectrum of activity is not influenced by the choice of formulation. When resistance occurs, it is generally attributed to reductions in ergosterol biosynthesis and the synthesis of alternative sterols that lessen the ability of amphotericin B to interact with the fungal membrane. Primary resistance is common for *Aspergillus terreus* and for *Scedosporium* and *Trichosporon* species. Among the *Candida* species, primary resistance is noted at meaningful frequencies most often for *Candida lusitaniae.* Development of resistance in isolates of normally susceptible species is uncommon. In some studies, the principal pharmacodynamic driver of in vivo response has been the ratio of the peak serum concentration to the minimal inhibitory concentration (MIC).

Available Formulations

There are four commercially available amphotericin B formulations: amphotericin B deoxycholate (ABD) and three lipid-associated formulations—amphotericin B colloidal dispersion (ABCD), amphotericin B lipid complex, and liposomal amphotericin B. All formulations must be infused in 5% dextrose with no electrolytes added. Infusion bottles need not be protected from light. In attempts to produce less expensive lipid-associated formulations, some reports have advocated mixing ABD with a parenteral fat emulsion. Although less nephrotoxicity has been observed in adults given this preparation at a dose of 1 mg/kg/day compared with infusions of ABD in 5% dextrose, no advantage was found in children. Serum amphotericin B concentrations were also lower with the fat emulsion, raising the possibility that amphotericin B was simply aggregating in the fat emulsion, but the cloudiness could not be perceived in the milky-looking lipid. Use of such preparations should be reserved for investigational settings.

Amphotericin B Deoxycholate

Formulation

ABD for intravenous use is a colloidal suspension. If a filter with a 0.22-μm pore diameter is placed in the infusion line, considerable drug is removed by the filter. The addition of electrolyte aggregates the colloids, so the solution becomes cloudy. ABD is available from several generic manufacturers, and significant differences in the formulations have been reported, which may account in part for the intersubject variation in toxicities observed.

Pharmacology

Most of the drug leaves the circulation promptly, with only a small percentage being excreted in urine or bile. Amphotericin B is stored in the liver and other organs; the drug appears to re-enter the circulation slowly. Blood levels are uninfluenced by hepatic or renal failure. Hemodialysis does not alter blood levels, except in an occasional patient with lipemic plasma who may be losing drug owing to its adherence to the dialysis membrane. Concentrations of amphotericin B in fluid from inflamed areas, such as pleura, peritoneum, joint, vitreous humor, and aqueous humor, are roughly two thirds of the nadir serum level. Amphotericin B penetrates poorly into either normal or inflamed meninges, saliva, bronchial secretions, brain, pancreas, muscle, bone, vitreous humor, and normal amniotic fluid. Urine concentrations are similar to serum concentrations. Peak serum concentrations with conventional intravenous doses are roughly 0.5 to 2.0 μg/mL; these concentrations fall rapidly and then slowly approach a plateau of roughly 0.2 to 0.5 μg/mL. The initial half-life is about 24 hours; the β-phase half-life is roughly 15 days. Serum concentrations can be detected for at least 7 weeks after the end of therapy, presumably reflecting release from cell membranes. The drug also has complex immunomodulatory properties that are potentially of clinical significance.

Nephrotoxicity

ABD causes a dose-dependent decrease in the glomerular filtration rate. The direct vasoconstrictive effect of amphotericin B on afferent renal arterioles results in reduced glomerular and renal tubular blood flow. Other effects on the kidney include potassium, magnesium, and bicarbonate wasting and decreased erythropoietin production. Loss of renal function is due to the destruction of renal tubular cells, disruption of tubular basement membrane, and loss of functioning nephron units. Saline loading, such as the infusion of 1 L saline before ABD, has been associated with reduced nephrotoxicity in some studies. Potassium wasting often requires supplemental oral or intravenous potassium. Renal tubular acidosis from bicarbonate wasting rarely requires base replacement, but other drugs and diseases that promote acidosis may act synergistically.

Azotemia caused by amphotericin B is often worse in patients taking other nephrotoxic drugs. Hypotension, intravascular volume depletion, and other preexisting renal disease all magnify the management problems associated with amphotericin B–induced azotemia. These toxicities are lessened by use of the lipid-associated formulations of amphotericin B.

Early in the course of therapy with ABD, azotemia may increase rapidly; it often improves a little and then stabilizes after several days. Adults with no other renal disease have an average serum creatinine level of 2 to 3 mg/dL at therapeutic doses, and therapy should not be withheld unless azotemia exceeds this level. Attempting to give ABD to an adult without causing azotemia usually leads to inadequate therapy.

Other Chronic Toxicity

Nausea, anorexia, and vomiting are common. Phlebitis occurs if peripheral vein catheters are used. Normocytic normochromic anemia occurs gradually. The hematocrit rarely falls below 20 to 25% unless other causes of anemia are present. Rarely, thrombocytopenia, modest leukopenia, arrhythmias, coagulopathy, hemorrhagic enteritis, tinnitus, vertigo, encephalopathy, seizures, hemolysis, or dysesthesia of the soles of the feet may be observed.

Acute Reactions

About 30 to 45 minutes after beginning the first few ABD infusions, chills, fever, and tachypnea may occur, peak in 15 to 30 minutes, and then slowly abate over 2 to 4 hours. A patient with underlying cardiac or pulmonary disease may have hypoxemia. These reactions are less common in young children or in patients receiving corticosteroids. Subsequent infusions of the same dose cause progressively milder reactions. Premedication with acetaminophen or the addition of hydrocortisone 25 to 50 mg to the infusion solution can diminish the reaction. Meperidine given early in a chill shortens the rigors but may induce nausea or emesis. Concern about this kind of reaction in an unstable patient had led some physicians to use a test dose of 1 mg given over a 15-minute period to assess the subsequent reaction over 1 hour before deciding whether to administer a full therapeutic dose. Patients with rapidly progressive mycoses should receive a full therapeutic dose within 24 hours. These reactions should not be mistaken for anaphylaxis or considered a contraindication to further amphotericin B. True allergic reactions are extremely rare.

Administration

ABD is infused over a 2- to 4-hour interval. Infusions 1 hour in duration generally appear to be safe for persons who have tolerated slower infusions. Rapid infusion in patients with severely compromised renal function may lead to acute, marked hyperkalemia and ventricular fibrillation.

Patients receiving a stable daily dose can be changed to a double dose on alternate days to reduce the frequency of infusion-associated toxicity, particularly anorexia, and to make outpatient therapy more convenient. Doses above 1.5 mg/kg are generally not given on this schedule because the toxicity of such infusions is not well described. Continuous infusion of amphotericin B with doses up to 2.0 mg/kg/24 hours is another approach (based on limited data) to reducing toxicity, but this is not consistent with the observation that the principal pharmacodynamic driver of efficacy for amphotericin B is peak drug concentration.

Dosage

Daily ABD doses of 0.3 mg/kg often suffice for esophageal candidiasis. A dose of 0.5 mg/kg is appropriate for blastomycosis, disseminated histoplasmosis, and extracutaneous sporotrichosis. Patients with cryptococcal meningitis are generally given doses of 0.6 to 0.8 mg/kg; those with coccidioidomycosis may require doses of 1 mg/kg. Patients with mucormycosis or invasive aspergillosis are given daily doses of 1 to 1.5 mg/kg until improvement is clearly present. Doses of 0.5 to 1.0 mg/kg are often used in neutropenic patients receiving empirical amphotericin B. Local instillation of amphotericin B into cerebrospinal fluid (CSF), joints, or pleura is rarely indicated. One exception is coccidioidal meningitis, which is treated with intrathecal ABD because it may produce superior results to systemic azole therapy, particularly in the long term, although with far greater toxicity. Intraocular administration for fungal endophthalmitis is occasionally used; doses of 10 μg appear to avoid retinal toxicity. Corneal baths with 1 mg/mL in sterile water are useful for fungal keratitis but are irritating.

Lipid-Associated Formulations of Amphotericin B

Pharmacology and Toxicity

The three lipid-associated formulations have quite different pharmacokinetic patterns. When compared on the basis of equal dosages (mg/kg), the lipid-associated formulations produce tissue amphotericin B concentrations that range from 90% lower to 500% higher than those seen with ABD, with the most consistent relative reduction seen in the kidney. The lipid-associated formulations are typically given at doses that are 3- to 12-fold higher than those used for ABD. All three formulations generally require higher doses in experimental animals to achieve the same therapeutic effect as ABD.

These higher but equipotent doses are notably better tolerated than ABD, with reductions in both the frequency and the severity of acute infusion-related reactions and chronic nephrotoxicity. An exception is ABCD, which generally induces acute infusion-related reactions similar to those for ABD.

Randomized clinical trials comparing ABD as therapy for a defined mycosis are limited to demonstrations that liposomal amphotericin B has a similar efficacy for cryptococcal meningitis and a greater efficacy for histoplasmosis. Randomized comparisons with ABD in persistently neutropenic and febrile cancer patients consistently demonstrate a better tolerability profile, but little data on differential antifungal effect. The aggregate open-label data on efficacy rates for the lipid-associated formulations are similar to those for ABD. Although the lipid-associated formulations are notably more costly than ABD, the purchase cost of the compound must be balanced against the morbidity of ABD-related nephrotoxicity and the financial costs of monitoring, treating, and managing it.

FLUCYTOSINE

Formulation and Pharmacology

Flucytosine (5-fluorocytosine) is the fluorine analogue of a normal body constituent, cytosine. Flucytosine is marketed as 250- and 500-mg capsules. Absorption from the gastrointestinal tract is rapid and complete, and approximately 90% is excreted unchanged in the urine. CSF concentrations are approximately 74% of simultaneous serum concentrations; the drug also penetrates well into aqueous humor, joints, bronchial secretions, peritoneal fluid, brain, bile, and bone, and it is readily cleared by hemodialysis and peritoneal dialysis.

The half-life of the drug in the serum of patients with normal renal function is 3 to 5 hours and is longer in newborns. Abnormal hepatic function has no influence, but decreased renal function prolongs the half-life.

Mechanisms of Action and Resistance

Isolates of *Candida* species are usually susceptible, as are most isolates of *Cryptococcus neoformans*. Flucytosine is often active against isolates of *Aspergillus* species and against the melanin-pigmented molds that cause chromoblastomycosis. The mechanism of antifungal action appears to be deamination to 5-fluorouracil and then conversion through several steps to 5-fluorodeoxyuridylic acid monophosphate, a noncompetitive inhibitor of thymidylate synthetase, which interferes with DNA synthesis, or conversion to 5-fluouridine triphosphate, which is incorporated into RNA and causes aberrant transcription. In some studies, the principal pharmacodynamic driver of response was the proportion of time the blood level exceeded the MIC. Resistance may be due to loss of the cytosine permease that permits flucytosine to cross the fungal cell membrane or loss of any of the enzymes that lead to its conversion into forms that interfere with DNA or RNA synthesis.

Administration and Dosage

Flucytosine is administered orally, 100 to 150 mg/kg/day, in four divided doses. As an approximation, the total daily dose should be reduced to 75 mg/kg with a creatinine clearance of 26 to 50 mL/minute and to 37 mg/kg when the creatinine clearance is 13 to 25 mL/minute. Ideally, the blood level should be measured in azotemic patients 2 hours after the last dose and immediately before the next dose. These values should range between 10 and 100 μg/mL. Patients requiring hemodialysis can be given a single post-dialysis dose of 37.5 mg/kg. Further doses are adjusted by blood level.

Flucytosine given alone to patients with normal renal, hematologic, and gastrointestinal function is infrequently associated with adverse effects, including rash, diarrhea, and hepatic dysfunction. In the presence of azotemia (such as that caused by concomitant amphotericin B), leukopenia, thrombocytopenia, and enterocolitis may appear. These complications seem to be far more frequent among patients whose flucytosine blood levels attain, and especially if they exceed, 100 to 125 μg/mL. Patients receiving flucytosine whose renal function is changing should have their serum flucytosine concentrations determined twice a week, and the leukocyte count, platelet count, alkaline phosphatase, and aminotransferase levels should be measured at a similar frequency. Patients in whom loose stools or dull abdominal pain suddenly develops or who have laboratory evidence consistent with flucytosine toxicity should have their flucytosine blood levels determined, and consideration should be given to withholding the drug until the situation is clarified. Patients with bone marrow and gastrointestinal toxicity from flucytosine often tolerate the drug at a reduced dosage. Uncommonly, vomiting, bowel perforation, confusion, hallucinations, headache, sedation, and euphoria have been reported. Flucytosine is contraindicated in pregnancy.

Conversion of flucytosine to 5-fluorouracil within the human body occurs to a sufficient degree to possibly account for the drug's toxicity to bone marrow and the gastrointestinal tract. It is likely that the drug is secreted into the gut, where flucytosine becomes deaminated by intestinal bacteria and is reabsorbed as 5-fluorouracil.

Flucytosine has a beneficial effect in patients with cryptococcosis, candidiasis, and chromoblastomycosis. It is not the drug of choice for any infection, however, because its clinical efficacy in the first two mycoses is inferior to that of amphotericin B, primary drug resistance is not uncommon in *Candida* infection, and secondary drug resistance is common in cryptococcosis and chromoblastomycosis.

Flucytosine and amphotericin B are at least additive in their effects in vitro and in mice. Flucytosine permits a lower dose of amphotericin B to be used to achieve the same therapeutic effect, and amphotericin B prevents the emergence of secondary drug resistance. The same advantages have been confirmed in two large multicenter studies of cryptococcal meningitis.

Flucytosine therapy is more difficult to manage in patients with diminished bone marrow reserve. Intravenous flucytosine is no longer available in the United States, but it is used at the same dosage as the capsule formulation.

Flucytosine resistance has occurred, albeit uncommonly, during combination therapy. Use of combination therapy in such patients incurs the risk of toxicity without evidence that flucytosine adds to the therapeutic effect. In most laboratories, a MIC of 20 μg/mL or less is considered susceptible.

AZOLE ANTIFUNGAL AGENTS

Mechanism of Action

The azole ring confers antifungal activity on a variety of synthetic organic compounds.

N-substitution of imidazoles has created a family of drugs called triazoles that have the same mechanism of action as imidazoles, a similar or broader spectrum of activity, and less effect on human sterol synthesis. Both imidazoles and triazoles inhibit C-14α demethylation of lanosterol in fungi; this leads to reduced concentrations of ergosterol, which is essential for a normal fungal cytoplasmic membrane. In some studies, the principal pharmacodynamic driver for response to the triazole antifungal agents has been the ratio of total drug exposure (area under the curve) to the MIC. Because of their interaction with the cytochrome P-450 (CYP) system and, in some cases, the P-glycoprotein pumps, the azoles as a class have a significant number of drug-drug interactions, only some of which are covered here. In any patient in whom azole therapy is contemplated, package inserts for the drug should be consulted to determine which of the patient's other medications could result in a significant drug-drug interaction.

Newer triazoles have properties that make them preferable to ketoconazole. These include not only less hormonal inhibition but also better distribution into body fluids, both parenteral and oral formulations, less hepatotoxicity, and a broader spectrum. Some have fewer drug interactions. Resistance to azoles in previously susceptible species is emerging. Resistance mechanisms include increased drug efflux and altered or increased C-14α demethylase. It has been speculated that some of the common mutations in this demethylase in *Aspergillus* isolates from certain geographic areas, resulting in resistance, may have arisen owing to the widespread agricultural use of azole fungicides. All agents in this class have the potential for embryotoxicity and teratogenicity and should be avoided during pregnancy.

Ketoconazole

Formulations and Pharmacology

Ketoconazole is available in tablet form. It is metabolized in the liver and excreted as inactive drug in bile and, to a small extent, urine. The drug is not removed significantly by hemodialysis or peritoneal dialysis. Decreased renal or hepatic function does not alter plasma drug levels. The initial half-life is

approximately 2 hours, with a β-phase half-life of about 9 hours commencing 8 to 12 hours after ingestion.

Oral absorption of ketoconazole differs among individuals. Serious gastrointestinal disease may lead to low blood levels. Inhibitors of gastric acid secretion should not be given to patients taking ketoconazole because blood levels of the latter drug are drastically reduced. The drinking of citrus fruit juices or cola beverages with ketoconazole improves absorption in hypochlorhydric patients. Patients who need antacids should take them 1 to 2 hours after ketoconazole. Rifampin causes substantial lowering of ketoconazole blood levels, by CYP enzyme induction. The levels of other co-administered drugs may be raised owing to CYP enzyme blockade. Cyclosporine blood levels should be monitored during ketoconazole therapy because they usually increase. Penetration into CSF is poor, even in the presence of inflammation. Low concentrations are found in vaginal secretions, saliva, and breast milk, but penetration into inflamed joints is better.

Uses

The main advantage of ketoconazole is its lower cost compared with triazoles. When used at a daily dose of 400 mg, the drug is effective in chronic mucocutaneous candidiasis, coccidioidomycosis, and paracoccidioidomycosis, but fluconazole or itraconazole is preferred. Some patients with chromoblastomycosis, histoplasmosis, blastomycosis, or cutaneous sporotrichosis respond to ketoconazole, as do patients with dermatophytosis, but itraconazole is preferred. Therapy is continued for 6 to 12 months or longer, if the response is slow, to prevent relapse. Improvement may not be evident for weeks to months. Although the dose can be advanced to 600 or 800 mg/day in patients who are not responding to therapy, there is more evidence of increased toxicity than increased efficacy. In coccidioidal meningitis, ketoconazole requires doses exceeding 400 mg/day and has limited efficacy. Aspergillosis does not respond to ketoconazole; additionally, the subsequent use of amphotericin B may be antagonized.

Adverse Effects

The most frequent toxic effects are anorexia, nausea, and vomiting. Dividing doses greater than 400 mg/day is not recommended because hormonal suppression is prolonged. Ketoconazole causes a dose-dependent depression in the serum testosterone- and adrenocorticotropic hormone–stimulated cortisol response. The effect of doses of 800 to 1200 mg/day is profound enough to have prompted trials in the treatment of Cushing's syndrome and prostate cancer. Hypertension is seen in a few of these high-dose patients, in association with increased mineralocorticoid precursors. Gynecomastia, oligospermia, and menstrual irregularities may also be seen during prolonged therapy. Allergic rash and pruritus have been noted.

Perhaps the gravest complication is hepatitis. Fortunately, this complication is estimated to occur in only 1 in 15,000 exposed individuals. A slight, asymptomatic elevation of transaminase levels occurs in 5 to 15% and is generally transient. Ketoconazole-associated hepatitis begins as anorexia, malaise, nausea, and vomiting. Eighty percent of cases occur within the first 3 months. Progression can be swift. If hepatotoxicity is suspected, serum transaminase and alkaline phosphatase levels should be measured. Some authorities have recommended that liver function be measured periodically. This procedure does not protect a patient who has a rapid onset of hepatitis in the interval between tests, but it does require that all patients with abnormalities be contacted to inquire about symptoms and to arrange for repeat testing.

Itraconazole

Formulations and Pharmacology

Itraconazole (Sporanox) is marketed as a capsule and as an oral suspension in cyclodextrin (an oligosaccharide ring). The ring entraps the hydrophobic, water-insoluble drug, thus making it soluble; it is then released either at the lipid membrane of the enterocyte after oral administration or directly into tissues after intravenous administration. The solution can be delivered through a nasogastric tube in intubated patients, and it makes the dosing of infants and small children more convenient. Oral absorption of the capsule is significantly enhanced by food, whereas absorption of the solution is best on an empty stomach. Co-administration of a cola beverage with itraconazole capsules increases absorption. Peak levels with either preparation are achieved 4 to 6 hours after a dose. Steady state is achieved only after 13 to 15 days, at which time the β-elimination half-life is about 19 to 22 hours. Absorption of the capsule is markedly depressed in bone marrow transplant recipients, probably because of hypochlorhydria, mucositis, and graft-versus-host intestinal changes, and in patients with acquired immunodeficiency syndrome (AIDS) because of enteritis, but this problem can be alleviated by using the solution.

For deep mycoses, an initial itraconazole dose of 200 mg three times a day is recommended for the first 3 days to quickly achieve high serum and tissue levels. Hydroxyitraconazole, a metabolite of itraconazole, appears in the blood in amounts roughly twice that of the parent drug; it has antifungal activity and pharmacokinetics similar to those of the parent compound.

Bioassays of itraconazole give much higher concentrations than does measurement by high-pressure liquid chromatography; the difference depends on the susceptibility of the bioassay organism to hydroxyitraconazole. Concentrations of itraconazole in tissue, pus, and bronchial secretions are generally higher than those in plasma, but CSF concentrations are usually unmeasurable, even in patients with meningitis. Ocular levels are low. Saliva concentrations persist for 8 hours after administration of the solution and may be beneficial in treating oral disease or eradicating oral colonization. The drug is metabolized in the liver and excreted in feces as metabolites. Of the cyclodextrin liquid administered, less than 0.5% is absorbed. No significant amount of bioactive itraconazole appears in urine. Plasma concentrations do not increase in patients with renal insufficiency or decrease with hemodialysis. The half-life is prolonged in those with cirrhosis.

Adverse Effects

The most common adverse effect is dose-related nausea and abdominal discomfort, but symptoms rarely necessitate stopping therapy. Dividing the dose and administering the drug twice daily can improve tolerance and raise blood levels. Hypokalemia and edema may occur at doses of 400 mg/day or higher. Allergic rash is seen occasionally. Itraconazole is rarely hepatotoxic. Diarrhea, nausea, and other gastrointestinal complaints are more frequent with the solution. A negative inotropic effect is rarely seen.

Drug Interactions

Blood levels are reduced by about half in patients taking drugs that decrease gastric acidity. Rifampin, rifabutin, isoniazid, phenytoin, carbamazepine, and phenobarbital decrease itraconazole blood levels. Itraconazole decreases rifampin blood levels and increases blood levels of some antihistamines, potentially causing polymorphic ventricular tachycardia (torsades de pointes), as well as increasing levels of warfarin, benzodiazepines, hepatic hydroxymethylglutaryl–coenzyme A reductase cholesterol-lowering agents, dihydropyridine calcium-channel blockers, digoxin, quinidine, cyclosporine, tacrolimus, methylprednisolone, human immunodeficiency virus (HIV) protease inhibitors (ritonavir, indinavir), and vinca alkaloids (vincristine, vinblastine).

Uses

Itraconazole is useful for the treatment of invasive aspergillosis, allergic bronchopulmonary aspergillosis, blastomycosis, histoplasmosis, meningeal and nonmeningeal coccidioidomycosis, paracoccidioidomycosis, sporotrichosis, phaeohyphomycosis, mucosal candidiasis, ringworm (including onychomycosis), and tinea versicolor. Itraconazole is also useful for the prevention of relapse in AIDS patients with disseminated histoplasmosis. Itraconazole may be useful for prophylaxis against fungal infections during neutropenia and as empirical therapy for febrile episodes in neutropenia.

Fluconazole

Formulations and Pharmacology

Fluconazole is currently available in tablets, as a powder for oral suspension, and as an intravenous formulation. Fluconazole is well absorbed from the gastrointestinal tract. Of the oral dose, 60 to 75% appears unchanged in the urine. Oral absorption is not decreased in patients with AIDS or patients taking H_2-blocking agents.

Concentrations of fluconazole in CSF are approximately 70% of simultaneous blood levels, whether or not the meninges are inflamed, and the drug penetrates into the brain. Penetration into saliva, sputum, urine, and other body fluids is also excellent.

The half-life in patients with normal renal function is 27 to 34 hours; it increases to 59 and 98 hours in groups with creatinine clearances of 35 and 14 mL/minute, respectively. The normal dose should be reduced to 50% when the creatinine clearance is reduced to 50 mL/minute and to 25% when the creatinine clearance is below 20 mL/minute. A loading dose of twice the daily dose is recommended. Patients receiving hemodialysis should have one daily dose after each session.

Drug Interactions

Fluconazole can cause significant increases in the blood level of phenytoin, glipizide, glyburide, tolbutamide, warfarin, rifabutin, or cyclosporine. Rifampin lowers fluconazole blood levels by about one fourth.

Adverse Effects

Adverse effects are uncommon. Even with chronic therapy, including doses exceeding 400 mg/day, headache, hair loss, and anorexia were the most common symptoms; 10% of patients had rises in aspartate aminotransferase levels. Alopecia is reversible, in some cases, even when the drug is continued at lower doses. Neurotoxicity has been described after heroic doses of 2000 mg/day. Rarely, anaphylaxis after the first dose or Stevens-Johnson syndrome has been observed.

Indications

Candidiasis

Provided the infection is not caused by fluconazole-resistant *Candida*, fluconazole is effective for the treatment of oropharyngeal and esophageal candidiasis. A single dose of 150 mg is approximately as effective as topical treatment of vulvovaginal candidiasis. Patients with candidemia who are not neutropenic or otherwise seriously immunosuppressed respond as well to intravenous fluconazole therapy as to amphotericin B. A study comparing fluconazole with a combination of fluconazole plus amphotericin as initial therapy of candidemia found that the combination might produce more rapid clearance of the blood stream. In a few patients with *Candida* endocarditis, long-term fluconazole therapy has been used to prevent relapse after amphotericin B therapy. For immunosuppressed patients and for rapidly progressing or severely ill patients with deep candidiasis, amphotericin B or caspofungin is preferred.

Cryptococcal Meningitis

Many authorities recommend amphotericin B or amphotericin B plus flucytosine for at least the first 2 weeks to treat cryptococcal meningitis. Therapy can then be changed to fluconazole 400 mg/day for 2 months if the patient is clinically stable. The propensity of AIDS patients to relapse has led to lifelong maintenance therapy with fluconazole 200 mg/day. Itraconazole capsules are inferior to fluconazole for maintenance therapy. Relapse because of fluconazole resistance is rare. Fluconazole is effective for the eradication of genitourinary foci. For patients without AIDS, fluconazole is useful for those who have completed a course of amphotericin B and seem to be at high risk for relapse.

Other Mycoses

Fluconazole is useful for coccidioidal meningitis and for disseminated nonmeningeal coccidioidomycosis, but a direct comparison with itraconazole found a trend favoring itraconazole owing to its superior efficacy for skeletal infections. The two drugs were similarly efficacious for soft tissue and pulmonary infections. Cutaneous sporotrichosis, ringworm, histoplasmosis, and blastomycosis may respond to fluconazole, but the results are inferior to those with itraconazole.

Prophylaxis in Neutropenic Patients

Fluconazole decreases the incidence of death from deep mycoses in bone marrow transplant recipients. All the protection afforded seems to be related to deep candidiasis. In a long-term follow-up of one study, bone marrow transplant recipients who received at least 75 days of fluconazole prophylaxis also had improved survival. Use of this drug for prophylaxis may result in shifts to less susceptible species.

Prophylaxis in Patients with AIDS

Fluconazole has reduced the incidence of oral and vulvovaginal candidiasis and cryptococcosis in patients with advanced HIV infection, but it has negligible effects on other mycoses. Cost, lack of effect on survival, and the possibility of azole resistance have led the advisory committee of the Infectious Diseases Society of America to recommend against fluconazole prophylaxis in AIDS patients.

Voriconazole

Formulations and Pharmacology

Voriconazole is marketed as a tablet and as a solution in sulfobutyl ether β-cyclodextrin for intravenous administration. Voriconazole is cleared by hepatic metabolism, with less than 2% of the dose excreted unchanged in the urine. Voriconazole exhibits nonlinear pharmacokinetics owing to saturation of the clearance pathways at higher doses. The principal enzyme involved in clearance is hepatic CYP2C19. This enzyme has significant genetic polymorphisms that affect the metabolism of this drug. Despite these differences in metabolism, the achieved plasma levels overlap, and an initial dose adjustment based on genotype or racial group is not necessary. Different studies have suggested that favorable outcomes correlate with serum concentrations greater than 1 to 2 μg/mL, and therapeutic drug monitoring with dose adjustments as necessary is recommended.

Standard loading doses followed by maintenance doses that are 50% of normal are recommended for individuals with mild to moderate hepatic cirrhosis. Dosage adjustments are not required for renal dysfunction, and voriconazole is not significantly cleared by hemodialysis. Because of nephrotoxicity from the cyclodextrin, the intravenous formulation should not be used in patients with a creatinine clearance less than 50 mL/minute.

Drug Interactions

Voriconazole has many drug interactions. Rifampin, carbamazepine, and long-acting barbiturates induce the hepatic enzymes responsible for the clearance of voriconazole and reduce voriconazole levels. Voriconazole and either rifabutin or phenytoin reciprocally alter their clearance. Sirolimus levels are increased dramatically. Reduction in the clearance of pimozide, quinidine, and some antihistamines may be sufficient to place the patient at risk for QTc prolongation. Reduction in the clearance of ergot alkaloids could lead to chronic ergot poisoning. Cyclosporine, tacrolimus, warfarin, oral coumarins, lipid-lowering statin agents, benzodiazepines, calcium-channel blockers, sulfonylureas, and vinca alkaloids can be co-administered, but the dosage of these drugs may need to be reduced, and clinical or laboratory monitoring is suggested. Voriconazole significantly reduces the rate of clearance of omeprazole. Other interactions are possible, and any CYP inhibitors, blockers, or inducers could have an interaction with voriconazole.

Adverse Effects

The most frequently reported adverse event is a transient, reversible visual disturbance beginning approximately 30 minutes after a dose. Patients should be advised to avoid activities that require keen visual acuity while experiencing visual changes. Hallucinations and confusion have also been reported, associated with higher blood levels. Liver enzyme abnormalities also appear to correlate with higher blood levels. Photosensitivity can be severe and has been associated with skin cancers in rare instances. Prolongation of the QT interval and tachyarrhythmias have been noted in patients with pro-arrhythmic factors, such as electrolyte abnormalities.

Indications

Aspergillosis

Voriconazole was licensed for the treatment of invasive aspergillosis on the basis of a randomized, unblinded comparative trial in which patients were randomized to receive initial therapy with either voriconazole or ABD.[2] Following the initial randomization, patients could be switched to other licensed therapies, as dictated by clinical events. After 12 weeks, 53% of the patients randomized to voriconazole, but only 32% of those randomized to ABD, had a successful outcome.

Other Mycoses

Voriconazole is also licensed for the treatment of invasive fusariosis and scedosporiosis, based on high response rates for these diseases. The drug is efficacious in esophageal candidiasis, invasive candidiasis, and refractory candidiasis. Although the drug has appeal for use in prophylaxis, there has been concern about breakthrough zygomycoses with long-term use.

Posaconazole

Formulations and Pharmacology

Posaconazole is available only as an oral suspension. Absorption is maximized by dividing the daily dose into four administrations, each with fatty food. Clearance is primarily by fecal excretion, with only 13% excreted via renal clearance. Hepatic metabolism via uridine diphosphate glucuronidation plays only a small role in clearance, and CYP-mediated oxidation does not occur. The dose is 800 mg/day for treatment of deep mycoses, although 600 mg has been used successfully for prophylaxis, and 200 mg has been used for mucosal candidiasis. At steady state, 800 mg/day produces a C_{max} (peak concentration) of 4.2 μg/mL. Blood levels appear to be rather unpredictable,

and outcomes in the treatment of aspergillosis correlate with levels. Therapeutic drug monitoring is advisable, and levels greater than 0.7 μg/mL have been recommended for prophylaxis. Dosage adjustment is not needed for hepatic or renal failure or hemodialysis.

Drug Interactions

Although posaconazole has fewer interactions than itraconazole and voriconazole, there are many significant ones, including increased levels of calcium-channel blockers, cyclosporine, sirolimus, tacrolimus, quinidine, rifampicin, and benzodiazepines. Posaconazole levels are reduced by cimetidine, carbamazepine, efavirenz, and rifampin.

Adverse Effects

The paucity of side effects is similar to that of fluconazole. Gastrointestinal symptoms and headache are occasionally seen. Electrolyte abnormalities should be rectified before therapy to avoid arrhythmias.

Indications

Posaconazole appears to possess a very broad spectrum of activity against molds, including many zygomycetes, a unique property among azoles. The main interest in the drug has been as prophylaxis and for salvage therapy of refractory mycoses. Efficacy in preventing opportunistic mycoses has been shown in the highest-risk patients, transplant patients with graft-versus-host disease, and those with hematologic malignancies and neutropenia.[3,4] Impressive results in salvage have been demonstrated in aspergillosis and coccidioidomycosis. Superficial candidiasis is also responsive.

ECHINOCANDIN ANTIFUNGAL AGENTS

General Features

The echinocandin antifungal agents act by inhibiting the synthesis of 1,3-β-D-glucan in the fungal cell wall. In studies, the principal pharmacodynamic driver of in vivo response has been the ratio of the peak concentration to the MIC. There are now three licensed echinocandins: caspofungin, micafungin, and anidulafungin. These agents are similar to one another, having very few drug interactions, an admirably low adverse event rate, and essentially identical antifungal spectra. Of the three drugs, caspofungin has the broadest array of approved indications and the most clinical data. Micafungin has the most detailed data on its use in neonates and children. Anidulafungin appears to have somewhat fewer drug-drug interactions. All are cyclic lipopeptides that must be given intravenously.

They are fungicidal against all *Candida* species, including isolates resistant to other agents. Reduced activity against isolates of *Candida parapsilosis* and *Candida guilliermondii* and a paradoxical effect whereby high concentrations permit growth in vitro have been noted in a minority of *Candida* isolates and do not appear to be clinically relevant. All are active against *Aspergillus* species, but activity is limited to growing and dividing hyphal elements. Their activity against other fungi is variable.

Caspofungin

Formulations and Pharmacology

Caspofungin is marketed for intravenous infusion. The clearance of caspofungin is through a combination of spontaneous chemical degradation, hydrolysis, and *N*-acetylation. Dose adjustments are not required for impaired renal function or hemodialysis. The clearance of caspofungin is modestly reduced in subjects with moderate hepatic insufficiency, and a reduction of the usual daily dose is recommended. Penetration into infected tissues appears to be good.

Drug Interactions

Caspofungin has few meaningful drug interactions. Cyclosporine co-administration increases caspofungin exposure and has been associated with increased hepatic transaminase levels, so concomitant use requires caution. Caspofungin reduces tacrolimus exposure by approximately 20%, and dosage adjustments may be required. Rifampin reduces caspofungin blood levels by approximately 30%, so the daily dosage of caspofungin should be increased from 50 mg to 70 mg if these drugs are co-administered. Likewise, limited data on other inducers of drug clearance (efavirenz, nevirapine, phenytoin, dexamethasone, carbamazepine) suggest that reduced caspofungin levels are possible and that increasing the daily dose to 70 mg should be considered.

Adverse Effects

Overall, the adverse reactions with caspofungin have been infrequent and minor. Symptoms possibly related to histamine release during rapid infusion have been reported.

Indications

Caspofungin is indicated for the treatment of invasive candidiasis[5] and esophageal candidiasis. Caspofungin is also indicated for invasive aspergillosis in patients who are refractory to or intolerant of other therapies. With its activity against these two major opportunistic pathogens, the use of caspofungin for empirical therapy in high-risk situations is logical and is supported by clinical trials.

Micafungin

Micafungin has an in vitro spectrum and properties similar to caspofungin. It is similarly cidal for *Candida* species and noncidal in vitro for *Aspergillus*.

Formulations and Pharmacology

The drug is light sensitive. After an intravenous infusion, the terminal half-life is about 15 hours. A 50-mg dose produces a C_{max} of 3.4 μg/mL. Metabolism appears to be mostly through fecal excretion; less than 1% is excreted in the urine. The drug appears to penetrate particularly well into the lungs, liver, kidneys, and gastric mucosa. No adjustment for hepatic or renal insufficiency is needed.

Drug Interactions

Micafungin has fewer drug interactions than caspofungin. There is no interaction with cyclosporine or rifampin.

Adverse Effects

Micafungin has an excellent safety profile. Histamine release, resulting most prominently in erythema over the body, can be avoided by slow infusion.

Indications

Efficacy is good in invasive candidiasis, similar to that of amphotericin or caspofungin.[6] In clinical dose-finding studies against *Candida* esophagitis, doses of 75 to 150 mg/day were particularly effective. A trial of prophylaxis in neutropenic patients with hematopoietic stem cell transplant showed efficacy at 50 mg/day.[7] Limited experience suggests comparable activity to caspofungin against aspergillosis.

Anidulafungin

Formulations and Pharmacology

Anidulafungin is slowly degraded by the chemical opening of its ring structure. A 100-mg dose produces a C_{max} of 8.6 μg/mL at a T_{max} (time of peak concentration) of 6 to 7 hours. The half-life is 30 to 40 hours. Dose adjustments are not required for renal or hepatic insufficiency.

Drug Interactions

Anidulafungin has no meaningful CYP enzyme interactions. It is not an inducer, inhibitor, or substrate and has no interaction with drugs cleared by these pathways or drugs that induce these pathways.

Adverse Effects

Histamine-mediated symptoms (e.g., rash, urticaria, flushing, pruritus, dyspnea, hypotension) have been noted on occasion, but they are infrequent when the rate of infusion does not exceed 1.1 mg/minute. Other adverse reactions to anidulafungin have generally been infrequent and minor.

Indications

Anidulafungin is indicated for the treatment of invasive candidiasis and esophageal candidiasis. Randomized trials indicate that anidulafungin is at least as efficacious as fluconazole.[8] Inefficacy against *C. parapsilosis* may be of greatest concern with this echinocandin.

OTHER AGENTS

Combinations of antifungal agents are increasingly being used in an effort to improve the appalling response rates in some diseases and to combine drugs with different mechanisms of action. Although synergy in vitro may be relatively easy to demonstrate, there are few examples of synergy in animal model studies. In patients, the costs are high, and the side effects are likely to be increased. The clinical advantages of the amphotericin-flucytosine

combination in cryptococcosis have yet to be documented definitively in other situations.

Immunomodulators, particularly cytokines, hold promise, but insufficient clinical data exist to determine where and how these drugs might be used. Granulocyte-macrophage colony-stimulating factor was shown to be effective in one trial when given prophylactically during induction therapy of high-risk leukemia patients.

Therapy of the various forms of tinea and of onychomycosis with systemic agents is discussed in Chapter 446. Although *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) is now classified among the fungi, the drugs used to treat it are principally used to treat parasitic infections (Chapter 349).

HISTOPLASMOSIS

CAROL A. KAUFFMAN

DEFINITION

Histoplasmosis is the most common endemic mycosis in the United States. Most infections are self-limited, but the organism has the ability to cause acute and chronic pulmonary infections and disseminated infection.

The Pathogen

Histoplasma capsulatum var *capsulatum* is a thermally dimorphic fungus. In the environment and at temperatures lower than 35° C, it exists as a mold that produces conidia, both tuberculate macroconidia, which are helpful for identification purposes in the laboratory, and microconidia, which are the infectious form. In tissues and at 35 to 37° C, *H. capsulatum* transforms into tiny 2- to 4-μm oval yeasts that reproduce by budding and parasitize macrophages. African histoplasmosis is caused by a different subspecies, *H. capsulatum* var *duboisii*, and has different disease manifestations.

EPIDEMIOLOGY

Histoplasmosis, though found worldwide, is primarily a disease of North and Central America. *H. capsulatum* is endemic in the Mississippi and Ohio River valleys, with extension into the St. Lawrence basin; microfoci exist in discrete isolated areas in several eastern states. Soil, caves, and abandoned buildings containing high concentrations of bird or bat guano support luxuriant growth of the organism. Every year, hundreds of thousands of individuals who live in areas endemic for *H. capsulatum* are infected. Most cases are sporadic and the exact source of exposure is unknown. Point source outbreaks that have included as few as 4 persons and as many as 100,000 have been well described in association with disruption of soil; cleaning attics, bridges, or barns; tearing down old structures laden with guano; and spelunking.

PATHOBIOLOGY

After inhalation of microconidia into the alveoli, a localized pulmonary infection ensues. Neutrophils and macrophages phagocytize the organism, now in the yeast phase; the organism is able to survive and travels within macrophages to the hilar and mediastinal lymph nodes and throughout the reticuloendothelial system by hematogenous dissemination. Such dissemination probably occurs in most persons who are infected and in normal hosts is associated with no symptoms. After several weeks, T cells specifically sensitized by *H. capsulatum* antigens activate macrophages, which are then able to kill the intracellular fungi. Histoplasmosis is a classic example of the pivotal importance of the cell-mediated immune system in containing intracellular pathogens.

The extent of disease is determined by both the number of conidia inhaled and the immune response of the host. A small inoculum can cause severe pulmonary infection or progress to acute symptomatic disseminated histoplasmosis in immunosuppressed patients. Conversely, severe life-threatening pulmonary infection may develop in a healthy individual if a large number of conidia are inhaled, as might occur during the demolition of old buildings or while spelunking in a heavily infested cave.

Reinfection can occur in persons who previously had histoplasmosis but is uncommon and almost always occurs in the setting of heavy exposure. Reactivation of latent infection takes place in patients who have deficient cell-mediated immunity, as evidenced by the occurrence of histoplasmosis in immunosuppressed persons who grew up in the endemic area but have not been back in that area for years.

CLINICAL MANIFESTATIONS

Acute Pulmonary Histoplasmosis

Infection is asymptomatic in most people infected with *H. capsulatum*. Those who do have symptomatic pulmonary infection usually have a self-limited illness that begins several weeks after exposure and is characterized by fever, chills, fatigue, nonproductive cough, anterior chest discomfort, and myalgias. A patchy lobar or multilobar nodular infiltrate is noted on chest radiographs.

The differential diagnosis of acute pulmonary histoplasmosis includes pneumonia from *Blastomyces dermatitidis*, *Mycoplasma pneumoniae*, *Legionella* sp, and *Chlamydia pneumoniae*. When enlarged hilar or mediastinal lymph nodes are present, histoplasmosis should be strongly considered. The most difficult to differentiate is acute pulmonary blastomycosis (Chapter 342) because the endemic areas overlap, a comparable history of outdoor activities is often obtained, and radiographs show similar findings.

In patients who have experienced heavy exposure to *H. capsulatum* and in those who are immunosuppressed, acute pulmonary histoplasmosis can be life-threatening. High spiking fevers, chills, prostration, dyspnea, and cough are prominent. Chest radiographs show diffuse reticulonodular pulmonary infiltrates, and respiratory failure can occur rapidly.

Chronic Pulmonary Histoplasmosis

Chronic cavitary pulmonary histoplasmosis is a progressive, often fatal form of histoplasmosis that develops almost exclusively in older patients who have chronic obstructive pulmonary disease. Symptoms include fever, fatigue, anorexia, weight loss, cough productive of purulent sputum, and hemoptysis. On chest radiography the usual findings are unilateral or bilateral upper lobe infiltrates with multiple cavities and extensive fibrosis in the lower lobes. Chronic pulmonary histoplasmosis mimics tuberculosis, other fungal pneumonias (especially blastomycosis and sporotrichosis), and nontuberculous mycobacterial infections with regard to symptoms, signs, and radiographic findings.

Complications of Pulmonary Histoplasmosis

The mediastinal and hilar lymph nodes frequently calcify as the infection resolves; years later they can erode into bronchi and cause hemoptysis and expectoration of broncholiths. Granulomatous mediastinitis is an uncommon syndrome characterized by continuing inflammation and necrosis in the mediastinal lymph nodes. The enlarged nodes are readily apparent on chest radiographs, and computed tomography (CT) shows central necrosis and, in some cases, impingement on adjacent structures, including the esophagus, airways, and blood vessels. Although the symptoms usually resolve without treatment, obstructive syndromes can be severe and the nodes can persist for years.

Fibrosing mediastinitis is a rare complication of histoplasmosis in which the host responds to the infection with an inappropriate excessive fibrotic response. Obstruction of the airways, superior vena cava, or the pulmonary arteries and veins can occur with resultant progressive right heart failure and respiratory insufficiency. Bilateral obstruction of the pulmonary vasculature is less common than unilateral involvement and carries a worse prognosis. Mediastinal widening is seen on chest radiographs, and CT and angiography define the extent of invasion and obstruction of mediastinal structures.

Pericarditis is a manifestation of a local inflammatory reaction to adjacent histoplasmosis. Patients respond promptly to anti-inflammatory medications without antifungal therapy. Hemodynamic compromise, though unusual, requires drainage of pericardial fluid; only rarely has progression to constrictive pericarditis been documented.

Disseminated Histoplasmosis

Symptomatic disseminated histoplasmosis occurs mostly in immunosuppressed patients. Patients with acquired immunodeficiency syndrome (AIDS) and $CD4^+$ counts lower than 150/μL, infants, and those who have a hematologic malignancy, have received an organ transplant, or are taking corticosteroids or tumor necrosis factor antagonists are at greatest risk for acute disseminated histoplasmosis. Symptoms and signs include chills, fever, anorexia, weight loss, hypotension, dyspnea, hepatosplenomegaly, and skin and mucous membrane lesions. Pancytopenia, diffuse pulmonary infiltrates on chest radiography and CT, findings of disseminated intravascular coagulation, and acute respiratory failure are common. This syndrome is indistinguishable from sepsis of any bacterial or viral cause. In AIDS patients, the differential diagnosis includes cytomegalovirus, disseminated *Mycobacterium avium* complex infection, and tuberculosis.

Chronic progressive disseminated histoplasmosis is a fatal form of histoplasmosis that occurs mostly in middle-aged to elderly men who have no known immunosuppressive illness. The illness is characterized by fever, night sweats, weight loss, anorexia, and fatigue. Patients appear chronically ill, hepatosplenomegaly and mucocutaneous ulcerations are common, and adrenal insufficiency can develop. An increased erythrocyte sedimentation rate, elevated alkaline phosphatase, pancytopenia, and diffuse reticulonodular infiltrates on chest radiography and CT are typical. Patients with this form of histoplasmosis often have fever of unknown origin. Miliary tuberculosis, lymphoma, and sarcoidosis must be excluded.

Involvement of almost every organ system has been reported with disseminated infection. Adrenal insufficiency must be sought in any patient who has unexplained hypotension, hyponatremia, and hyperkalemia. Abdominal CT shows markedly enlarged adrenal glands. Central nervous system involvement is manifested either as meningitis or as focal lesions seen on magnetic resonance imaging and is more common in patients with AIDS. Skin lesions, also more common in patients with AIDS, can be papular, pustular, or ulcerated. *Histoplasma* endocarditis is a rare form of disseminated infection.

DIAGNOSIS

The definitive diagnostic test for histoplasmosis is growth of the organism in culture. Unfortunately, *H. capsulatum* may take as long as 6 weeks to grow in vitro. Tissue samples, bronchoalveolar lavage fluid, sputum, and blood are appropriate for culture. For patients who have evidence of dissemination, blood cultures are best performed with the lysis-centrifugation (Isolator tube) system; bone marrow and liver biopsy material often yield *H. capsulatum* in the setting of dissemination. If pulmonary histoplasmosis is a diagnostic consideration, the laboratory should be informed so that a special medium that decreases the growth of commensal fungi can be used for the culture of pulmonary samples. As soon as growth of a mold has been detected, highly specific DNA probes for *H. capsulatum* allow rapid identification of the organism.

If the patient is acutely ill, tissue biopsy should be performed to search for the distinctive 2- to 4-μm oval yeasts with single buds, which allows a tentative diagnosis to be made as quickly as possible. Routine tissue stains do not show the tiny yeasts; biopsy material must be stained with methenamine silver or periodic acid–Schiff stains. In patients with disseminated disease, bone marrow, liver, skin, and mucocutaneous lesions usually reveal many organisms. The organisms can also be seen within neutrophils in peripheral blood smears from patients with acute disseminated infection. In patients with chronic pulmonary histoplasmosis or granulomatous mediastinitis, biopsy of the lung or lymph nodes may reveal the organism.

Serology plays an important role in the diagnosis of some forms of histoplasmosis. Complement fixation (CF) assays that use two different antigens, mycelial and yeast, and immunodiffusion (ID) tests are available. The ID test is more specific than the CF test, but CF tests are more sensitive. Antibody assays can remain positive at low titer for years after the infection. Serology is helpful in diagnosing acute pulmonary histoplasmosis when a four-fold rise in CF titer, a CF titer higher than 1:32, or the appearance of an M precipitin band by ID assay is found. These tests are also useful in patients with chronic forms of pulmonary or disseminated histoplasmosis, but they are rarely helpful in immunosuppressed patients, who often cannot mount an antibody response. Because serologic tests are not definitive in patients with mediastinal lymphadenopathy, the results should always be confirmed by tissue biopsy. An enzyme immunoassay for *H. capsulatum* polysaccharide antigen in urine and serum is extremely helpful in patients with disseminated infection and in those with acute pulmonary histoplasmosis. The sensitivity for antigen detection is higher in urine than in serum. Almost 75% of patients who have experienced heavy exposure and demonstrate diffuse pulmonary infiltrates and more than 90% of patients who have disseminated histoplasmosis will have a positive urinary antigen test. However, the assay is not useful for patients who have chronic cavitary histoplasmosis, granulomatous mediastinitis, or fibrosing mediastinitis. False-positive reactions have been noted commonly with blastomycosis, paracoccidioidomycosis, and penicilliosis and occasionally with acute coccidioidomycosis. Antigen levels usually become undetectable with successful therapy.

TREATMENT Rx

Guidelines for the treatment of histoplasmosis have been published by the Infectious Diseases Society of America (IDSA). Itraconazole is the drug of choice for mild to moderate histoplasmosis, and lipid formulations of amphotericin B should be used as initial therapy for severe, life-threatening infections. Fluconazole is less active and should be considered a second-line agent, and ketoconazole has become a second-line agent because of increased toxicity in comparison to itraconazole. There is only limited anecdotal experience using voriconazole or posaconazole, although both appear to be effective therapy. The echinocandins are not effective for histoplasmosis.

For all patients who are treated with itraconazole, serum levels should be determined when a steady state has been reached after 2 weeks of therapy to ensure adequate absorption. Serum concentrations should be greater than 1 μg/mL.

Pulmonary Histoplasmosis

Treatment is not usually given for acute pulmonary histoplasmosis; many times the diagnosis is not made until after the symptoms have resolved. However, if the patient remains symptomatic after 4 weeks, therapy with itraconazole, 200 mg once or twice daily for 6 to 12 weeks, should be given. All patients who have severe pulmonary histoplasmosis and all immunosuppressed patients should be treated with an antifungal agent. Lipid formulation amphotericin B, 3 to 5 mg/kg daily, is recommended for several weeks until a response is noted, at which time therapy can be changed to oral itraconazole, 200 mg three times daily for 3 days and then 200 mg twice daily. A short course of methylprednisolone is recommended in the IDSA guidelines for patients in whom respiratory distress develops in association with acute pulmonary histoplasmosis.

Antifungal therapy should be given to all patients with chronic pulmonary histoplasmosis. Itraconazole, 200 mg twice daily for 12 to 24 months, is recommended. A trial of itraconazole for 6 to 12 weeks is often given to patients with symptomatic granulomatous mediastinitis, although there are no data proving such therapy to be effective. Surgical resection of nodes causing obstructive symptoms may be beneficial. Antifungal therapy offers no benefit for patients with fibrosing mediastinitis. However, because of the inexorable downhill course of this illness, a several-month course of itraconazole is frequently tried. Surgery is not indicated and carries a high operative mortality rate. Intravascular stents have been used successfully in patients who have vascular obstruction.

Disseminated Histoplasmosis

All patients with symptomatic disseminated histoplasmosis should receive antifungal therapy. Patients who have only mild to moderate symptoms with acute disseminated disease and most patients with chronic progressive disseminated histoplasmosis can be treated with itraconazole, 200 mg twice daily after a loading dose of 200 mg three times daily for 3 days. A total of 12 months of therapy is generally adequate, but for those with chronic progressive disease, the duration of treatment may need to be longer.

Patients who have moderately severe to severe disseminated histoplasmosis should be treated with liposomal amphotericin B, 3 mg/kg daily.[1] Therapy can be changed to itraconazole after the patient has responded to therapy, generally in a few weeks. Therapy should continue for a total of 12 months. For those who are immunosuppressed, therapy with itraconazole, 200 mg daily, should continue until the immunosuppression resolves. For AIDS patients, suppressive therapy can be safely stopped in those who have had a year of therapy, are receiving antiretroviral therapy, and have $CD4^+$ counts greater than 150 cells/μL.[2]

Prevention of histoplasmosis is difficult because exposure can occur without the person's knowledge in highly endemic areas. Persons who are immunosuppressed should be advised to avoid demolition areas, spelunking, and cleaning of farm buildings or attics. A randomized, blinded, placebo-controlled trial in AIDS patients found that itraconazole, 200 mg daily, was effective in preventing infection.[3] Recommendations are to use prophylaxis only for patients whose $CD4^+$ counts are lower than 150/μL and who live in a highly endemic area with a rate of histoplasmosis that is greater than 10 cases per 100 patient years. There are no recommendations for prophylaxis for other immunosuppressed patients.

PROGNOSIS

Acute pulmonary histoplasmosis is usually a self-limited disease. Patients who require treatment generally respond promptly to antifungal agents. However, the response of patients with chronic cavitary pulmonary histoplasmosis is often poor, primarily because of their severe underlying pulmonary disease. Mediastinal fibrosis has a poor prognosis, but intravascular stenting has led to improvement in many patients. Patients with disseminated histoplasmosis, even those with advanced AIDS, usually respond promptly to antifungal therapy; most deaths in immunosuppressed patients occur when the diagnosis is delayed. Older patients with chronic progressive disseminated histoplasmosis have a slower, but usually complete response to therapy.

COCCIDIOIDOMYCOSIS

JOHN N. GALGIANI

DEFINITION

Coccidioidomycosis is a systemic fungal infection caused by *Coccidioides* species endemic to some deserts of the Western Hemisphere (Table 341-1).

The Pathogen

Coccidioides immitis and *Coccidioides posadasii* are dimorphic fungi classified as Ascomycetes by ribosomal gene homology. In their vegetative state, mycelia with true septations mature to produce arthroconidia, single cells approximately 2 to 5 μm in diameter. After infection, an arthroconidium enlarges to a spherule up to 75 μm in diameter and undergoes internal septation to produce scores of endospores. When the spherules rupture, packets of endospores are released and produce more spherules in infected tissue or revert to mycelia if removed from the body.

EPIDEMIOLOGY

Coccidioides organisms can be recovered from the soil of the low deserts of Arizona; the Central Valley of California; parts of other states, including New Mexico and Texas; and parts of Central and South America. Endemic regions follow the climatologic Sonoran life zone, which is characterized by modest rainfall, mild winters, and low humidity. Mycelia bloom beneath the surface during periods of rain, and arthroconidia develop as the earth dries. Rates of infection are highest during dry months and are accentuated when soil is disturbed by windstorms or construction equipment. Exposure to contaminated bales of cotton or other fomites can result in infection beyond the endemic regions, but this is rare. Person-to-person transmission of pulmonary infection has not been reported, and isolation precautions are unnecessary. *Coccidioides* species are listed by the Centers for Disease Control and Prevention as select agents that could be used for bioterrorism.

Incidence and Prevalence

In general, the annual risk for infection within the most strongly endemic areas is 3%, resulting in approximately 150,000 new infections. Reported infections within endemic areas is increasing. For example, from 2000 to 2010, reported infections increased more than five-fold in Arizona. With unusually intense exposure, such as at archaeology sites or during military

TABLE 341-1 COCCIDIOIDOMYCOSIS: CLINICAL CHARACTERISTICS AND TREATMENT

CHARACTERISTIC	DESCRIPTION
Causative fungi	*Coccidioides immitis* and *Coccidioides posadasii*
Primary geographic distribution	Lower Sonoran deserts of the Western Hemisphere, including parts of Arizona, California, and New Mexico; western Texas; parts of Central and South America
Primary route of acquisition	Respiratory (inhalation of arthroconidia)
Principal site of disease	Lungs most common; spread to skin, bones, meninges, and other viscera uncommon but serious
Opportunistic infection in compromised hosts	Diffuse pneumonia and widespread infections common in patients with T-lymphocyte defects or during high-dose corticosteroid therapy
Drug of choice for most patients	No antifungal is required for uncomplicated pneumonia; fluconazole or itraconazole for progressive forms of infection
Alternative therapy	Amphotericin B (especially with diffuse pneumonia or rapidly progressive infections), voriconazole, posaconazole

maneuvers within endemic regions, infections can develop in the majority of persons exposed for only a matter of days. More than 60% of new infections are likely to occur in Arizona because of the rapid growth of populations in the Phoenix and Tucson areas.

PATHOBIOLOGY

Inhaling as few as a single arthroconidium to the level of the terminal bronchiole initiates virtually all coccidioidal infections. Fungal proliferation engenders both granulomatous inflammation, which is associated with intact spherules, and acute inflammation, including eosinophils, which is associated with spherule rupture. Focal pneumonia is often associated with ipsilateral hilar adenopathy; less frequently, infection enlarges the paratracheal, supraclavicular, and cervical nodes. Lesions occurring elsewhere are the result of hematogenous dissemination, and most become apparent within 2 years of the initial infection. Although progressive dissemination occurs in less than 1% of infections, as many as 8% of persons with self-limited infection manifest asymptomatic chorioretinal scars, suggesting that subclinical hematogenous spread may be frequent. Within weeks after infection, durable T-cell immunity normally arrests fungal proliferation, which allows the inflammation to resolve and prevents reinfection in the future. Mutations of receptors for interferon-γ and interleukin-12 have been associated with disseminated infections. However, control of the infection may occur without sterilizing lesions, and reactivation of the dormant infection is possible, even many years later, in patients whose cell-mediated immunity becomes deficient.

CLINICAL MANIFESTATIONS

At least two thirds of infections are asymptomatic and are detected only by finding dermal hypersensitivity to coccidioidal antigens. Those who become ill usually experience self-limited pulmonary syndromes. However, complications or progressive forms of infection that display a broad variety of manifestations and pose difficult management problems develop in a few patients.

Primary Pulmonary Infections

Symptoms develop within 5 to 21 days after exposure. For residents of or recent visitors to southern Arizona, coccidioidomycosis accounts for approximately one third of cases of community-acquired pneumonia. Fever, weight loss, fatigue, dry cough, and pleuritic chest pain are common but nonspecific complaints. Arthralgia of multiple joints without significant effusion is also frequent and is referred to as "desert rheumatism." Occasionally, skin manifestations develop, including a short-lived nonpruritic maculopapular rash, erythema multiforme, or erythema nodosum. These arthritic and dermatologic manifestations are mediated by circulating immune complexes or other immunologic phenomena rather than by fungal dissemination. Radiographs of the chest may show no abnormalities or may demonstrate pulmonary infiltrates, either segmental or lobar. Hilar adenopathy is often a distinctive finding. Peripneumonic pleural effusions may occur and generally resolve without intervention, although cultures of pleural biopsies usually yield *Coccidioides* species. Eosinophilia may be a prominent finding in differential leukocyte counts of peripheral blood, and the erythrocyte sedimentation rate is generally elevated. Symptoms may persist for several weeks before improvement is clearly under way, and the illness, especially lassitude, may persist for months.

The primary pulmonary process produces a variety of sequelae. The most frequent is the development of a pulmonary nodule (Fig. 341-1), typically measuring 1 to 4 cm and lying within 5 cm of the hilum. Despite their harmless nature, coccidioidal nodules may cause concern because of their similarity to a malignant mass. Positron emission tomography scans are typically positive. For these reasons, management usually requires percutaneous needle aspiration or resection. Another consequence of pulmonary coccidioidomycosis is cavitation of the infiltrate, which occurs in approximately 5% of cases of pneumonia. Most cavities are solitary and thin walled and reside in an upper lobe, close to the pleura. Occasionally, they produce pain, hemoptysis, or adjacent infiltrates. Cavities may acquire mycetomas from either *Coccidioides* species or some other colonizing mold. Infrequently, a cavity ruptures and forms a pyopneumothorax. This is usually the first symptom of coccidioidal infection and typically occurs in otherwise healthy young men. An air-fluid level in the pleural space, detectable by roentgenography, often helps differentiate this problem from a spontaneous pneumothorax. Surgical resection of the cavity is the preferred treatment of this complication. The least common pulmonary complication is persistent fibrocavitary infection that progresses to involvement of both lungs.

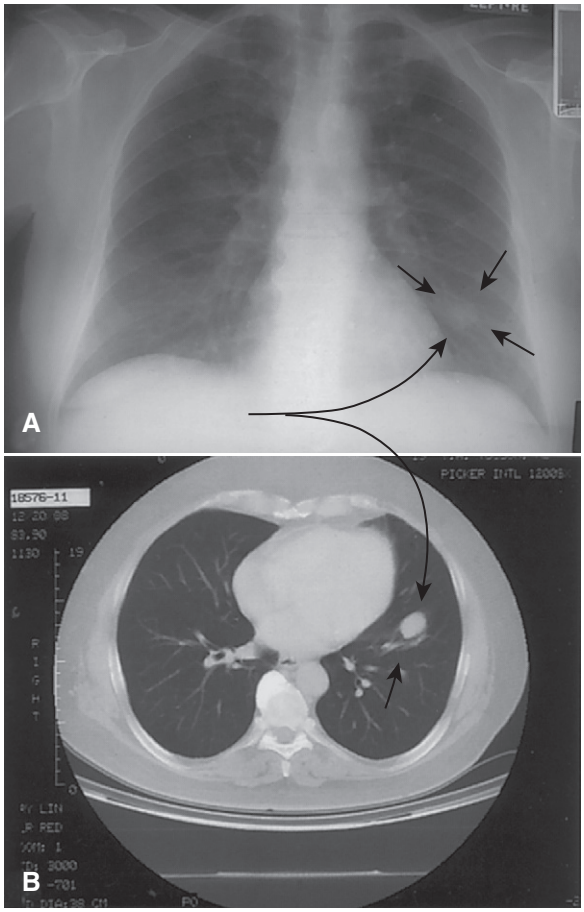

FIGURE 341-1. Coccidioidomycosis. A, Benign nodule secondary to coccidioidomycosis *(arrows)*. **B,** Computed tomography scan of the nodule shown in **A** *(arrows)*.

Extrapulmonary Dissemination

Coccidioidomycosis in immunosuppressed patients, such as solid organ recipients, those with acquired immunodeficiency syndrome (AIDS) or lymphoma, and women during their third trimester of pregnancy, usually results in dissemination beyond the lungs. Mutations of the genes for gamma-interferon or the IL-12 receptors also predispose persons to dissemination. However, disseminated infection also occurs in some patients who have no underlying disease and do not manifest heightened susceptibility to other infections. The most common locations for disseminated lesions are the skin (cutaneous papules or subcutaneous abscesses); joints (especially the knee); bones, including the vertebrae; and basilar meninges. Such infections may produce one or many lesions and are frequently subacute or chronic in their manifestation. In broadly immunosuppressed patients, coccidioidal infections may be more fulminant, with fungemia detectable in blood cultures and diffuse reticulonodular embolic pulmonary infiltrates. Although the kidneys and the urinary bladder are rarely involved, *Coccidioides* may be recovered from concentrated specimens of urine, usually because of focal dissemination to the prostate. In contrast to histoplasmosis, the gastrointestinal tract is rarely involved in coccidioidomycosis.

DIAGNOSIS

The diagnosis is firmly established by recovering *Coccidioides* species from clinical specimens. On direct examination of respiratory specimens or tissue, spherules appear as large structures with refractile walls and internal organization; they are also seen on hematoxylin-eosin, silver, or periodic acid–Schiff stains of histologic preparations. Gram stain does not detect spherules. In culture, mycelial growth is often evident within the first week of incubation, and DNA probing with commercially available kits allows rapid species identification. Recovery of *Coccidioides* species from patients with only scant respiratory secretions associated with the initial pneumonia and from the cerebrospinal fluid of patients with meningitis may be difficult.

A presumptive diagnosis of coccidioidal infection is often based on the detection of specific antibodies in serum. Within the first weeks of the initial infection, a precipitin-type antibody is detected, usually by immunodiffusion

techniques. Later, complement fixation (CF)–type antibodies generally appear. However, these tests may be falsely negative as often as half the time in patients with early infections. When reported quantitatively, concentrations of CF antibodies are usually highest in the most extensive infections and decrease in patients whose infections are controlled. An important means of diagnosing coccidioidal meningitis is the detection of CF antibodies in cerebrospinal fluid, along with other abnormalities such as leukocytosis, elevated protein concentration, or low glucose concentration. Coccidioidal antigens are sometimes found in the urine or serum of patients with widespread infection.

TREATMENT

Rx

The role of antifungal therapy for primary uncomplicated infections is controversial because clinical trials have not been performed to determine whether treatment either shortens the course of symptoms or diminishes the chance of complications. However, the value of treatment is clear for patients with progressive illness. Because many coccidioidal infections are chronic in nature, initial treatment often consists of oral azole antifungal agents, such as fluconazole and itraconazole. Responses to these two drugs are similar, but itraconazole is preferred in patients with skeletal infections.■ Doses of these azoles are 400 mg/day or higher, and treatment is usually continued for a year or more. Satisfactory responses are obtained in approximately two thirds of patients. Fluconazole is effective therapy for coccidioidal meningitis and has greatly reduced the number of patients treated with intrathecal amphotericin B. Unfortunately, cessation of azole therapy is often followed by a recurrence of symptoms, especially in those with coccidioidal meningitis. Therefore, many patients need protracted or even lifelong therapy to control disease activity. Newer azole antifungals (voriconazole, posaconazole) are also effective and are sometimes useful for refractory infections. Amphotericin B remains a rational choice when treatment with azole antifungals has failed. Daily doses range from 0.4 to 1 mg/kg, and cumulative therapy ranges from 0.5 to 3 g. Occasionally, in a patient with rapid disease progression, amphotericin B may produce a more rapid therapeutic response and is therefore the preferred initial therapy. Delivery of amphotericin B in liposomes or lipid complexes is also effective and is generally less toxic than amphotericin B suspended with deoxycholate. In addition to antifungal agents, surgical removal of necrotic tissue is often essential to control the damage from specific lesions.

PROGNOSIS

After resolution of the initial infection, most patients maintain lifelong immunity, and infections after re-exposure are rare. However, cessation of symptoms is frequently accomplished without eradicating *Coccidioides* completely, and recurrence of the original infection many years after the original episode is a well-recognized risk of intercurrent profound immunosuppression. For patients in whom the initial infection cannot be resolved, the disease typically follows a protracted course. Although infection is more often debilitating than fatal, fulminant respiratory failure can occur, and if untreated, coccidioidal meningitis is nearly always fatal within 2 years.

BLASTOMYCOSIS

CAROL A. KAUFFMAN

DEFINITION

Blastomycosis (North American blastomycosis) is an endemic mycosis that primarily causes infection of the lungs and skin and, less commonly, infection of the osteoarticular and genitourinary systems.

The Pathogen

Blastomyces dermatitidis is a thermally dimorphic fungus. In the environment in the mold phase, the organism produces conidia, which when aerosolized and inhaled cause infection. At 37° C on culture media and in tissues, the organism is a yeast that is 5 to 20 μm in diameter, has a thick refractile cell wall, and produces single broad-based buds.

EPIDEMIOLOGY

B. dermatitidis exists in many diverse geographic areas worldwide, but most cases of blastomycosis are reported from the south central and north central regions of the United States and the Canadian provinces surrounding the Great Lakes. The natural niche of *B. dermatitidis* is thought to be soil and decaying vegetation, especially in areas associated with rivers and lakes. Although most cases occur sporadically, several well-described outbreaks have occurred in association with activities along waterways. The typical patient in whom blastomycosis develops is a middle-aged man who has an outdoor occupation or hobby. The association of blastomycosis developing in both hunters and their dogs is well known in endemic areas.

PATHOBIOLOGY

After the inhalation of conidia, *B. dermatitidis* transforms into the yeast phase and causes pulmonary infection. Although many patients manifest only pulmonary symptoms, others have cutaneous lesions in the absence of other organ involvement or have disseminated infection. It is likely that most patients have asymptomatic hematogenous dissemination after the initial pulmonary infection. Thus, cutaneous lesions should be viewed as a manifestation of hematogenous spread of the organism. Except in rare instances, blastomycosis is not acquired by inoculation. Cellular immunity involving T lymphocytes and macrophages is an important component of the host response to infection with *B. dermatitidis*, but neutrophils also play a role. Most patients with blastomycosis are healthy hosts. Patients who are immunosuppressed are more likely to have severe disease. Infection in an immunosuppressed host can occur after new exposure to *B. dermatitidis* or from reactivation of a latent focus of infection acquired years earlier.

CLINICAL MANIFESTATIONS

Pulmonary

Most patients with acute pulmonary blastomycosis are asymptomatic or are thought to have community-acquired pneumonia. Patients with acute pneumonia have fever, malaise, a nonproductive cough, and a pulmonary infiltrate that shows lobar or multilobar patchy or nodular infiltrates on chest radiographs. Development of skin lesions is a strong clue for blastomycosis. Chronic pulmonary blastomycosis must be differentiated from tuberculosis, other fungal infections, and lung cancer. Fever, night sweats, weight loss, fatigue, cough, sputum production, hemoptysis, and dyspnea are commonly noted. On chest radiograph the lesions are cavitary, nodular, fibrotic, or mass-like in appearance. Hilar and mediastinal lymphadenopathy and pleural effusions are not commonly seen. Overwhelming pulmonary disease with acute respiratory distress syndrome occurs infrequently and has a high mortality rate. Whether this is due to inhalation of a large number of conidia or to an exuberant host response is not known.

Disseminated Infection

Cutaneous lesions are the most common manifestation of disseminated blastomycosis. The lesions are usually well-circumscribed, painless papules, nodules, or plaques that become verrucous and develop multiple punctate draining areas in the center. Cutaneous lesions, sometimes single but more

often multiple, are most common on the face and extremities but can appear anywhere. The skin lesions of blastomycosis clinically mimic those associated with nontuberculous mycobacteria, other fungal infections, mycosis fungoides, and bromide use. An uncommon manifestation, seen more often in immunocompromised patients, is the appearance of hundreds of pustular lesions that readily reveal the organism when aspirated.

Another manifestation of disseminated blastomycosis is osteoarticular involvement. Osteomyelitis can be associated with contiguous skin lesions or can appear at sites distant from cutaneous lesions. It is helpful to obtain a bone scan in all patients with disseminated blastomycosis because of the propensity of the organism to infect bone. Genitourinary involvement may be asymptomatic or be associated with signs of prostatism and the presence of a nodule on digital examination. Infrequently occurring findings include laryngeal and oropharyngeal nodules; ocular lesions; central nervous system (CNS) involvement, either meningitis or intracerebral mass lesions; and dissemination to the liver, spleen, and lymph nodes.

DIAGNOSIS

The definitive diagnostic test for blastomycosis is growth of the organism from an aspirate, tissue biopsy specimen, sputum, or body fluid. Urine obtained before and after prostatic massage should be sent for fungal culture in those with disseminated blastomycosis. The mold phase takes several weeks to grow at room temperature. Once growth has occurred, the organism can be rapidly identified as *B. dermatitidis* with highly specific and sensitive DNA probes. Histopathologic examination of cutaneous or pulmonary lesions, cytologic examination of sputum, bronchoalveolar lavage fluid, or other tissue fluids, and calcofluor fluorescent staining of sputum or purulent material from pustular lesions should be performed to look for the distinctive large, thick-walled yeast with a single broad-based bud. Identification of characteristic organisms allows a tentative diagnosis of blastomycosis and initiation of antifungal therapy before culture results are known. Serologic assays for blastomycosis are neither sensitive nor specific. A urine enzyme immunoassay for *Blastomyces* cell wall antigens may prove to be useful for diagnosis, but more experience is required to define the role of this assay in disseminated and pulmonary blastomycosis.

TREATMENT

Rx

Guidelines for the treatment of blastomycosis have been published by the Infectious Diseases Society of America (IDSA). With the exception of patients who have acute pulmonary blastomycosis that has totally resolved before the diagnosis is established, all patients with blastomycosis should be treated with an antifungal agent. Patients who have mild to moderate pulmonary or disseminated blastomycosis should be treated with itraconazole, 200 mg once or twice daily. The length of treatment is 6 to 12 months to achieve mycologic cure and prevent relapse. Fluconazole is not as effective as itraconazole. However, if the patient is unable to take itraconazole, fluconazole can be used, but the dosage should be 400 to 800 mg daily for 6 to 12 months. Anecdotal case reports describe success with voriconazole; there are no reports of treatment of blastomycosis with posaconazole. The echinocandins are not active against *B. dermatitidis* and should not be used.

Patients who have severe pulmonary or disseminated blastomycosis, all patients with CNS infection, and most immunosuppressed patients should be treated initially with amphotericin B, preferably a lipid formulation. The dosage is 3 to 5 mg/kg daily, except for CNS infection, for which 5 mg/kg daily should be used. Some physicians prescribe corticosteroids for patients with acute respiratory distress syndrome associated with blastomycosis, but this remains controversial and was not recommended in the IDSA guidelines. After clinical improvement has occurred, usually within several weeks, therapy can be changed to itraconazole, 200 mg twice daily for a total of at least 12 months of therapy.

PROGNOSIS

The prognosis for patients with pulmonary or disseminated blastomycosis treated with itraconazole is excellent; more than 90% are cured. If relapse does occur, a second course of itraconazole is usually successful. Most reported deaths occur in patients with overwhelming pneumonia and acute respiratory distress syndrome.

PARACOCCIDIOIDOMYCOSIS

CAROL A. KAUFFMAN

DEFINITION

Paracoccidioidomycosis (South American blastomycosis) is a subacute to chronic mycosis that is endemic in Central and South America. The disease is characterized primarily by pulmonary, mucous membrane, and cutaneous lesions, but disseminated disease also occurs.

The Pathogen

Paracoccidioides brasiliensis is a thermally dimorphic fungus. In the environment and at temperatures below 35° C, the organism is a mold that produces conidia, the infectious form. In tissues and at 37° C in vitro, the organism assumes the yeast form with multiple narrow-based daughter cells attached to the mother cell.

EPIDEMIOLOGY

P. brasiliensis exists only in humid areas of Central and South America. More than 80% of cases are from Brazil. The presumed ecologic niche is in soil, but the exact conditions that favor growth of the organism have not been elucidated. The disease is most prevalent in middle-aged to elderly men from rural areas. The reason for the sexual imbalance (male-to-female ratio of 14:1) is possibly related to the inhibitory effects of estrogens on growth of the organism rather than solely environmental exposure. Although the disease classically develops later in life, it is likely that initial exposure occurs in childhood. Cases seen in areas outside Central and South America have all been linked to previous residence in the endemic area.

PATHOBIOLOGY

Paracoccidioidomycosis develops after the inhalation of aerosolized conidia encountered in the environment. Once in the alveoli, the mycelial phase converts to the yeast phase. The infection may remain localized to the lungs, although it is likely that asymptomatic hematogenous dissemination occurs during most infections. In most patients, manifestations of disease do not develop at the time of the initial infection. The primary host defense mechanism against *P. brasiliensis* appears to be cell-mediated immunity, but neutrophils also play a role in host defense. The histopathologic picture includes both neutrophilic and granulomatous responses. There have been increasing reports of paracoccidioidomycosis in patients infected with human immunodeficiency virus (HIV) and in other immunosuppressed patients; in these patients there is widespread dissemination, and histopathology shows poorly formed granulomas. Reactivation of latent infection acquired years earlier is the presumed pathogenesis of most cases of the chronic adult form of paracoccidioidomycosis and cases that appear years after the patient has left the endemic area.

CLINICAL MANIFESTATIONS

Acute-Subacute (Juvenile) Paracoccidioidomycosis

The acute-subacute form of paracoccidioidomycosis occurs in less than 10% of patients. It is a disease of the reticuloendothelial system with widespread

dissemination to the liver, spleen, lymph nodes, and bone marrow. Patients younger than 30 years typically have this form of paracoccidioidomycosis; however, older adults, especially those who are immunosuppressed, can also manifest this type of rapidly progressive disease. In patients with HIV infection, rapid progression occurs with multiple cutaneous lesions, lymphadenopathy, hepatosplenomegaly, and severe pulmonary involvement with hypoxemia.

Chronic (Adult) Paracoccidioidomycosis

Chronic paracoccidioidomycosis is seen in more than 90% of patients, most of whom are older men. The disease progresses slowly over a period of years. Pulmonary involvement is prominent and clinically mimics tuberculosis and other chronic fungal pneumonias. Radiographically, nodular, interstitial, or cavitary lesions are seen but differ from those of tuberculosis and histoplasmosis in that the infiltrates tend to be in the middle and lower lung fields rather than the apices. Most patients with the adult form of paracoccidioidomycosis also have ulcerative or nodular mucous membrane lesions, primarily in the anterior nares and oral cavity. Cutaneous lesions, particularly on the face, are also common and may be papular, nodular, ulcerative, or plaquelike. The mucocutaneous lesions must be differentiated from mucocutaneous leishmaniasis and squamous cell carcinoma. Adrenal involvement has been reported in more than 90% of cases at autopsy, but adrenal insufficiency is only noted in about half.

DIAGNOSIS

Definitive diagnosis of paracoccidioidomycosis is established by growth of *P. brasiliensis* in culture. The organism may take as long as 4 weeks to grow. For seriously ill patients, direct examination of body fluids, sputum, or purulent material treated with KOH or calcofluor fluorescent stain or histopathologic examination of tissue biopsy samples can provide a presumptive diagnosis while awaiting culture results. The characteristic appearance of *P. brasiliensis* consists of thick-walled yeast cells that have multiple small, circumferentially attached, narrow-based budding daughter yeast cells—a distinctive morphologic picture likened to a ship's steering wheel.

A variety of immunodiffusion assays, enzyme immunoassays, and complement fixation assays are available in endemic areas, but sensitivity and specificity vary greatly. The immunodiffusion assay appears to be most useful. An assay for circulating cell wall antigens of *P. brasiliensis* has also been developed in endemic areas, but its role has not been established.

TREATMENT

Rx

The drug of choice for the treatment of paracoccidioidomycosis is itraconazole (200 mg daily for 6 to 12 months). Ketoconazole at a dosage of 200 to 400 mg daily for 1 year is effective and certainly less expensive than itraconazole, but the incidence of side effects is greater and relapses occur more frequently than with itraconazole. Fluconazole is less effective and should not be used unless no other agent is available. Voriconazole has been shown to be as effective as itraconazole in a randomized open-label pilot study, and there are scattered reports of the successful use of posaconazole as salvage therapy. Sulfonamides have been used for years to treat paracoccidioidomycosis and are clearly the most inexpensive form of treatment. In some areas of Brazil they are the agent of choice for mild to moderate disease; however, relapse rates are higher than with the azoles. Amphotericin B is effective but rarely required, except in immunosuppressed patients with life-threatening disseminated disease. Most HIV-infected patients with paracoccidioidomycosis have been treated with amphotericin B as initial therapy, followed by lifelong suppressive therapy with either itraconazole or trimethoprim-sulfamethoxazole. The latter is preferred in patients with acquired immunodeficiency syndrome because it also prevents infections with *Pneumocystis jiroveci* and *Toxoplasma gondii.*

PROGNOSIS

Patients with paracoccidioidomycosis have an excellent response to antifungal therapy, although HIV-infected patients respond less well. Patients who have extensive pulmonary involvement at the time of diagnosis are at risk for progressive fibrosis despite antifungal therapy.

344 CRYPTOCOCCOSIS

CAROL A. KAUFFMAN

DEFINITION

Cryptococcosis occurs most often in persons who are immunosuppressed, especially those infected with human immunodeficiency virus (HIV). Meningitis is the most common clinical manifestation, but pulmonary and other organ involvement occur as well.

The Pathogen

Cryptococcus neoformans is a yeast in both the environment and tissues. In tissues, the organism is enveloped by a large polysaccharide capsule that is a major virulence factor. In the environment, *C. neoformans* yeast cells are smaller and less encapsulated and thus more easily aerosolized and inhaled. There are two varieties of the species, *C. neoformans* var *neoformans* and *C. neoformans* var *grubii*; both are pathogenic and cause similar disease manifestations. Most laboratories do not differentiate these varieties. *C. neoformans* var. *neoformans* accounts for most cases of human disease throughout the world.

Cryptococcus gattii is now a separate species distinct from *C. neoformans* and more often infects normal hosts than patients with HIV. It is more restricted in the environment and found mostly in the subtropical and tropical areas of Australia and Southeast Asia, where the ecologic niche is the eucalyptus tree. The epidemiology of *C. gattii* is evolving with its emergence in the past decade in British Columbia and the Pacific Northwest region of the United States. *C. gattii* will not be discussed further.

EPIDEMIOLOGY

C. neoformans has been linked to pigeons; the birds do not become infected, but rather the organism grows luxuriantly in dried pigeon excreta because of its high nitrogen content.

Before highly active antiretroviral therapy (HAART), cryptococcosis occurred in 5 to 10% of patients with acquired immunodeficiency syndrome (AIDS). Patients at highest risk were those with fewer than 50 $CD4^+$ cells/μL. Though less commonly seen now in Europe and North America, cryptococcosis remains extremely common in AIDS patients in Africa, where it is estimated that the prevalence among HIV-infected patients is as high as 30%. In the non-AIDS population, cryptococcosis is a frequent opportunistic infection in patients who have received an organ transplant, have been treated with corticosteroids, or have diabetes mellitus, renal failure, liver dysfunction, or chronic pulmonary disease. For some patients, the only risk factor appears to be older age. In every reported series, separate from those dealing only with HIV infection, approximately 20% of patients have no known underlying illness.

PATHOBIOLOGY

The organism is inhaled from the environment and causes pulmonary infection initially. The primary host defense at this stage is complement-dependent macrophage and neutrophil phagocytosis and killing. Natural killer cells also have the ability to kill the organism. Ultimately, however, T-cell immunity is the most important host determinant in limiting the replication of *C.*

neoformans. In most normal hosts, the infection remains localized to the lungs and does not cause symptomatic infection. It is likely that a few organisms exist as walled-off subpleural granulomas in many who have had pulmonary infection. If the host becomes immunosuppressed, the organism can then reactivate and disseminate to other sites. *C. neoformans* is clearly neurotropic, and the primary disease manifestation is meningoencephalitis. However, dissemination to many organs is likely, especially in those with deficient T-cell immunity.

Virulence factors for *C. neoformans* include the capsule, which requires opsonization for efficient phagocytosis, and the production of melanin, which has been shown to occur in vivo and enables the organism to resist intracellular killing. Both these factors may help explain the virulence of the organism once it has reached the central nervous system (CNS). Antibody and complement levels are low in the brain, and thus phagocytosis of the organism is minimal. Brain tissue provides high concentrations of substrates, such as catecholamines, for the phenol oxidase enzyme systems of *C. neoformans* that produce melanin, thereby aiding survival of the organism.

CLINICAL MANIFESTATIONS

Central Nervous System Infection

The most common manifestation of cryptococcosis is CNS infection. The typical picture is subacute to chronic meningoencephalitis. Patients usually have increasingly severe headaches over a period of several weeks. Other symptoms and signs include nuchal rigidity, lethargy, personality changes, confusion, visual abnormalities (photophobia, diplopia, decreased visual acuity, papilledema, extraocular nerve palsies), and nausea and vomiting. Less commonly, hearing loss, ataxia, and seizures occur. Fever is present in only approximately half the patients. Elderly persons with cryptococcal meningitis may have just dementia, without other neurologic findings. AIDS patients often have subtle CNS symptoms but usually have fever and other constitutional symptoms and rapidly manifest signs of dissemination.

Pulmonary Infection

In non–HIV-infected patients, the most common underlying risk factor for pulmonary cryptococcal infection is chronic obstructive pulmonary disease, followed by corticosteroid use and receipt of a solid organ transplant. *C. neoformans* may merely be an airway colonizer in some patients; in others, symptomatic infection, mostly manifested by fever, cough, and dyspnea, requires treatment with an antifungal agent. The typical lesion noted with pulmonary cryptococcosis is a pleural-based nodular lesion. However, patchy pneumonitis, multiple nodular lesions, cavitary lesions, masslike lesions, and diffuse pulmonary infiltrates have all been noted with pulmonary cryptococcosis. Patients with advanced HIV infection are likely to have diffuse infiltrates that can progress rapidly to acute respiratory insufficiency. All immunosuppressed patients who have pulmonary cryptococcosis and all patients with any CNS symptoms should undergo lumbar puncture to be certain that meningitis is not present. Whether normal hosts with isolated pulmonary cryptococcosis and negative serum antigen tests require lumbar puncture is controversial. The most conservative approach is to perform lumbar puncture in all patients who have pulmonary cryptococcal infection.

Involvement of Other Organs

C. neoformans has been reported to infect most organs during the course of disseminated infection, especially in AIDS patients. Skin lesions are a prominent clue to dissemination. Papules that resemble molluscum contagiosum or an acneiform rash, nodules, ulcers, plaques, draining sinuses, and cellulitis have all been reported. Focal involvement can occur in the prostate and other organs of the genitourinary tract, in osteoarticular structures, in the breast, and in the eye, larynx, and other head and neck structures. The prostate, in particular, has been noted as a sanctuary from which persisting organisms can later disseminate.

DIAGNOSIS

The diagnosis of cryptococcosis is established when the yeast is grown in culture. Appropriate specimens for culture include cerebrospinal fluid (CSF), blood, sputum, material from skin lesions, and other body fluids or tissues that appear to be infected. The organism grows in several days on most standard agar media. Most automated blood culture systems allow rapid growth of *C. neoformans*. Visualization of the capsule and performance of a few simple tests differentiate *C. neoformans* from other yeasts. Tissue biopsy shows the 5- to 10-μm yeast surrounded by the capsule. Definitive diagnosis of cryptococcosis can be made by mucicarmine staining, which selectively stains the polysaccharide capsule a deep rose color. In CSF or other body fluids, an India ink preparation allows visualization of the budding yeast cells surrounded by the large capsule, but it is not currently done by many laboratories.

The latex agglutination assay for cryptococcal polysaccharide antigen (CRAG) is a highly sensitive and specific diagnostic test. CRAG is positive in CSF in almost 100% and in serum in about 75% of patients who have meningitis. In AIDS patients, serum CRAG is almost always positive and is an excellent screening tool; titers in both CSF and serum are exceptionally high because of the enormous burden of organisms. In non-AIDS patients who have nonmeningeal, pulmonary cryptococcosis, the CRAG assay is positive in only 25 to 50% of cases. False-positive results with the CRAG assay are uncommon, are generally low in titer, and are more likely with serum than with CSF. Patients with *Trichosporon asahii* infection can have a positive CRAG test because of cross-reacting antigens shared by both fungi.

The CSF of patients with cryptococcal meningitis typically has an increased number of white blood cells (but rarely >500/μL), a predominance of lymphocytes (although neutrophils are sometimes prominent early in the course), elevated protein, and decreased glucose. AIDS patients most often have normal or only mildly abnormal findings as a result of their markedly defective immune response. Despite normal CSF findings with regard to cells, protein, and glucose, every AIDS patient with a headache must have a CRAG test, India ink preparation, and culture performed on CSF. It is extremely important that an opening pressure be obtained when lumbar puncture is performed. Especially in AIDS patients, extremely high intracranial pressure (>350 mm H_2O) has been associated with poor outcomes and must be aggressively lowered.

All patients with cryptococcal meningitis should undergo computed tomography or magnetic resonance imaging of the brain to look for mass lesions and to assess ventricular size. Obstructive hydrocephalus is uncommon but requires a shunting procedure to decrease the pressure. More commonly, the increased intracranial pressure with cryptococcal infection is associated with normal-sized ventricles and is due to blockage at the arachnoid villi or increased brain edema (or both), perhaps related to the osmotic effect of the polysaccharide capsule. Different methods for reducing pressure are used in this situation.

TREATMENT Rx

Guidelines for the treatment of cryptococcal infection have been published by the Infectious Diseases Society of America (IDSA).

Central Nervous System Infection

Early multicenter randomized trials in non-AIDS patients showed superiority of the combination of amphotericin B and flucytosine for 6 weeks over amphotericin B alone for 10 weeks. Subsequent randomized trials in the azole era have been performed only in the AIDS population. They have confirmed the benefit of flucytosine added to amphotericin B for induction therapy and have shown that initial therapy with fluconazole alone or with amphotericin B alone is not as effective as therapy with amphotericin B and flucytosine.[1] The combination of amphotericin B and flucytosine has been shown to be the most rapidly fungicidal regimen.[2] Regimens using amphotericin B with fluconazole or flucytosine with fluconazole[3] are less effective, but reasonable alternatives when the preferred regimen of amphotericin B plus flucytosine is not available.

Current recommendations for AIDS patients are to give induction therapy with intravenous amphotericin B deoxycholate, 0.7 to 1 mg/kg daily, combined with oral flucytosine, 100 mg/kg daily given in four divided doses for at least 2 weeks, followed by consolidation therapy with oral fluconazole, 400 mg daily for a minimum of 8 weeks, and then suppressive therapy with fluconazole, 200 mg daily. Lipid formulations of amphotericin B at daily dosages of 3 to 5 mg/kg should be used for patients who have preexisting renal insufficiency and those at risk for nephrotoxicity, including all transplant recipients. For patients who have undergone 12 months of antifungal therapy, who have $CD4^+$ counts higher than 100/μL, and whose HIV viral load is undetectable on antiretroviral therapy, the suppressive therapy can be stopped.[4] Suppressive therapy with fluconazole for transplant recipients is recommended for 6 to 12 months. The IDSA guideline recommendations for non–HIV-infected, nontransplant recipients are to treat with amphotericin B deoxycholate, 0.7 to 1.0 mg/kg daily, plus flucytosine, 100 mg/kg daily, in four divided doses for at least 4 weeks for induction therapy, followed by consolidation therapy with fluconazole, 400 mg daily for 8 weeks, and suppressive therapy with fluconazole, 200 mg daily for 6 to 12 months. Many physicians use lipid formulations of amphotericin B, 3 to 5 mg/kg daily, in this population, many of whom are older and have underlying medical illnesses.

There are only a few case reports on the use of voriconazole and posaconazole for salvage treatment of cryptococcal meningitis. The echinocandins are not active against *C. neoformans* and should not be used.

A significant observation from the AIDS treatment trials was the role of increased intracranial pressure as a cause of early death from cryptococcal meningitis. An aggressive approach to the diagnosis and treatment of increased intracranial pressure in both AIDS and non-AIDS patients is mandatory and should include daily lumbar puncture or placement of a temporary lumbar drain or ventriculostomy until the opening pressure remains lower than 190 mm H_2O. Treatment with corticosteroids, acetazolamide, or mannitol has not proved efficacious in this setting.

Another issue that has emerged is the development of immune reconstitution inflammatory syndrome (IRIS), which can occur in patients with AIDS who are receiving effective antiretroviral therapy that increases the $CD4^+$ count (Chapter 402). Symptoms of meningitis reappear and are due to the inflammatory response and not a relapse of disease. IRIS can also occur in transplant recipients in whom immunosuppressive therapy is decreased rapidly. Generally, no specific therapy is needed for mild IRIS, but sometimes corticosteroids are needed if increased intracranial pressure occurs.

Pulmonary and Other Nonmeningeal Infections

Treatment of nonmeningeal cryptococcosis depends on the severity of the infection. Many patients with isolated pulmonary or other focal infections are not severely ill, and oral fluconazole, 400 mg daily for 6 to 12 months, is recommended. For patients who are severely ill, therapy is the same as noted earlier for CNS infection.

PROGNOSIS

The outcome for both AIDS and non-AIDS patients with cryptococcal meningitis has improved markedly in the developed world, However, in Africa the mortality from cryptococcal meningitis in AIDS patients approaches 100% in some areas because of lack of access to specific therapy. Dementia, which usually occurs in older patients, hearing loss, and visual loss may not be reversed even though mycologic cure is achieved.

SPOROTRICHOSIS

CAROL A. KAUFFMAN

DEFINITION

Sporotrichosis is a subacute or chronic infection that is usually localized to cutaneous and lymphocutaneous structures, but pulmonary, osteoarticular, and disseminated infection can occur in patients who have certain underlying diseases.

The Pathogen

Sporothrix schenckii is a thermally dimorphic fungus. In the environment at temperatures lower than 35 to 37° C, the organism is a mold and produces conidia, the infectious form. In tissues and at 35 to 37° C, *S. schenckii* transforms into the yeast phase; the yeasts are 4 to 6 µm in diameter; are cigar shaped, round, or oval; and reproduce by budding.

EPIDEMIOLOGY

S. schenckii is found worldwide in climates ranging from temperate to tropical. The organism exists in a variety of environmental niches, including soil, sphagnum moss, hay, decaying wood, and other vegetation. Infection is seen almost entirely in persons whose vocation, avocation, or living condition brings them into contact with the organism in the environment. Landscaping activities, gardening, farming, and motor vehicle accidents have been associated with sporotrichosis. Most cases of sporotrichosis are sporadic, but outbreaks have been described. Inhalation of *S. schenckii* conidia occurs less commonly and results in pulmonary and, rarely, disseminated sporotrichosis.

PATHOBIOLOGY

Infection is almost always acquired by inoculation of conidia and remains localized to the immediate and contiguous cutaneous, subcutaneous, and lymphatic structures. Some strains of *S. schenckii* grow poorly at temperatures higher than 35° C; these strains usually cause fixed cutaneous lesions without lymphatic spread. The typical host response to infection with *S. schenckii* is a mixed neutrophilic and granulomatous reaction. Antibody is not protective; T lymphocytes are important in containing the infection. In individuals who have underlying illnesses, including alcoholism, diabetes mellitus, and chronic obstructive pulmonary disease, *S. schenckii* is more likely to involve osteoarticular structures and the lungs. Widespread dissemination develops in persons infected with human immunodeficiency virus (HIV) but is a distinctly unusual event in normal hosts.

CLINICAL MANIFESTATIONS

Lymphocutaneous

Days to weeks after inoculation of *S. schenckii* conidia, a papular lesion develops at the inoculation site; the lesion becomes nodular and often ulcerates (Fig. 345-1). Drainage is not grossly purulent, and the lesion is not terribly painful. Similar lesions occur along the lymphatic channels proximal to the primary lesion. Verrucous or ulcerative fixed cutaneous lesions do not exhibit lymphatic extension. The differential diagnosis of lymphocutaneous sporotrichosis includes *Nocardia* infections (Chapter 338), particularly *Nocardia brasiliensis*; atypical mycobacterial infections (Chapter 333), especially *Mycobacterium marinum*; *Leishmania brasiliensis* infections (Chapter 356); and tularemia (Chapter 319).

Visceral and Osteoarticular

Pulmonary sporotrichosis occurs most often in middle-aged men who have chronic pulmonary disease and abuse alcohol. Fever, night sweats, weight loss, fatigue, dyspnea, cough, purulent sputum, and hemoptysis are common. Chest radiographs show unilateral or bilateral upper lobe cavities with variable amounts of fibrosis and nodular lesions. The disease mimics reactivation tuberculosis in many aspects. Osteoarticular sporotrichosis is found most often in middle-aged men and occurs more frequently in alcoholics. Infection

FIGURE 345-1. Lymphocutaneous sporotrichosis with a papular lesion at the inoculation site that becomes nodular and often ulcerates. (From CID, Dr. Watanakunakorn, University of Chicago Press.)

may involve one or multiple joints; the joints most commonly affected are the knee, elbow, wrist, and ankle joints. Isolated bursitis, tenosynovitis, and nerve entrapment syndromes have been reported. Osteoarticular infection can follow local inoculation, but most patients probably have had hematogenous spread. Isolated case reports document sporotrichosis involving the pericardium, eye, perirectal tissues, larynx, breast, epididymis, spleen, liver, bone marrow, lymph nodes, and meninges. Disseminated sporotrichosis, manifested as widespread ulcerative cutaneous lesions with or without visceral involvement, is uncommon; most cases have been reported in patients with advanced HIV infection.

DIAGNOSIS

Growth of *S. schenckii* from culture of material aspirated from a lesion, a tissue biopsy specimen, sputum, or body fluid is the most effective method of establishing the diagnosis of sporotrichosis. Growth of the mold phase of the organism is usually evident within a few days. Histopathologic examination of biopsy material shows a mixed granulomatous and pyogenic process; however, the organisms are often present in small numbers and are frequently not visualized. Serology is not useful in the diagnosis of sporotrichosis.

TREATMENT

Rx

Because sporotrichosis is usually a localized subacute to chronic infection, oral antifungal agents are preferred; amphotericin B is reserved for severe visceral infections. Guidelines for the management of sporotrichosis have been published by the Infectious Diseases Society of America. Itraconazole is the drug of choice for lymphocutaneous sporotrichosis. The usual dosage is 200 mg daily, and treatment should continue for several weeks after all lesions have disappeared, generally for a total of 3 to 6 months. Saturated solution of potassium iodide (SSKI) has been used to treat sporotrichosis for almost a century. The initial dose is 5 to 10 drops three times daily in water or juice, with the dose increasing over a period of several weeks to a maximum of 40 to 50 drops three times daily. SSKI has many side effects, including salivary gland swelling, metallic taste, rash, and fever; the only advantage is that it is inexpensive. Fluconazole is less effective than itraconazole but for occasional patients can be used at a dosage of 400 to 800 mg daily. Voriconazole is not active against *S. schenckii*, and there is no reported clinical experience with posaconazole. Terbinafine appears to be effective for sporotrichosis at a dosage of 500 mg twice daily, but few patients have been treated with this agent to date. Local hyperthermia, induced by a variety of different warming devices or baths, has been shown to be effective in some patients with fixed cutaneous lesions.

Osteoarticular and pulmonary sporotrichosis is usually treated with itraconazole, 200 mg twice daily for 1 to 2 years. Other azoles are less effective, and SSKI is ineffective. In a seriously ill patient with pulmonary sporotrichosis, 3 to 5 mg/kg of amphotericin B daily, preferably a lipid formulation, should be used as initial therapy. After the patient has shown improvement, therapy can be changed to itraconazole. Amphotericin B is the drug of choice for disseminated sporotrichosis. Therapy can be changed to itraconazole, 200 mg twice daily, once the patient has stabilized. Patients with acquired immunodeficiency syndrome and disseminated sporotrichosis should remain on lifelong maintenance therapy with itraconazole, 200 mg daily.

PROGNOSIS

The prognosis for patients with cutaneous and lymphocutaneous sporotrichosis is excellent. Almost all patients are cured with one course of therapy; relapses occur in only a small proportion of patients. Extracutaneous forms of sporotrichosis do not respond well to therapy, partly because of delays in diagnosis and partly because of the underlying diseases that are frequently found in those who have extracutaneous sporotrichosis. The outcome of disseminated sporotrichosis in patients with HIV infection has been especially poor.

346

CANDIDIASIS

CAROL A. KAUFFMAN

DEFINITION

Candidiasis encompasses a wide variety of clinical syndromes caused by yeasts of the genus *Candida.* Of the species that cause infection in humans, *Candida albicans* is the most common; *Candida glabrata, Candida parapsilosis,* and *Candida tropicalis* are responsible for most of the remaining infections. Organisms such as *Candida krusei, Candida lusitaniae,* and *Candida guilliermondii* are less common causes of infection.

The Pathogen

Candida species are 2- to 6-μm yeast-like organisms that reproduce by budding. Most species, with the exception of *C. glabrata,* form pseudohyphae (elongated buds that remain attached to the mother cell) and hyphae in tissues.

Candida species cause a wide spectrum of diseases ranging in severity from localized mucous membrane infection to life-threatening disseminated disease. The major determinant of the severity of infection is the host's immune response. Local infections are often related to overgrowth of *Candida* as a result of changes in the normal flora. Invasive infections that remain within an organ system, such as urinary tract infections, usually occur because of local anatomic abnormalities. In an immunosuppressed host, especially a patient with neutropenia, widespread visceral dissemination is common.

EPIDEMIOLOGY

Candida species are part of the normal human flora of the gastrointestinal and genitourinary tracts and skin. As colonizers, *Candida* species do not cause infection unless there is a defect in host defense mechanisms or unless exogenous factors, such as antibiotic use, have upset the ecology of the normal flora. *C. albicans* is the species most commonly found colonizing humans; *C. glabrata* is the second most common species, and *C. tropicalis, C. parapsilosis,* and others are found less often. The species of *Candida* colonizing patients change during hospitalization and with the use of antifungal agents. *C. glabrata,* a species that is increasingly resistant to fluconazole, and *C. krusei,* which is intrinsically resistant to fluconazole, are associated with increased use of this agent in the hospital setting.

Though uncommon, acquisition of *Candida* from health care workers or from environmental sources has been noted. The *Candida* species most often associated with transmission from contaminated fluids or devices, especially central intravenous catheters, has been *C. parapsilosis.* This species is also the most frequent colonizer of the hands of health care workers.

Candidiasis is the most common opportunistic fungal infection as a result of both the organisms' ubiquity and the increasing number of patients with risk factors for infection with these organisms. The classic immunosuppressed host at risk for serious *Candida* infections was a neutropenic patient with a hematologic malignancy who had received cytotoxic agents and corticosteroids. Increasingly, however, candidiasis is seen in patients in intensive care units (ICUs). Risk factors for the development of serious *Candida* infections in ICU patients include the use of broad-spectrum antimicrobials, indwelling central venous catheters, previous surgical procedures, renal failure, parenteral nutrition, and high Acute Physiology and Chronic Health Evaluation (APACHE) score. Certain ICU populations, especially very low birthweight neonates and burn victims, are at even higher risk for *Candida* infection than is the typical ICU patient.

The acquired immunodeficiency syndrome (AIDS) epidemic has led to a marked increase in *Candida* infections. However, in contrast to candidiasis in the hospital setting, the primary manifestation of *Candida* infection in AIDS patients is mucocutaneous infection, especially oropharyngeal candidiasis. The development of mucosal *Candida* infection is related to deficient T-cell immunity as reflected by a low $CD4^+$ lymphocyte count. With appropriate antiretroviral therapy, oropharyngeal candidiasis has become an uncommon opportunistic infection; it is now seen almost exclusively in patients with advanced human immunodeficiency virus (HIV) infection that is untreated or has become refractory to therapy.

PATHOBIOLOGY

The usual mode of infection with *Candida* is egress from its normal niche into the blood stream or other tissues; the source is usually the gastrointestinal tract, but the skin and genitourinary tract are other sources. The primary host defense in response to this event is phagocytosis and killing by neutrophils, monocytes, and macrophages. Phagocytosis is enhanced in the presence of specific anti-*Candida* antibody and complement. Several different mechanisms are operative within neutrophils and macrophages that allow the killing of yeasts. Thus, patients who are neutropenic, especially those with chemotherapy-induced disruption of the gut mucosa, are at great risk for invasion with *Candida* species. Once *Candida* gains access to the blood stream, widespread hematogenous dissemination is the rule. Biopsy of many different organs usually shows multiple microabscesses composed of neutrophils (in a host who has these cells), budding yeasts, and often pseudohyphae or hyphae. Over time, the lesions show a mixed neutrophilic and granulomatous response.

T-cell immunity is also an important host defense against infection with *Candida.* T-cell immunity controls *Candida* at mucosal surfaces. In contrast to those with neutropenia, patients with deficient T-cell immunity are at risk for persistent and recurrent mucocutaneous candidiasis, but invasive infection rarely develops.

CLINICAL MANIFESTATIONS

Mucocutaneous Candidiasis

Oropharyngeal Candidiasis

Local mucous membrane and cutaneous lesions are the most common forms of *Candida* infection. Oropharyngeal candidiasis, or thrush (Chapter 433), can be due to either local factors or T-cell dysfunction. Local factors include the use of broad-spectrum antimicrobials or inhaled corticosteroids, xerostomia, and radiation treatment of the head and neck. Denture stomatitis occurs frequently in persons who wear full upper dentures, especially those who do not remove their dentures at night.

Thrush secondary to T-cell dysfunction is most commonly seen in patients with HIV infection (Chapter 397) and is the most frequent opportunistic infection noted in patients with AIDS. The appearance of thrush in a previously healthy individual with no known risk factors should immediately raise suspicion of HIV infection.

Thrush manifests with white plaques on the buccal mucosa, palate, oropharynx, or tongue (Fig. 346-1). Scraping the lesions with a tongue depressor reveals an erythematous, nonulcerated mucosa under the plaques. Denture stomatitis almost always manifests as a painful erythematous palate without plaques. Angular cheilitis, or perlèche, which is the presence of painful cracks at the corners of the mouth, can occur with or without thrush.

Esophagitis

Esophagitis may accompany oropharyngeal candidiasis or may occur independently of lesions in the oropharynx (Chapter 140). The development of *Candida* esophagitis is almost always related to immune dysfunction and not simply to local factors. *Candida* esophagitis occurs in AIDS patients with low CD4 counts, patients with leukemia, and others taking immunosuppressive agents. The classic symptom of *Candida* esophagitis is odynophagia localized to a discrete substernal area. The differential diagnosis includes ulcerations due to herpes simplex or cytomegalovirus and, in AIDS patients, idiopathic ulcers.

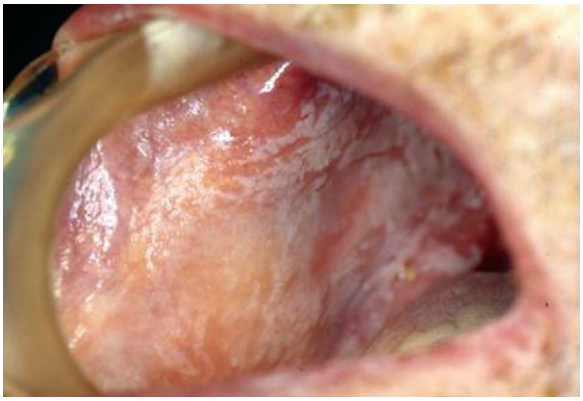

FIGURE 346-1. Thrush.

Vulvovaginitis

Candida vulvovaginitis is a common infection in women of childbearing age and is the most frequent mucocutaneous manifestation of *Candida* infection. Risk factors include conditions associated with increased estrogen levels, such as the use of oral contraceptives and pregnancy, diabetes mellitus, therapy with corticosteroids or broad-spectrum antimicrobials, and HIV infection. Symptoms include vaginal discomfort, discharge, and vulvar pruritus. The discharge is usually curd-like, but it can also be thin and watery. The labia are erythematous and swollen, and the vaginal walls show erythema and white plaques. Although most women have only a few episodes throughout their lives, a minority have frequent recurrences; in most of these patients, no discrete risk factor is found, and the cause is presumed to be local immune dysregulation.

Cutaneous Candidiasis

Candida infection of the skin (Chapter 444) occurs mostly in the intertriginous areas or under a large pannus or pendulous breasts. The lesions are erythematous, pruritic, and frequently pustular; have a distinct border; and are almost always associated with smaller satellite lesions. The presence of satellite lesions helps distinguish candidiasis from tinea cruris or corporis. *Candida* onychomycosis results in thickened, opaque, and onycholytic nails. *Candida* can also cause paronychia, especially in those whose occupation involves frequent immersion of the hands in water.

Chronic Mucocutaneous Candidiasis

This uncommon syndrome usually begins in childhood and is characterized by recalcitrant and relapsing thrush, vaginitis, onychomycosis, and hyperkeratotic skin lesions on the face, scalp, and hands. It is thought to be due to a specific defect in the T-cell response to *Candida* antigens. Some patients have associated endocrinopathies such as hypoparathyroidism, hypothyroidism, and hypoadrenalism.

Disseminated Infections

Candidemia

The most common manifestation of disseminated *Candida* infection is candidemia. However, candidemia merely implies the presence of *Candida* in blood; it does not define the extent of visceral involvement. *Candida* obtained from a blood culture should never be considered a contaminant and should always prompt a search for the probable source and the extent of infection. Risk factors for candidemia include broad-spectrum antimicrobial therapy, central intravenous catheters, parenteral nutrition, renal failure, surgical procedures involving the gastrointestinal tract, neutropenia, and corticosteroid therapy. The attributable mortality from candidemia approaches 40%; overall mortality is higher in the elderly and neonates.

Although candidemia is the most obvious manifestation of serious infection with *Candida* species, septic shock can also occur, along with invasion

FIGURE 346-2. Skin lesions in invasive candidiasis.

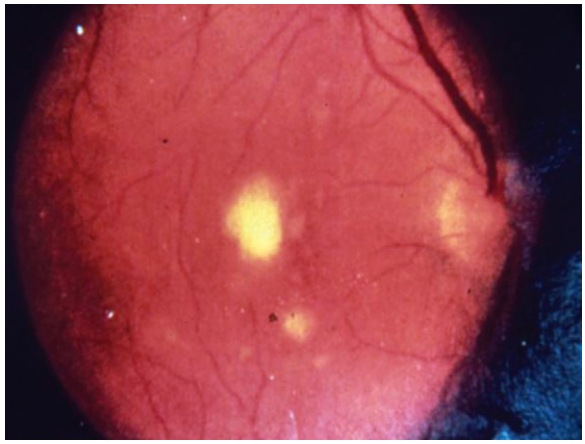

FIGURE 346-3. Retinal involvement.

of multiple viscera, in the absence of positive blood cultures. The clinical picture of disseminated candidiasis is indistinguishable from that of bacterial infection. The histologic picture characteristic of disseminated candidiasis consists of multiple microabscesses in many organs. The eyes, kidneys, liver, spleen, and brain are the most commonly involved sites, but virtually all organs have been noted to have microabscesses caused by *Candida.* Clinical clues to the diagnosis of disseminated candidiasis include the appearance of the skin and retinal lesions. The nonpainful, nonpruritic skin lesions are papular to pustular and surrounded by a zone of erythema (Fig. 346-2). The eye lesions appear as distinctive white exudates in the retina (Fig. 346-3); with extension into the vitreous body, the retina becomes obscured.

Endocarditis

Candida endocarditis is an uncommon and often fatal complication of candidemia. It occurs most often in intravenous drug users, patients who have prosthetic cardiac valves, and those with central venous catheters in place. Blood cultures are usually persistently positive, and echocardiography reveals large vegetations that can readily embolize to major vessels.

Chronic Disseminated (Hepatosplenic) Candidiasis

This syndrome almost always occurs in leukemic patients who have had an episode of neutropenia. After the neutrophil count returns to normal, fevers that are often quite high, right upper quadrant tenderness, and nausea develop. The alkaline phosphatase level is generally elevated, and distinctive punched-out lesions are seen in the liver, spleen, and sometimes the kidneys on computed tomography (Fig. 346-4). Biopsy of these lesions shows microabscesses that contain budding yeasts.

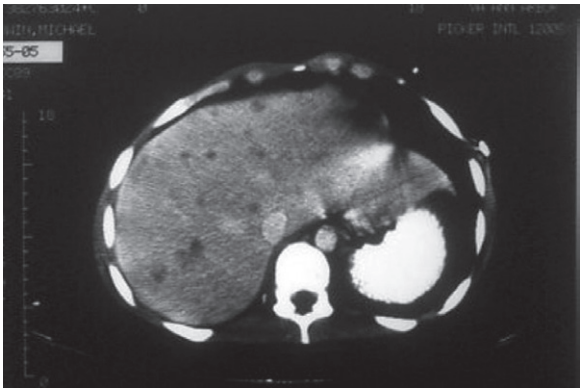

FIGURE 346-4. Computed tomography of a patient with chronic disseminated candidiasis (hepatosplenic candidiasis). Note the distinctive punched-out lesions in the liver.

Focal Invasive Infections

These forms of candidiasis result from local inoculation, contiguous spread, or hematogenous spread. Hematogenous spread, which often goes undetected, is probably the most common pathogenetic mechanism.

Urinary Tract Infections

Candiduria is a frequent finding in hospitalized patients and is related to factors such as diabetes mellitus, broad-spectrum antimicrobial treatment, indwelling urinary devices, and genitourinary tract structural abnormalities. Most patients with candiduria have only bladder colonization and not infection. Urinary tract infection with *Candida* species can arise by two mechanisms. Patients with candidemia can develop multiple microabscesses secondary to hematogenous spread to the kidneys. Other patients, who have the risk factors noted earlier, can develop cystitis or ascending infection with pyelonephritis. Patients with cystitis or pyelonephritis have symptoms indistinguishable from those of bacterial infections. A fungus ball composed of fungal hyphae can develop at any level of the collecting system and lead to obstruction, with subsequent infection.

Osteoarticular Infections

Osteoarticular infections arise secondary to hematogenous seeding or exogenous inoculation during intra-articular injection, a surgical procedure, or trauma. Vertebral osteomyelitis is probably the most common manifestation of osteoarticular candidiasis. The symptoms of back pain and fever may occur many weeks after an episode of fungemia. A unique triad of face, scalp, and upper chest folliculitis; endophthalmitis; and sternoclavicular or costochondral septic arthritis is reportedly due to *C. albicans* in drug users who inject brown heroin intravenously.

Endophthalmitis

Exogenous endophthalmitis occurs secondary to trauma or ophthalmic surgery. Most often, the procedure involved is cataract extraction, with or without lens implantation, and the most common infecting species is *C. parapsilosis.* Primary infection occurs in the anterior chamber, but ultimately the posterior chamber is also involved. Endogenous *Candida* endophthalmitis results from hematogenous seeding of the choroid and retina and is one of the most serious complications of candidemia. Characteristic white lesions are visible in the retina, and with progression of the infection, vitritis occurs; the risk for loss of vision is quite high.

Peritonitis

Candida peritonitis can follow bowel surgery or perforation. Symptoms are the same as those noted in bacterial peritonitis. Usually, this type of infection is polymicrobial, and abscess formation is common. In patients maintained on continuous ambulatory peritoneal dialysis, *Candida* peritonitis generally develops as a late infection after previous episodes of bacterial peritonitis. A cloudy dialysate, abdominal pain, and fever are typically noted.

Meningitis

Acute *Candida* meningitis occurs as part of disseminated infection, especially in low-birthweight neonates. Chronic meningitis, an uncommon

manifestation of candidiasis, resembles cryptococcal or tuberculous meningitis with regard to symptoms and cerebrospinal fluid findings.

DIAGNOSIS

The diagnosis of mucocutaneous candidiasis is often made clinically. Culture is rarely indicated. Confirmation can be sought by scraping the lesions and performing either a potassium hydroxide preparation or a Gram stain to look for budding yeasts and pseudohyphae (Chapter 444). Pseudohyphae are not always noted and are never seen in infection with *C. glabrata.* In cases in which the disease is recurrent or unresponsive to standard therapy, lesions should be cultured to establish whether a more resistant species, such as *C. glabrata* or *C. krusei,* is the causative agent. In the event of suspected esophagitis, endoscopy should be performed; biopsy of the plaque-like lesions or ulcerations shows mucosal invasion with budding yeasts and pseudohyphae.

The diagnosis of invasive or disseminated candidiasis is more difficult. Evidence of dissemination is usually sought by culturing blood or other sterile body sites. The automated blood culture systems used by most hospitals are as sensitive as the lysis-centrifugation system for growing *Candida* from blood. However, no system is sensitive enough for clinicians to rely on blood cultures to establish the diagnosis of invasive candidiasis in all cases or to rule out candidiasis as a diagnostic possibility. In addition, 1 to 4 days is required for growth to occur; in a desperately ill patient, this delay is problematic.

The tips of intravenous catheters that have been removed should be sent for culture. However, no studies have evaluated the number of yeasts that is indicative of infection, and many physicians accept the growth of any yeast as affirming infection that requires treatment. Because osteomyelitis and other focal forms of candidiasis are generally indistinguishable from bacterial infection, biopsy should be performed for histopathologic and culture studies.

In a seriously ill patient suspected of having candidiasis, the development of pustular skin lesions or typical retinal lesions can be helpful. Budding yeasts typical of *Candida* species should be sought by smearing material from a pustule on a slide and staining it with Gram stain or by performing a biopsy of a lesion and staining the tissue section with a silver stain. All patients who are candidemic or suspected of having disseminated *Candida* infection should undergo a dilated ophthalmologic examination, preferably by an ophthalmologist, to look for typical retinal lesions.

Imaging studies are invaluable for certain forms of candidiasis, especially chronic disseminated candidiasis, and they can be of major help in defining the extent of infection in other types of *Candida* infection, such as osteoarticular and urinary tract infections and endocarditis.

The serum β-D-glucan assay, which detects a component of the cell wall of many different fungi, may prove beneficial in the diagnosis of invasive fungal infections, including candidiasis; however, more experience is needed to verify this test's usefulness.

TREATMENT Rx

Guidelines for treatment of the various forms of candidiasis were recently published by the Infectious Diseases Society of America (IDSA). Mucocutaneous disease is obviously treated in a much different fashion than disseminated life-threatening infection. Because diagnostic tests are not sensitive, empirical therapy is indicated in some circumstances, and for patients at the highest risk for *Candida* infection, antifungal prophylaxis can decrease that risk.

Mucocutaneous Infections

Most mucocutaneous infections should initially be treated with local creams, solutions, troches, or suspensions. For thrush, clotrimazole troches (10 mg four or five times daily) are preferred to nystatin suspension (commonly given as "swish and swallow" four times daily). Patients with AIDS may not respond to local therapy, especially when their CD4 counts are low; in this situation, oral fluconazole 100 mg daily, or itraconazole solution 200 mg daily, should be used. Posaconazole is as effective as fluconazole but more expensive.[1] For vaginitis, a variety of creams and vaginal tablets (miconazole, clotrimazole, and others) are effective, but many women prefer to take a single 150-mg fluconazole tablet orally. Recurrent vaginitis is a more complicated therapeutic issue and often requires chronic suppressive therapy with fluconazole. Esophagitis should always be treated with a systemically absorbed agent; the usual treatment is fluconazole 200 mg/day for 14 days.

In patients with advanced AIDS and low CD4 counts, who are often taking fluconazole to prevent recurrent candidiasis, fluconazole-refractory disease may develop. For these patients, increasing the dosage of fluconazole or switching to itraconazole suspension, oral voriconazole, or posaconazole should be effective. If oral tablets and solutions are no longer effective, intravenous amphotericin B, caspofungin, anidulafungin, and micafungin are alternative agents that can be used. Patients with the syndrome of chronic mucocutaneous candidiasis require lifelong suppressive therapy with oral azole agents.

Candidemia and Invasive Candidiasis

All patients with candidemia should be treated with an antifungal agent, including patients who have only one blood culture that yields *Candida* and those with a vascular catheter tip that yields *Candida.* The rationale for this recommendation is related to the high rate of metastatic foci in major organs associated with hematogenously disseminated candidiasis. Randomized controlled trials have shown the effectiveness of the following antifungal agents for the treatment of candidemia: fluconazole 400 or 800 mg/day; the three echinocandins—caspofungin 50 mg/day, anidulafungin 100 mg/day, and micafungin 100 mg/day; voriconazole 3 mg/kg twice daily; amphotericin B 0.7 mg/kg/day; and a lipid formulation of amphotericin B 3 to 5 mg/kg/day.[2,3] The IDSA guidelines recommend fluconazole for patients who are not severely ill and have not had recent azole exposure, and an echinocandin for severely ill patients and those who have had recent azole exposure. Patients who have stabilized clinically and are found to have an isolate, such as *C. albicans*, that is likely to be susceptible to fluconazole can be transitioned to fluconazole from an echinocandin. Voriconazole is recommended for step-down therapy rather than initial therapy, and amphotericin B formulations are used infrequently, except for patients who are neutropenic and for neonates. All vascular catheters should be removed, because removal has been shown to help clear *Candida* from blood more quickly. Repeated blood cultures should be obtained to ascertain that the fungemia has resolved, and treatment should continue for 2 weeks after the date of the first negative blood culture.

Because diagnostic tests are not sensitive, seriously ill patients who could have invasive candidiasis may need to be treated before culture confirmation. This approach is used frequently in neutropenic patients, whose outcomes are poor if disseminated fungal infection goes untreated. Several different antifungal agents can be used empirically, including a lipid formulation of amphotericin B, caspofungin, or voriconazole[2,3]; these agents have activity against filamentous fungi as well as *Candida* species. Empirical therapy has also been used in ICU patients. A placebo-controlled, randomized trial failed to show a benefit with empirical therapy; however, there were acknowledged problems with the chosen end point, and the rate of candidemia was too low to allow a proper evaluation of empirical therapy with fluconazole.[10] The IDSA guidelines recommend that empirical therapy be reserved for febrile, critically ill patients who have risk factors for invasive candidiasis; the decision to treat should be based on clinical assessment of risk, serologic markers for invasive candidiasis, and culture data from nonsterile sites. The agents recommended are either fluconazole or an echinocandin, with the caveats noted earlier for treating patients with documented candidemia.

Endocarditis should be treated with a lipid formulation of amphotericin B, with or without flucytosine. Echinocandins are an acceptable alternative. Infected valves should be replaced. In a few patients for whom valve replacement was not an option, lifelong suppression with fluconazole appeared to be effective.

Chronic disseminated candidiasis generally requires months of therapy for cure. Most patients begin therapy with a lipid formulation of amphotericin B and are then switched to fluconazole and treated until the lesions disappear on computed tomography scanning.

Focal Invasive Infections

Treatment of focal infections depends on the organ system involved. Perhaps the simplest to treat are urinary tract infections. Most patients with candiduria are not infected but merely colonized; removing the selective pressure of antimicrobials and indwelling catheters eliminates candiduria in many of these patients. For those who have infection, oral fluconazole at a dosage of 200 mg/day for 2 weeks is recommended. Bladder irrigation with amphotericin B should not be used because it eradicates only bladder colonization, requires that a catheter be placed in the bladder, and is associated with a high recurrence rate. None of the newer antifungal agents has a role in the treatment of urinary tract infections.

Osteoarticular infections require months of therapy; amphotericin B or an echinocandin can be given initially, followed by long-term therapy with an azole. Peritonitis associated with chronic ambulatory peritoneal dialysis can be treated with amphotericin B, fluconazole, or an echinocandin, depending on the species of *Candida* causing infection. Intraperitoneal administration of amphotericin B can be extremely irritating and should not be attempted. The dialysis catheter should be removed. Meningitis should be treated initially with amphotericin B and flucytosine; patients with more chronic disease can be switched to fluconazole for a longer duration of therapy.

Treatment of *Candida* eye infections varies with the extent of ocular involvement. Lesions discovered early at the stage of choroidal or retinal involvement might be treated effectively with systemic antifungal agents (amphotericin B,

an echinocandin, fluconazole, or voriconazole) alone, but there are no data that prove this. Many physicians prefer to use an agent, such as voriconazole or fluconazole, that achieves higher concentrations in the eye. Lesions extending into the vitreous body require more aggressive therapy. The best results have been obtained with pars plana vitrectomy, which also provides material for culture; injection of amphotericin B or voriconazole into the vitreous; and a systemic antifungal agent such as fluconazole, voriconazole, or amphotericin B. Clearly, management must be individualized and performed in concert with an ophthalmologist experienced in the treatment of this infection. Treatment of endophthalmitis associated with an intraocular lens implant requires removal of the implant, vitrectomy, and local amphotericin B injections, as well as therapy with fluconazole or voriconazole.

PREVENTION

For certain populations at the highest risk for invasive fungal infection, prophylactic antifungal agents can prevent infection. The populations for whom prophylaxis is recommended include stem cell transplant recipients, patients with acute leukemia who are undergoing induction chemotherapy, high-risk liver transplant recipients, and pancreas and small bowel transplant recipients; in these groups, a variety of different agents are effective. In the ICU population, prophylaxis with fluconazole can be effective, but it is recommended only in units that have a high rate of invasive candidiasis, and only in those patients at the highest risk for infection. Restricting the use of prophylaxis is essential to prevent the widespread use of azoles, with subsequent selection of resistant species.

PROGNOSIS

The prognosis for patients with mucocutaneous infections is excellent. The prognosis for focal invasive infections depends on the organ involved and the patient's immune status. For example, whereas pyelonephritis may respond well to antifungal therapy, endocarditis and meningitis are more difficult to treat and have poor outcomes. Invasive candidiasis has a high mortality rate. Early treatment with an effective antifungal agent is extremely important for a favorable outcome.

ASPERGILLOSIS

THOMAS J. WALSH AND DAVID A. STEVENS

DEFINITION

Aspergillosis is defined as infection with one or more species of the genus *Aspergillus*. Sporelike structures called conidia are aerosolized from the mold form of the organism growing in the environment. When conidia reach tissue, they germinate to form invasive filaments called hyphae.

The Pathogens

The most common species infecting humans are *Aspergillus fumigatus*, *Aspergillus flavus*, *Aspergillus terreus*, and *Aspergillus niger*. The species are usually identified in culture by the characteristic microscopic features of their hyphae and the structures producing conidia. When some species are not readily identifiable, they may be reported by the clinical laboratory as "*Aspergillus* species or *Aspergillus* sp." Molecular methods are increasingly being used for identification. *A. fumigatus* may be reported as "*A. fumigatus* species complex." Some species within the *A. fumigatus* complex may be particularly drug resistant. *A. terreus* is frequently resistant to amphotericin B. Aspergilli within tissue appear as dichotomously branched (Y-shaped) septate hyphae. *Scedosporium* spp and *Fusarium* spp may also produce septate hyphae in tissue. The presence of septa and dichotomous branching differentiates *Aspergillus* spp from the Mucorales, which are the causative organisms of mucormycosis (Chapter 348).

EPIDEMIOLOGY

Aspergillus spp are ubiquitous organisms in the external environment, including soil, decaying matter, and air, and can grow at temperatures as high as 40 to 50° C. Aspergilli are easily isolated from houses, particularly from basements, crawl spaces, bedding, humidifiers, ventilation ducts, potted plants, dust, condiments (e.g., pepper), and marijuana samples. Aspergilli cause abortion in cattle and are important pathogens of marine organisms, insects, and domesticated and wild birds. Aflatoxin, which is one of the most potent carcinogens known, is produced by strains of *A. flavus* at ambient temperature on stored grain, spices, and nuts. Food-borne ingestion of preformed aflatoxin may cause hepatic necrosis or hepatocellular carcinoma (Chapter 202) in animals and humans.

Aspergillus spp may be acquired from airborne conidia in inpatient and outpatient settings. Nosocomial aspergillosis is associated with building renovation, new construction, unfiltered air, contaminated ventilation systems, and fireproofing materials. Hospital water, which may become aerosolized during activities such as showering, is a newly described potential source of aspergilli. As human pathogens, *Aspergillus* spp may cause acute invasive disease, chronic infection, or allergic symptoms. A classification of aspergillosis is presented in Table 347-1.

Acute invasive aspergillosis develops in immunocompromised patient populations, particularly those with hematologic malignancies, hematopoietic stem cell transplantation (HSCT), severe aplastic anemia, primary immunodeficiencies, and solid organ transplantation, especially heart, lung, and liver transplants. Persistent neutropenia, use of corticosteroids and other immunosuppressive agents, graft-versus-host disease, and cytomegalovirus disease are the most frequently observed risk factors. The mortality associated with acute invasive aspergillosis varies from as high as 100% with central nervous system (CNS) infection to approximately 65% with pulmonary infection in HSCT recipients. Early recognition of the clinical manifestations followed by prompt initiation of antifungal therapy may improve the ominous prognosis of patients with acute invasive aspergillosis.

CLINICAL MANIFESTATIONS

Invasive Aspergillosis

The classic clinical manifestations of *invasive pulmonary aspergillosis* (IPA) in immunocompromised hosts are fever and focal pulmonary infiltrates, nodules, or wedge-shaped densities resembling infarcts (see Table 347-1). Cough, pleuritic pain, and hemoptysis may also be present. Focal pulmonary infiltrates may progress to a cavity on recovery from neutropenia. Pulmonary

TABLE 347-1 CLASSIFICATION OF ASPERGILLOSIS

CATEGORY	SPECIFIC FORMS OF ASPERGILLOSIS
Acute invasive aspergillosis	Invasive pulmonary aspergillosis Empyema Tracheobronchial infection Extrapulmonary aspergillosis Acute sinusitis Focal rhinitis Cerebral, cerebellar, or brain stem infarction Endophthalmitis Osteomyelitis Epidural abscess Cardiac aspergillosis Myocarditis Endocarditis Pericarditis Gastrointestinal aspergillosis Renal infection Cutaneous lesions (nodules, ulcers) Disseminated aspergillosis
Chronic aspergillosis	Aspergilloma Chronic necrotizing pulmonary aspergillosis Chronic cavitary pulmonary aspergillosis *Aspergillus* otomycosis
Allergic forms of aspergillosis	Allergic bronchopulmonary aspergillosis Extrinsic allergic alveolitis Allergic *Aspergillus* sinusitis

infiltrates may also be manifested as bronchopneumonia in an immunosuppressed patient. The pulmonary pathology in all these entities is hemorrhagic infarction caused by the organism's capacity to invade blood vessel walls (angioinvasion). These processes lead to the formation of a necrotic center surrounded by a ring of hemorrhage and edema, which correlates radiographically with a "halo sign" surrounding the nodular density. Concomitant pleural effusion may develop and represents *Aspergillus* empyema. Tracheobronchial aspergillosis in immunocompromised patients is manifested as ulcerative, pseudomembranous, or plaquelike large-airway disease that may presage pulmonary parenchymal invasion.

Acute Aspergillus sinusitis may occur concomitantly or independently of IPA. Although symptoms may include fever, localized pressure, and pain, they may be absent in severely immunocompromised patients. Eschars on the nasal septum and turbinates may be observed by speculum examination or endoscopy. Acute *Aspergillus* sinusitis of the ethmoid and sphenoid sinuses may progress to cavernous sinus thrombosis with symptoms referable to cranial nerves III, IV, V_1, V_2, and VI. *A. flavus* has a high propensity for causing acute sinusitis.

The tissue targets of *extrapulmonary* and *disseminated aspergillosis* most commonly include the CNS, where abscesses and infarcts are characteristic. Patients with CNS aspergillosis suffer from focal paresis, cranial nerve deficits, and seizures. The glucose level in cerebrospinal fluid (CSF) is usually normal, and cultures of CSF are negative. Other extrapulmonary manifestations include endophthalmitis, myocardial infarction, gastrointestinal disease, renal infarction, cutaneous lesions, and Budd-Chiari syndrome. Esophageal ulcers and mesenteric thrombosis may produce gastrointestinal bleeding. Renal infection may cause flank pain and hematuria.

Aspergillus endocarditis usually begins as an isolated infection in intravenous drug users or following cardiac valvular surgery. *Aspergillus* endocarditis is most commonly manifested as major arterial emboli. Blood cultures, which are seldom positive, may be delayed in growth by as much as 14 to 21 days. Diagnosis is difficult, and despite valve replacement and antifungal therapy, mortality approaches 100%. *Aspergillus pericarditis* may arise from contiguous pulmonary lesions or from transmural invasion from an endocardial infection.

Locally invasive aspergillosis is usually manifested in immunocompromised patients as cutaneous ulcers, focal rhinitis, osteomyelitis, and septic arthritis. Cutaneous ulcers have been associated with the use of contaminated adhesive tape and arm boards. Blood-borne infection in illicit intravenous drug users may result in foci of dissemination in the brain, lung, kidney, and bone. Keratitis, endophthalmitis, and infection of burn wounds may develop as a result of traumatic inoculation in otherwise immunocompetent patients.

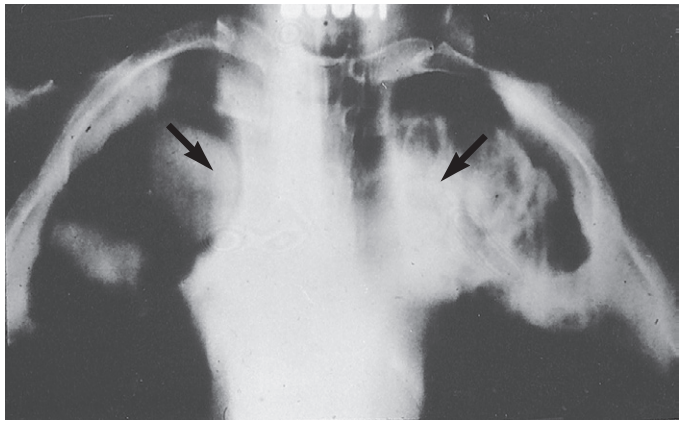

FIGURE 347-1. Tomogram of pulmonary aspergillomas *(arrows)*.

Chronic Pulmonary Aspergillosis

Aspergilloma appears on chest radiographs as a ball in a cavity. The fungus ball consists of matted hyphae and debris in a preformed cavity from previous pulmonary tuberculosis, histoplasmosis, or fibrocystic sarcoidosis (Fig. 347-1). Symptomatic patients exhibit cough, hemoptysis, dyspnea, weight loss, fatigue, chest pain, or fever. Sputum culture is typically positive for *Aspergillus* spp. Pleural aspergillosis may complicate surgical resection of an aspergilloma or develop spontaneously as a bronchopleural fistula or concomitantly with tuberculosis.

As a stage in the repair process of infarcted lung tissue in neutropenic patients, one or more apparent "aspergillomas" may develop in consolidated lesions during recovery from neutropenia. These apparent aspergillomas do not develop in preexisting cavities. Instead, they create a radiographic "air-crescent sign," or Monod sign, during their formation.

Chronic necrotizing pulmonary aspergillosis (CNPA) and *chronic cavitary pulmonary aspergillosis* (CCPA) occur in patients with underlying chronic lung disease, chronic immunosuppression, such as that due to prolonged use of systemic corticosteroids, or both. CNPA characteristically causes slowly progressive inflammatory destruction of lung tissue superimposed on chronic lung disease. The clinical manifestations of worsening pulmonary function, cough, and dyspnea in CNPA may be indistinguishable from those of concomitant primary chronic respiratory disease.

CCPA is defined as the presence of multiple *Aspergillus*-related cavities, which may or may not contain an aspergilloma. Patients with CCPA may have genetically mediated deficits in innate host defenses. Occurring in association with symptoms of cough, hemoptysis, and dyspnea, the progressive cavities of CCPA tend to coalesce and result in the loss of functional lung tissue.

Aspergillus otomycosis is a chronic infection that usually involves the external auditory canal and causes symptoms of pain, pruritus, hypoacusis, and otic discharge in patients with impaired mucocutaneous immunity, such as those with chronic eczema, hypogammaglobulinemia, diabetes mellitus, human immunodeficiency virus infection, and conditions requiring the administration of corticosteroids. *Aspergillus* may involve the middle ear and extend into the mastoid sinus if the tympanic membrane has been perforated.

Allergic Forms of Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) develops most frequently in patients with a history of chronic asthma or cystic fibrosis. Occurring in genetically susceptible patients exposed to specific *Aspergillus* antigens, ABPA is characterized by episodic airway obstruction, fever, eosinophilia, positive sputum cultures, mucous plugs containing hyphae, the presence of grossly visible brown flecks in sputum (hyphae), transient infiltrates, parallel "tramline" or ring markings on chest radiographs, proximal bronchiectasis, upper lobe contraction, and elevated levels of total immunoglobulin E (IgE). Eosinophilia may be present in blood, sputum, and lung tissue. Mucous plugs contribute to development of pulmonary infiltrates, atelectasis, and peribronchial inflammation. The parallel or ring markings are caused by thickened ectatic bronchi, whereas the upper lobe changes are due to progressive apical fibrosis. The pulmonary infiltrates in ABPA may be nonsegmental and transient in association with eosinophilia and asthma; alternatively, they may be segmental and associated with bronchial

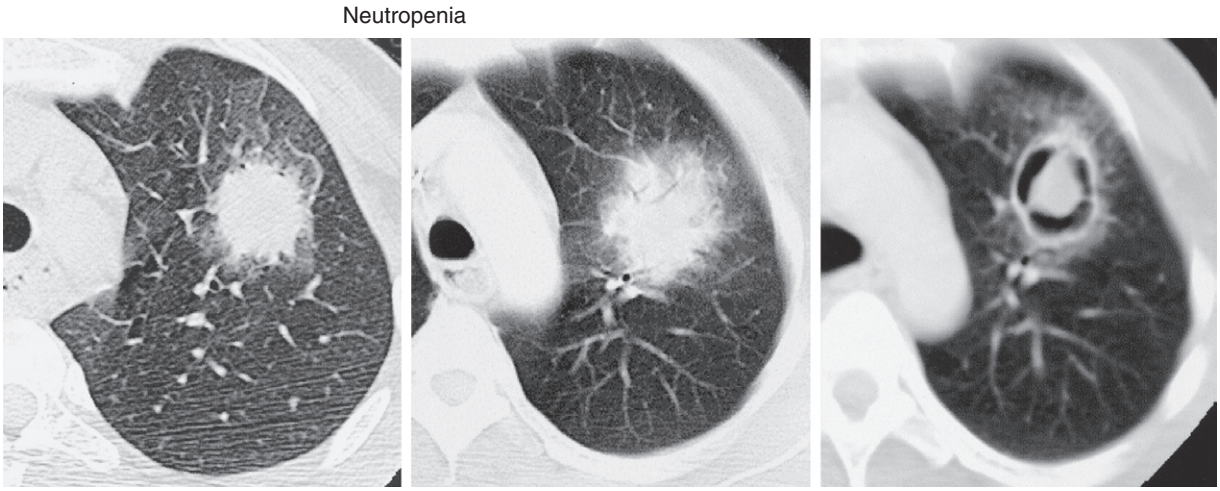

FIGURE 347-2. Evolution of the radiographic appearance of invasive aspergillosis in an immunocompromised host. D = days after the lesion is first noted.

obstruction by mucous plugs, in which case asthma and eosinophilia may be absent.

Extrinsic allergic alveolitis is an unusual allergic form of *Aspergillus* lung disease that has most frequently been associated with *Aspergillus clavatus* in malt workers. A hypersensitivity pneumonitis with dyspnea and fever develops approximately 4 hours after exposure. Diffuse reticulonodular interstitial infiltrates may be present at the time of symptoms. Patients have IgG precipitins and cell-mediated immune reactions against *Aspergillus* antigens. Granulomas are present in lung tissue. In contrast to ABPA, eosinophilia is not a feature of *Aspergillus* extrinsic allergic alveolitis.

Allergic Aspergillus sinusitis (AAS) is a noninvasive form of sinus disease that typically occurs in patients with asthma, nasal polyps, sinus opacification, and eosinophilia. Sinus aspiration yields mucinous material containing eosinophils, Charcot-Leyden crystals, and hyphal elements. AAS and ABPA may coexist in some patients. Advanced forms of AAS may be accompanied by proptosis and optic neuropathy and thus necessitate prompt surgical intervention.

DIAGNOSIS

Invasive Aspergillosis

Diagnosis of IPA and disseminated aspergillosis is difficult. None of the aforementioned clinical manifestations are diagnostic of invasive aspergillosis. Advances in computed tomography have revealed characteristic features of nodules, halo signs, wedge-shaped infiltrates, and air-crescent signs in immunocompromised patients with IPA (Fig. 347-2). However, infections caused by *Fusarium* spp, *Scedosporium* spp, the Mucorales, and *Pseudomonas aeruginosa* may be radiologically indistinguishable from IPA. Microbiologic confirmation, when possible, is important to differentiate aspergillosis from other filamentous fungal infections. Bronchoalveolar lavage (BAL), percutaneous needle aspiration, video-assisted thoracoscopic biopsy, and if necessary, open lung biopsy are standard procedures for establishing a microbiologic diagnosis of invasive aspergillosis. Specimens obtained from these procedures may demonstrate dichotomously branching septate hyphae by direct microscopy or may grow *Aspergillus* species in culture. Each of these procedures is associated with false-negative results, as well as with complications. Conversely, detection of *Aspergillus* by direct examination or culture of tissue from an immunocompromised host with pulmonary nodules or well-circumscribed infiltrates carries a high probability of diagnosis of invasive aspergillosis.

Galactomannan, which is a heteropolysaccharide of the *Aspergillus* cell wall, is a useful biomarker that is released into the circulation and alveolar spaces during IPA. Detection of galactomannan by enzyme immunoassay (EIA) in serum or BAL above certain thresholds is strong microbiologic evidence of a diagnosis of invasive aspergillosis in immunocompromised patients with characteristic clinical manifestations. Nonetheless, false-positive results have been reported in patients who have received piperacillin-tazobactam or amoxicillin-clavulanate, in instances in which Plasma-Lyte was used for BAL, and in other deeply invasive mycoses such as blastomycosis and histoplasmosis. Serum galactomannan may be falsely negative in patients receiving antifungal prophylaxis or empirical therapy.

(1→3)-β-D-Glucan is another *Aspergillus* cell wall polysaccharide that is detected in serum during invasive disease. The sensitivity of the *Limulus* spectrophotometric assay for detection of (1→3)-β-D-glucan in patients with invasive aspergillosis appears to be comparable to that of the galactomannan EIA. However, because (1→3)-β-D-glucan is also present in the cell wall of other medically important fungi, including *Candida* spp, the specificity of (1→3)-β-D-glucan for *Aspergillus* spp is less than that of galactomannan.

Even though molecular diagnostic tools such as quantitative polymerase chain reaction (PCR) for the diagnosis of invasive aspergillosis are promising, they also remain investigational for this infection. Ultimately, the combined use of improved diagnostic imaging, microscopy, culture methodology, cell wall biomarkers, and possibly PCR in conjunction with careful bedside assessment of risk factors and clinical manifestations will improve the diagnosis of invasive aspergillosis and lead to early initiation of therapy.

Diagnosis of locally invasive extrapulmonary aspergillosis causing mucocutaneous lesions, osteomyelitis, and septic arthritis is best accomplished with biopsy, direct microscopy, and culture. A diagnosis of *Aspergillus* keratitis is established by careful culture of corneal lesions by an ophthalmologist.

Allergic Forms of Aspergillosis

The diagnosis of ABPA is based on the presence of a combination of clinical, biologic, and radiologic criteria (Fig. 347-3). Consensus criteria for establishing a diagnosis of ABPA differ depending on the presence of cystic fibrosis. For patients with ABPA without cystic fibrosis (Chapter 89), the criteria for ABPA include asthma, an immediate cutaneous reaction to *A. fumigatus* antigen, a total serum IgE concentration greater than 1000 ng/mL, elevated *A. fumigatus*–specific serum IgE levels, precipitating serum antibodies to *A. fumigatus*, central bronchiectasis, peripheral blood eosinophilia, and characteristic pulmonary infiltrates. The latter two features (eosinophilia and pulmonary infiltrates) are considered nonessential because they may be present only during the acute phase of ABPA.

In patients with cystic fibrosis, distinguishing between ABPA and an episode of clinical deterioration with colonization by *Aspergillus* spp is challenging. The current criteria of the Cystic Fibrosis Foundation help define ABPA in this setting: clinical deterioration (coughing, wheezing, increased sputum production, exercise intolerance, and decrease in pulmonary function), immediate hypersensitivity to *A. fumigatus* (positive skin test or IgE response), total serum IgE concentration greater than 1000 kIU/L, precipitating antibodies to *A. fumigatus*, and abnormal findings on chest radiography (infiltrate, mucous plugs, or unexplained changes in comparison to previous chest radiograph).

A biphasic skin test response may assist in the diagnosis. A scratch test with *Aspergillus* antigens produces an immediate wheal and flare reaction that is mediated by IgE and blocked by antihistamines but not by corticosteroids. An intracutaneous test with the antigens produces a later (6 to 8 hours) reaction that is mediated by IgG and complement and blocked by corticosteroids.

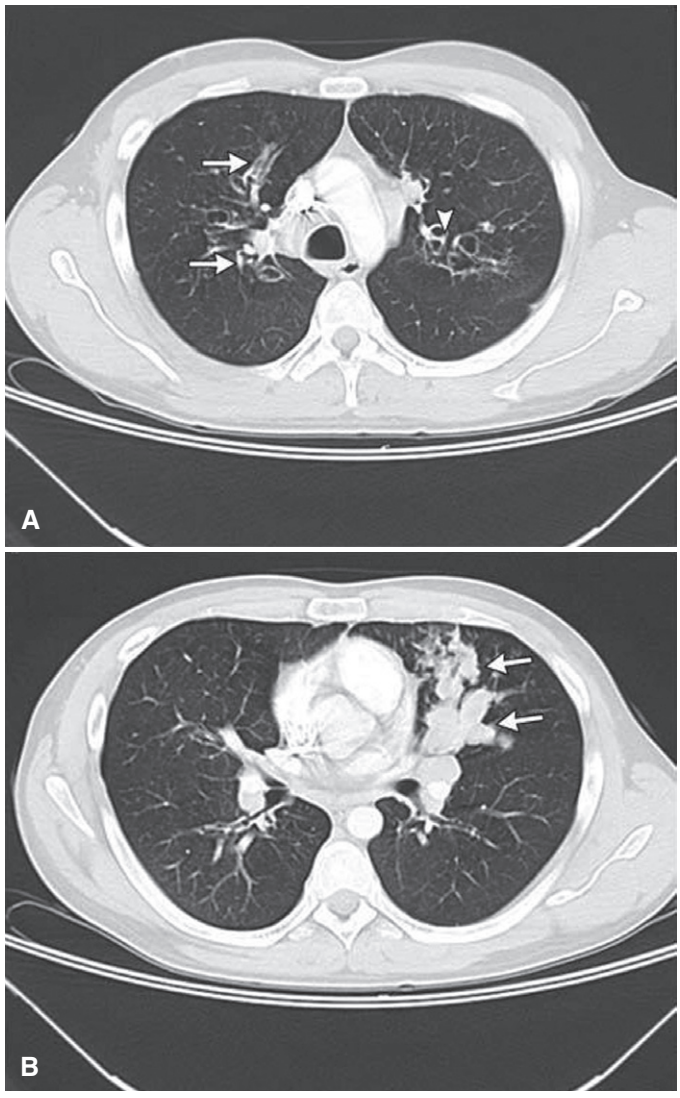

FIGURE 347-3. Allergic bronchopulmonary aspergillosis in a patient with a long history of asthma. Chest radiographs showed multilobar infiltrates. Computed tomography shows areas of tubular (**A,** *arrows*) and cystic (**A,** *arrowhead*) bronchiectasis, predominantly in the upper lobes, and bilateral mucous plugging (**B,** *arrows*) with mediastinal and hilar lymphadenopathy. (Reproduced with permission from Chen T, Hollingsworth H. Allergic bronchopulmonary aspergillosis [images in Clinical Medicine]. *N Engl J Med.* 2008;359:e7.)

An occupational history of exposure is critical for the diagnosis of *extrinsic allergic alveolitis*. A typical history of recurrent episodes developing within 24 hours after the inhalation of conidial antigens in an agricultural environment in conjunction with a negative scratch test, a positive intradermal test, and granulomas with immunoglobulins and complement in tissue is diagnostically consistent with *Aspergillus* extrinsic allergic alveolitis.

Recurrent sinusitis in a patient with asthma, nasal polyps, eosinophilia, sinus opacification, and a sinus aspirate yielding mucinous material containing eosinophils, Charcot-Leyden crystals, and hyphal elements establishes a diagnosis of AAS.

TREATMENT

Invasive Aspergillosis

The foundation of treatment of invasive aspergillosis consists of (1) antifungal medical therapy, (2) reversal of immunosuppression, and when appropriate, (3) surgical resection of infected lesions. Dosages of antifungals are listed in Table 347-2. Voriconazole is recommended in most patients for the primary treatment of invasive aspergillosis, including pulmonary, disseminated, and extrapulmonary isolated infection. This recommendation is based on a randomized controlled trial in which voriconazole was found to be superior to deoxycholate amphotericin B as primary treatment of invasive aspergillosis. However, not all patients are candidates to receive voriconazole, including those with substantially elevated hepatic transaminases, hepatic dysfunction, and a history of hypersensitivity to or intolerance of voriconazole. Such patients should receive liposomal amphotericin B (L-AmB) as primary therapy. This recommendation is based on a randomized trial in which comparable efficacy of approximately 70% was demonstrated with L-AmB dosages of 3 and 10 mg/kg/day in patients predominantly with hematologic malignancies. L-AmB is also indicated as primary therapy for patients in whom there is a suspicion or documentation of concurrent mucormycosis.

Second-line or salvage antifungal therapy is indicated for patients who are intolerant of primary therapy or whose infection is unresponsive to primary therapy. Among the antifungal agents used in this setting are a lipid formulation of amphotericin B, posaconazole, itraconazole, or an echinocandin (caspofungin is the only agent licensed for this indication). For patients who are already receiving voriconazole, a change in class to a lipid formulation, addition of an echinocandin, and use of another azole are possibilities. Such decisions are complicated and warrant infectious disease consultation with consideration of pharmacokinetic and host factors.

Reversal of immunosuppression is a critical factor in the successful management of invasive aspergillosis. Recovery from neutropenia and a decrease in the daily dosage or discontinuation of corticosteroids, when feasible, are two of the most important methods of improving host response. Depending on the protocol used, granulocyte transfusions may stabilize *Aspergillus* lesions until recovery from neutropenia. Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) may accelerate recovery from neutropenia. The role of GM-CSF, G-CSF, or interferon-γ in immunocompromised non-neutropenic patients with invasive aspergillosis remains to be defined further.

Surgical management of infected lesions is an important adjunctive component of primary therapy for several forms of invasive aspergillosis: endocarditis, pericarditis, osteomyelitis, epidural abscess, infected vascular catheters and prosthetic devices, and skin and soft tissue infection. Surgical management is also important for several conditions associated with IPA: recurrent hemoptysis from a single cavitary lesion, invasion of a pulmonary lesion into the chest wall, and pulmonary lesions contiguous with great vessels or the pericardium. *Aspergillus* empyema requires closed chest tube drainage and possibly débridement of the infected pleural cavity. Débridement of sinus aspergillosis, particularly when the ethmoid and frontal sinuses are infected, may prevent extension into the orbit or into the cavernous sinus. Surgical resection of selected lesions of the CNS may be indicated for establishing a diagnosis, reducing increased intracranial pressure, or protecting critical neural centers. Location of the CNS lesions and neurologic sequelae after resection are critical factors in the neurosurgical management of aspergillosis.

Local infusion of antifungal agents, particularly intravitreal therapy for endophthalmitis or nephrostomy irrigation for renal disease, provides high concentrations to compartments that may not be reached by systemic therapy. Topical irrigation with voriconazole, amphotericin B, or if available, pimaricin is an important adjunct to the management of *Aspergillus* keratitis.

TABLE 347-2 ANTIFUNGAL THERAPY FOR INVASIVE ASPERGILLOSIS*

FIRST-LINE TREATMENT IN ADULTS†	
Drug of choice:	
Voriconazole	IV therapy: 6 mg/kg q12h for 2 doses, then 4 mg/kg q12h Oral therapy: 200 mg or 4 mg/kg bid
Alternative (see text for conditions):	
Liposomal amphotericin B	3-5 mg/kg IV daily
SECOND-LINE OR SALVAGE TREATMENT IN ADULTS†	
Amphotericin B lipid complex	5 mg/kg IV daily, *or*
Caspofungin	70 mg IV daily for the first dose, then 50 mg IV daily, *or*
Posaconazole	200 mg PO qid or 400 mg PO bid, *or*
Itraconazole	400 mg PO (capsules) daily (in either 1 or 2 doses) or 2.5 mg/kg PO (solution) bid

*Refer to package insert for dose modification of antifungal agents in patients with liver disease or renal impairment.

†The duration of antifungal therapy depends on the therapeutic response of documented lesions, the burden of disease, and host immunocompetence. Guidelines from the Infectious Diseases Society of America recommend at least 6 to 12 weeks for invasive pulmonary aspergillosis. Patients who are immunosuppressed continue treatment throughout the period of immunosuppression and until resolution of the lesions. In patients with previously diagnosed invasive aspergillosis, antifungal therapy should be continued or reinitiated during subsequent periods of immunosuppression (e.g., chemotherapy, stem cell transplantation, graft-versus-host disease) to prevent recrudescence. (See Walsh TJ, Anaissie EJ, Denning DW, et al. Treatment of aspergillosis: clinical practice guidelines of the Infectious Diseases Society of America (IDSA). *Clin Infect Dis.* 2008;46:327-360.)

Chronic Aspergillosis

Medical therapy has shown limited benefit in treatment of aspergilloma; however, some patients may benefit from extended use of an antifungal triazole. Lifelong commitment to an antifungal triazole should be balanced against the natural history of approximately 10% of aspergillomas resolving spontaneously. By comparison, medical therapy with itraconazole or voriconazole is the standard of treatment of CCPA. Patients with CCPA typically achieve improvement in symptoms and stabilization or improvement in radiologic changes. Patients with CNPA also receive an antifungal triazole; however, assessment of response is more difficult as a result of the underlying chronic lung disease. The role of surgical resection in patients with a solitary aspergilloma or CCPA is limited because of the development of a bronchopleural fistula, *Aspergillus* infection of the pleural space, and potentially further worsening of already compromised pulmonary function. However, surgical resection may have a more important role in treating patients with recurrent and severe hemoptysis, in whom the benefits of removing the cavity usually outweigh the known risks. Bronchial artery embolization and transthoracic direct intracavitary instillation of antifungal agents for aspergilloma have only transient benefits but substantial risk.

Topical irrigating solutions of boric or acetic acid or an antifungal azole cream may be effective in treating *Aspergillus* otomycosis. Voriconazole, posaconazole, or itraconazole may be necessary for refractory cases or perforated tympanic membranes.

Allergic Forms of Aspergillosis

APBA is treated with a combination of corticosteroids and itraconazole. Corticosteroid therapy is the mainstay of treatment of ABPA. However, chronic administration of corticosteroids causes severe immunosuppression and multisystem metabolic abnormalities. Addition of itraconazole reduces organism burden, attenuates the antigenic stimulus for destructive bronchial inflammation, and provides a corticosteroid-sparing effect. Intermittent use of corticosteroids or substantially raising the dose in patients receiving chronic therapy can produce rapid resolution of marked symptomatic episodes or deteriorating forced expiratory volume in 1 second (FEV_1).

Extrinsic allergic alveolitis is best managed by removing patients from the allergenic environment. An accurate occupational history is critical for this intervention.

AAS is treated by endoscopic drainage to relieve obstruction by tenacious mucin. Itraconazole, nasal corticosteroids, and systemic corticosteroids, alone or in combination, may be beneficial in some patients with AAS. Caution is warranted with the chronic use of systemic or nasal corticosteroids. Itraconazole may have a corticosteroid-sparing effect.

Combination Antifungal Therapy

Combinations of polyenes, triazoles, and echinocandins are being explored. Therapy should be continued after the lesions are resolving, cultures are negative, and reversible underlying predispositions have abated. Reinstating therapy in patients who have previously responded should be considered if immunosuppression is reinstituted or neutropenia recurs.

PREVENTION

Several strategies may be used for the prevention of invasive aspergillosis in immunocompromised patients: primary prophylaxis, empirical therapy, and secondary prophylaxis. Posaconazole is used for the prophylaxis of invasive aspergillosis in patients with hematologic malignancies and in HSCT recipients. Voriconazole and intraconazole are also used for this indication, but with less evidence. Empirical antifungal therapy provides early treatment of persistently febrile immunocompromised patients and systemic prophylaxis for high-risk hosts with or without pulmonary infiltrates. L-AmB, caspofungin, and voriconazole have been used for this strategy. Secondary prophylaxis of invasive aspergillosis with voriconazole is used in patients with a history of previous aspergillosis who are scheduled for a subsequent cycle of immunosuppression that may increase the risk for recurrence.

Reduction of exposure to airborne conidia, such as by high-efficiency particular air (HEPA) filtration of hospital air, avoiding activities that increase conidial aerosols (room maintenance, dust exposure, and contaminated material, e.g., potted plants), and providing clean water distribution systems, may reduce the acquisition of *Aspergillus* by immunosuppressed or neutropenic patients.

For patients with allergic forms of aspergillosis, the use of corticosteroids and itraconazole, alone or in combination, may prevent debilitating exacerbations. The toxicity associated with chronic administration of prednisone warrants strategies for intermittent administration of prednisone or corticosteroid-sparing use of itraconazole.

PROGNOSIS

Untreated invasive aspergillosis is associated with severe morbidity and high mortality in immunocompromised patients. The prognosis is improved by early initiation of antifungal therapy, reversal of immunosuppression, and successful treatment of the underlying primary disease. For patients with chronic aspergillosis, multidisciplinary specialized supportive care may improve outcome and quality of life.

348 MUCORMYCOSIS

DIMITRIOS P. KONTOYIANNIS

DEFINITION

Mucormycosis describes infections caused by fungi belonging to the order Mucorales. Zygomycosis, an alternative term used to describe these life-threatening infections, has become less accurate because of a recent taxonomic reclassification (using molecular methods) that abolished Zygomycetes as a class (and placed the order Mucorales in the subphylum Mucormycotina). Mucorales organisms typically cause aggressive, acute-onset, frequently fatal angioinvasive infections, especially in immunosuppressed hosts.

EPIDEMIOLOGY AND RISK FACTORS

Mucorales fungi are distributed worldwide and found in decaying organic substrates. The true incidence of mucormycosis is not known and probably underestimated because of difficulties in antemortem diagnosis. In a recent review of more than 900 reported cases, the most common microbiologically confirmed infecting members of the order Mucorales were *Rhizopus* (47%), *Mucor* (18%), *Cunninghamella bertholletiae* (7%), *Apophysomyces elegans* (5%), *Absidia* (5%), *Saksenaea* (5%), and *Rhizomucor pusillus* (4%). Some Mucorales fungi causing infection have unique geographic distributions. The thermophilic fungi *Saksenaea vasiformis* and *A. elegans* are typically isolated in regions with warmer climates; clinical infection with these organisms has shown similar geographic distributions. Additionally, infections may vary seasonally, with the majority of infections occurring in late August to November. Moreover, major natural disasters have been associated with infections by infrequently isolated species, such as *Syncephalastrum racemosum* in areas affected by hurricane Katrina and wound infections caused by *A. elegans* in victims of the 2004 Indian Ocean tsunami.

The classic risk factors for mucormycosis include hematologic malignancy, hematopoietic stem cell or solid organ transplantation, poorly controlled diabetes mellitus, chronic acidemia, prematurity, iron overload, profound chronic debilitation, trauma, burns, and intravenous drug use. Nosocomial cutaneous infections can develop in surgical wound and at intravenous catheter insertion sites. Finally, breakthrough mucormycosis has increasingly been observed in patients with leukemia and recipients of hematopoietic

stem cell transplants administered *Aspergillus*-active drugs such as voriconazole (which has no anti-Mucorales activity). This association has been a topic of debate.

PATHOBIOLOGY

Mucorales species are saprophytic, rapidly growing fungi. Angioinvasive growth results in infarction and necrosis of surrounding tissue and is the hallmark of mucormycosis. The major modes of transmission are inhalation, ingestion, and cutaneous inoculation, with inhalation of spores from environmental sources being the most common. Cutaneous or percutaneous transmission occurs with traumatic disruption of skin barriers, and it is the most important mode of transmission in immunocompetent hosts. Gastrointestinal acquisition, which is less common, has occurred in patients repeatedly ingesting non-nutritional substances (pica) containing spores during severe malnutrition and in individuals ingesting contaminated herbal/homeopathic products.

Host immunity in healthy individuals prevents the germination of fungal spores unless the inoculum is heavy. To establish invasive infection, the spores must overcome both innate and adaptive immune responses to germinate into hyphae. Defects in phagocytic activity caused by insufficient numbers (i.e., neutropenia) and functional defects caused by glucocorticoids, hyperglycemia, or acidosis allow unimpeded proliferation of fungi because of the absence of coordinated, effective host responses. Mucormycosis is often disseminated in severely immunosuppressed patients, with high mortality rates. However, lymphopenia may not be as critical in patients as evidenced by the rarity of mucormycosis in patients with acquired immunodeficiency syndrome.

Free iron is an essential component of the pathogenesis of mucormycosis as suggested by the unique predisposition of patients with iron overload (Chapter 219) to such infections. These patients often receive the iron chelator deferoxamine. Both iron overload and use of deferoxamine (which is also used to treat aluminum overload in dialysis recipients) are risk factors for angioinvasive mucormycosis. *Rhizopus oryzae* can use deferoxamine as a xenosiderophore to form a ferrioxamine complex and thereby obtain more iron for its use. The newer iron chelator agents (e.g., deferasirox) are not associated with increased risk for mucormycosis; on the contrary, in preclinical models, deferasirox has exhibited direct fungicidal effects against Mucorales via iron starvation.

Historically, poorly controlled diabetes mellitus (types 1 and 2) has been a major predisposing factor (Chapters 236 and 237) that has been reported in 36 to 88% of all cases of mucormycosis. In particular, diabetic patients with ketoacidosis are susceptible to mucormycosis. Normal human serum cannot support the growth of *R. oryzae*, whereas serum from diabetic patients can. Acidosis disrupts the inhibitory activity of serum by attenuating the ability of transferrin to bind iron from the fungus. In addition, phagocytic cell dysfunction occurs in diabetic patients with ketoacidosis and may play a role in pathogenesis.

CLINICAL MANIFESTATIONS

The clinical manifestations of mucormycosis depend on the host's underlying immune and medical condition. Hence, pulmonary mucormycosis is most common in neutropenic or corticosteroid-treated patients (e.g., hematopoietic stem cell and solid organ transplant recipients). In contrast, rhino-orbital or rhinocerebral mucormycosis is the characteristic finding in patients with diabetic ketoacidosis. Finally, cutaneous mucormycosis in both immunocompetent and immunocompromised hosts is typically seen following the breakdown of skin integrity or after subcutaneous tissue injuries. Infectious syndromes associated with Mucorales are grouped according to clinical manifestation into one of six categories: (1) rhinocerebral, (2) pulmonary, (3) cutaneous, (4) gastrointestinal, (5) disseminated, and (6) unusual manifestations.

Rhinocerebral Mucormycosis

Rhinocerebral mucormycosis describes an infection originating in the paranasal sinuses after the inhalation of Mucorales spores and extending to the orbit (sino-orbital) or brain (rhinocerebral), particularly in patients with diabetic ketoacidosis or those with profound neutropenia. Early signs and symptoms of sinus invasion by rhinocerebral mucormycosis may be indistinguishable from common causes of sinusitis. Common symptoms include sinus pain, congestion, headache, mouth pain, otologic symptoms, and hypo-osmia/anosmia. Involved tissues become red, then violaceous, and finally black with thrombosis and tissue necrosis. Necrotic eschars of the nasal cavity and turbinates, facial lesions, and exophytic or necrotic lesions of the hard palate are signs of extensive, rapidly progressing infection. A painful black eschar on the palate or nasal mucosa is a "classic," yet late sign. Absence of this finding does not rule out rhinocerebral infection because necrotic nasal or palatal lesions occur in only 50% of patients within 3 days of the onset of infection. Extension into the periorbital region is not uncommon at initial evaluation. Signs and symptoms of periorbital and orbital involvement include periorbital swelling, preseptal or orbital cellulitis (or both), proptosis, chemosis, blurred vision or rapidly progressing external ophthalmoplegia, diplopia, eyelid gangrene, retinal detachment, and endophthalmitis. In addition, patients with extensive rhino-orbital or rhinocerebral disease may have trigeminal or other cranial nerve palsy, which is consistent with the frequent histologic findings of perineural invasion. Infection can progress rapidly through the cavernous sinuses into the central nervous system and result in cavernous sinus and internal carotid artery thrombosis. A bloody nasal discharge may be the only sign that the infection has invaded through the nasal turbinates into the brain. Patients with advanced infection may have multiple cranial neuropathies, altered consciousness, or both; bone destruction; retinal artery, internal carotid artery, cavernous, and less often, sagittal sinus thrombosis; frontal lobe necrosis; epidural and subdural abscesses; and basilar artery aneurysm.

Plain films and cerebrospinal fluid findings lack sensitivity in diagnosing rhinocerebral mucormycosis. Computed tomography (CT) and magnetic resonance imaging (MRI) are more useful for revealing soft tissue involvement around the nerve sheaths and bone destruction. CT frequently shows mucosal thickening, air-fluid levels, and bone erosion. Orbital thickening may be detected earlier with MRI than with CT. Findings in the orbits on CT and MRI may be unremarkable during the initial stages of mucormycosis, thus highlighting the importance of serial imaging in monitoring disease progression. Extraorbital muscle thickening is often the first sign of orbital involvement and should prompt empirical antifungal therapy followed by surgical exploration or biopsy.

Accurate diagnosis and prompt medical and surgical intervention are critical because of rapid progression of the infection. Definitive diagnosis of necrotic lesions by biopsy and rapid histologic assessment of frozen sections should be performed as soon as possible because it has a direct impact on outcome. In a review of 929 patients with documented mucormycosis, the mortality rate was 62% in those with rhinocerebral mucormycosis, 24% in those with sino-orbital involvement, and 16% in those with isolated sinus disease. Isolated sinusitis is curable with timely surgical intervention and systemic antifungal therapy.

Pulmonary Mucormycosis

The clinical manifestations of pulmonary mucormycosis are indistinguishable from those of invasive pulmonary aspergillosis (Chapter 347). Patients may have fever refractory to broad-spectrum antibiotics, nonproductive cough, and progressive dyspnea. Less commonly, pleuritic chest pain, hemoptysis, and pleural effusion are seen. If the major pulmonary blood vessels are invaded by hyphae, massive, potentially fatal hemoptysis can occur. Pulmonary mucormycosis can progress and invade adjacent organs by traversing tissue planes, including the diaphragm, chest wall, and pleura (Fig. 348-1). Clues for distinguishing pulmonary mucormycosis from invasive pulmonary aspergillosis include the presence of pansinusitis, a history of prophylaxis with antifungals against *Aspergillus* but not Mucorales (e.g., voriconazole, echinocandins), and possibly, continual absence of detectable *Aspergillus* galactomannan antigen in serum. In rare circumstances, pulmonary mucormycosis can be manifested as an endobronchial or tracheal lesion with a less fulminant course, especially in diabetics. Endobronchial mucormycosis may cause airway obstruction or erosion of major pulmonary blood vessels and fatal hemoptysis. In more immunocompetent hosts, pulmonary mucormycosis may be characterized by more atypical, slowly progressing forms. Like *Aspergillus* species, Mucorales fungi can form mycetomas in preexisting lung cavities and cause slowly necrotizing pneumonia and hypersensitivity syndromes. *Rhizopus* species have also been implicated in allergic alveolitis in farm workers or sawmill workers (wood trimmer's disease).

Because the first-line antifungal typically used for aspergillosis is voriconazole, which lacks activity against Mucorales, timely diagnosis of pulmonary mucormycosis is critical; delay in appropriate antifungal therapy (e.g., amphotericin B) rapidly worsens outcome.

Skin and Soft Tissue Mucormycosis

Cutaneous mucormycosis typically starts as erythema and skin induration at a puncture site and progresses to necrosis with a black eschar. Cutaneous

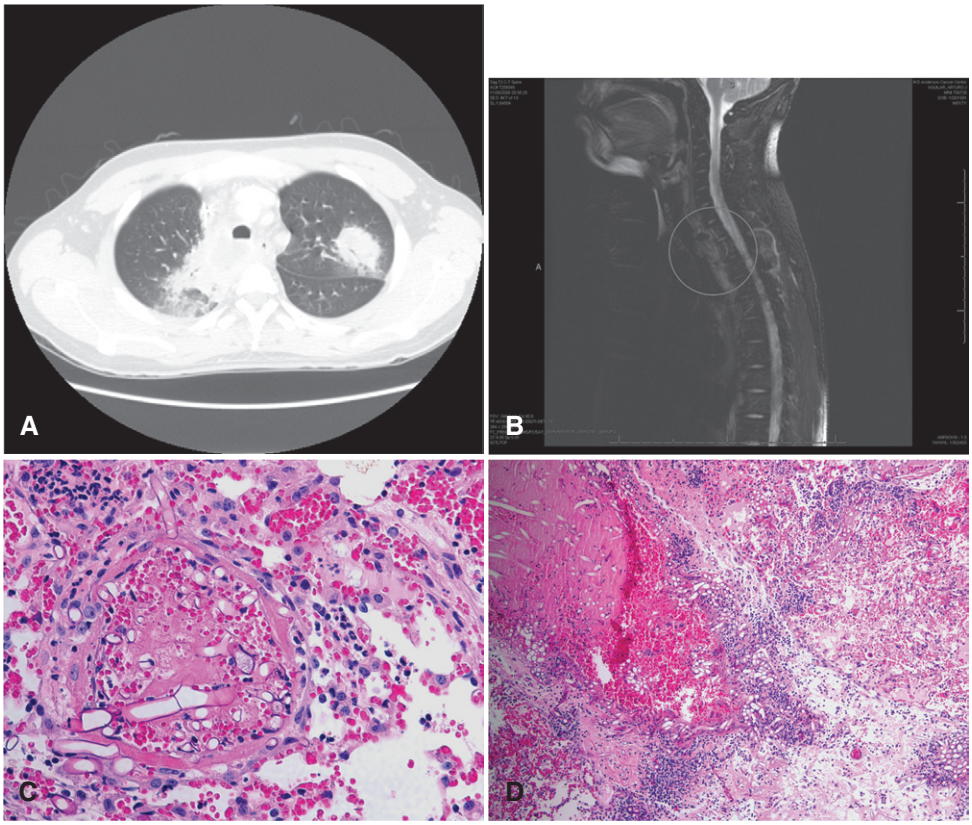

FIGURE 348-1. Extensive, progressive pulmonary mucormycosis in a young patient with acute myelogenous leukemia and prolonged severe neutropenia. Pneumonia is multifocal with areas of cavitation. Characteristic extension of the infection across tissue planes to the trachea (producing a fistula) and mediastinum (**A**) and adjacent thoracic spine (**B**) are shown by CT and MRI, respectively. The histopathologic characteristics of profound necrosis and hemorrhage (**C**) and pauciseptate, broad-based, ribbon-like Mucorales (**D**) are also shown.

infections can quickly extend into the deep fascia and muscle layers. Necrotizing fasciitis is rare and has a poor prognosis. Neutropenic patients in particular are susceptible to lymphatic and blood vessel invasion, infarction, and necrosis with eventual dissemination. Skin lesions in patients with suspected mucormycosis should raise concern about disseminated disease. Because the differential diagnosis of necrotic skin lesions is broad, especially in neutropenic patients, biopsy specimens should be obtained from the center of a lesion down to subcutaneous fat. Excision and wide débridement of cutaneous lesions coupled with systemic antifungal therapy and, on occasion, hyperbaric oxygen therapy can further reduce mortality rates.

Gastrointestinal Mucormycosis

Primary gastrointestinal mucormycosis is rare and can be manifested as necrotizing enterocolitis and involve any part of the alimentary system with mortality rates higher than 85%. It occurs primarily in malnourished patients and premature infants, in whom the stomach is the most commonly affected site, followed by the colon and ileum. The liver, spleen, and pancreas can also be involved. Physicians have described liver abscesses following the ingestion of herbal products contaminated by *Mucor indicus*. Fungi can invade the bowel wall and blood vessels and result in bowel perforation, peritonitis, and massive gastrointestinal hemorrhage. In neutropenic patients, seeding of the gastrointestinal tract is probably more common than previously thought inasmuch as 75% of cases of gastrointestinal mucormycosis are diagnosed postmortem. Symptoms and signs of gastrointestinal mucormycosis include fever, abdominal distention, nausea, vomiting, abdominal pain, diarrhea, melena, hematemesis, hematochezia, and masslike appendiceal and ileal lesions.

Disseminated Mucormycosis

Disseminated mucormycosis is rarely apparent antemortem. Severely immunosuppressed patients and those receiving deferoxamine are at highest risk. Symptoms vary depending on the site of dissemination and the degree of vascular infarction of the affected organs. The most common organ source of dissemination is the lung, and the most common site of spread is the brain. Diagnosis of disseminated mucormycosis is challenging and requires a high level of suspicion because the infection may be manifested as an unexpected acute vascular event. Biopsy of suspected sites is critical because of the low yield of blood cultures and suboptimal recovery of the fungus from respiratory specimens. Without appropriate timely treatment, virtually all patients with disseminated mucormycosis die.

Rare Clinical Manifestations of Mucormycosis

Mucormycosis has protean manifestations that can involve any organ. Authors have reported isolated cases of tracheal, mediastinal, bone, heart, kidney, external auditory canal, and corneal involvement. Renal mucormycosis can occur in patients with intravenous drug abuse or those receiving corticosteroids. Cerebral mucormycosis, often manifested as brain abscess involving the basal ganglia and occurring in conjunction with infective endocarditis, has typically been observed in patients using illicit intravenous drugs. In all cases of device-related mucormycosis, prompt removal of the device and several weeks of systemic antifungal therapy are essential for resolution of the infection.

DIAGNOSIS

The clinical signs and symptoms of mucormycosis are nonspecific. Therefore, a high level of suspicion in susceptible patient populations is of paramount importance. Biopsy analysis and culture from sterile sites remain critical. Tissue swabs and cultures of sputum, sinus secretions, and bronchoalveolar lavage fluid are not usually diagnostic. Fungal contamination of clinical specimens and therefore growth in culture may not represent clinically significant invasive disease. However, the value of Mucorales-positive cultures (especially repetitive cultures) as an important indication of infection in immunocompromised patients is quite high. The site of infection has a major impact on the yield of histopathologic diagnosis (e.g., the ease of accessibility of sinuses).

Histopathology

Histopathologic examination of infected tissue typically shows characteristic broad (3 to 25 μm in diameter), thin-walled, primarily aseptate hyphae, focal bulbous dilation, and nondichotomous irregular branching at occasional right angles accompanying tissue necrosis and fungal angioinvasion (see Fig. 348-1). Perineural invasion is found in 90% of tissues containing nerves.

Culture

Blood cultures are rarely positive for these pathogens despite their angioinvasive nature, even when fungal hyphae are seen on histopathologic analysis. Recovery of Mucorales from tissue can be improved by mincing (not homogenizing) tissue specimens and using culture techniques that simulate in vivo fungal growth. Data on the antifungal susceptibility of Mucorales spp are limited, and minimal inhibitory concentration (MIC) testing is rarely available outside research laboratories. The correlation between clinical responses and MIC values is uncertain. Mucorales organisms are resistant to many antifungals, including flucytosine, ketoconazole, fluconazole, voriconazole, and the echinocandins, whereas they have variable susceptibility to itraconazole.

The importance of early differentiation of Mucorales from more common opportunistic molds such as *Aspergillus* spp has generated considerable interest in the development of culture- or histopathology-independent diagnostic tests such as detection of specific antigens or nucleic acids with polymerase chain reaction or in situ hybridization techniques. Molecular techniques for detecting Mucorales are few, not widely available, and investigational. This is an important unmet need for the management of mucormycosis.

TREATMENT

Rx

Successful treatment of mucormycosis relies on a multifaceted approach that includes (1) aggressive attempts at diagnosis and rapid initiation of effective antifungal therapy, (2) extensive surgical débridement, and (3) rapid control of any underlying medical conditions.

Early diagnosis is critical to patients' outcome. Small focal lesions should be surgically resected before they progress to involve critical structures or distal organs. Patients often have indolent clinical findings until extensive invasion or dissemination of the infection takes place.

Antifungal Therapy

Delayed administration of systemic antifungal therapy increases the risk for death. No prospective controlled studies on the treatment of primary mucormycosis have been performed. Most of the knowledge about the activity of currently used antifungals comes from small case series, anecdotal reports, and animal models of infection. Therefore, the optimal treatment approach is uncertain. Most of the clinical experience has been with amphotericin B (AMB). Previously, the recommended antifungal therapy for mucormycosis included AMB deoxycholate at the maximum tolerated dosage, usually 1.0 to 1.5 mg/kg/day. Unfortunately, regular AMB had nephrotoxic and systemic toxic effects, which led to the development of lipid formulations of AMB (liposomal AMB, AMB lipid complex, AMB colloidal dispersion). These agents are less nephrotoxic than regular AMB and can be given at high doses (5 to 10 mg/kg/day). Lipid formulations of AMB are considered the drugs of choice for mucormycosis. Furthermore, use of percutaneous or aerosolized AMB in conjunction with concomitant systemic therapy has been successful in selected patients with pulmonary cavitary mucormycosis. Topical therapy with AMB, as well as other polyenes (natamycin), may be effective against primary cutaneous and ocular mucormycosis. Treatment of mucormycosis with AMB-based combinations has been successful in small retrospective case series. In particular, a benefit was suggested for an echinocandin–liposomal AMB combination in 41 diabetic patients with rhino-orbital mucormycosis over the use of amphotericin B lipid complex or liposomal AMB alone. This benefit was most pronounced in patients with cerebral involvement.

Although azoles have traditionally been inactive against Mucorales, the new broad-spectrum triazole posaconazole has demonstrated promising activity. In an open-label study evaluating posaconazole as salvage therapy (800 mg/day) in 24 patients with refractory mucormycosis, the agent's overall success rate was 70%. Furthermore, posaconazole was well tolerated. Similarly, a retrospective survey of posaconazole-based salvage therapy in 91 patients with refractory mucormycosis indicated an overall success rate of 61%. Determining whether posaconazole alone or combined with a lipid formulation of AMB or another agent (e.g., deferasirox) is of value requires further study. Posaconazole has limitations: absorption of the oral suspension is suboptimal in patients with mucositis, severe diarrhea, acid suppression therapy, or poor oral intake. In addition, steady-state plasma concentrations of posaconazole are not reached until around 1 week of therapy.

The duration of antifungal therapy should be determined on an individual basis. Near normalization of radiographic imaging, negative follow-up biopsy specimens and cultures from the affected site, and recovery from immunosuppression are important indicators for stopping antifungal therapy.

Surgery

Surgical débridement of cutaneous lesions is crucial and must be done without delay because of the aggressive nature of mucormycosis. A coordinated effort among all subspecialties involved (surgery, infectious diseases, head and neck, ophthalmology, pathology, clinical microbiology, and plastic surgery) is crucial, and the internist can play a vital role in coordinating this effort.

Repeated removal of necrotic tissue or aggressive surgical measures such as enucleation of the eye may be required for control of the infection. Decisions regarding the extent of débridement are often made at the bedside. CT or MRI before surgery and intraoperative frozen section analysis help determine the extent of tissue and tissue margin involvement. Low platelet counts must be corrected with transfusions before surgical intervention. Unfortunately, bleeding problems can limit surgical options. Surgery in conjunction with systemic antifungal therapy has resulted in significantly improved survival rates.

Management of Comorbid Conditions and Adjunctive Treatments

Rapid correction of underlying conditions, such as control of hyperglycemia, reversal of ketoacidosis, rapid tapering of glucocorticoid therapy, and discontinuation of deferoxamine-based treatment, influences outcomes. Hyperbaric oxygen therapy is a beneficial adjunctive therapy for mucormycosis, particularly in diabetic patients with rhinocerebral disease. Specifically, the increased oxygen pressure achieved seems to improve neutrophil activity and oxidative killing of polyene antifungals. Furthermore, high concentrations of oxygen can inhibit the growth of Zygomycetes in vitro and improve the rate of wound healing by increasing the release of tissue growth factors. However, this treatment has not been studied vigorously to determine its general efficacy and cannot be routinely recommended. In neutropenic patients, granulocyte-macrophage colony-stimulating factor or granulocyte transfusions may be beneficial until granulocyte recovery occurs, but this approach has yet to be studied sufficiently in patients with mucormycosis. Finally, the new iron chelator deferasirox could act as an adjunctive antifungal agent based on preclinical studies and very limited human experience in patients with refractory mucormycosis.

349 *PNEUMOCYSTIS* PNEUMONIA

JOSEPH A. KOVACS

DEFINITION

Pneumocystis jirovecii is a fungus that causes pneumonia almost exclusively in immunodeficient patients. *Pneumocystis* was first described by Chagas in 1909, when he mistakenly identified it as part of the life cycle of *Trypanosoma cruzi*. The Delanoes recognized it as a unique organism in 1912 and named it *Pneumocystis carinii,* in honor or Antonio Carini, another early investigator. *Pneumocystis* was first associated with human disease in 1942; in the 1950s, it was recognized as the cause of an epidemic interstitial plasma cell pneumonia that occurred primarily in premature and malnourished infants. During the 1960s and 1970s, *Pneumocystis* pneumonia (PCP) was seen with increasing frequency in immunodeficient patients, especially those receiving immunosuppressive chemotherapy. In the early 1980s, an epidemic of PCP in previously healthy adults heralded the onset of the HIV/AIDS epidemic; in the United States and in many other parts of the world, PCP has been the most common life-threatening opportunistic infection in this population. Although the frequency of PCP decreased in HIV-infected patients first in association with the widespread use of anti-*Pneumocystis* prophylaxis and later with the introduction of effective combination antiretroviral therapy, it continues to be seen with regularity in HIV-infected and other immunodeficient patients.

The Pathogen

Pneumocystis, which was long thought to be a protozoan, has now been definitively classified as an ascomycete fungus, based primarily on molecular studies demonstrating that a large number of genes have a high level of homology to other fungi rather than to protozoa. Molecular as well as antigenic studies have further demonstrated that the genus *Pneumocystis* includes a group of closely related organisms that appear to be unique species, each of which can infect only a single host species. This has led to the application of new species names to the group of organisms previously called *Pneumocystis carinii*, although this approach has not been universally accepted among investigators in the field. *P. carinii* is reserved for a species that infects rats (there is also a second species, *P. wakefieldiae*, that can infect rats). The organism infecting humans has been renamed *P. jirovecii,* in honor of Otto Jirovec, one of the investigators who recognized that this organism is the causative agent of interstitial plasma cell pneumonia. Despite the name change, the acronym PCP continues to be used to designate the disease in humans.

Pneumocystis species show a strict host specificity: attempts to transmit, for example, rat or human *Pneumocystis* to mice have been unsuccessful. Molecular evolutionary studies suggest that *Pneumocystis* species co-evolved with their hosts, with rat and mouse *Pneumocystis* diverging an estimated 33 million years ago, similar to the time rat and mouse species diverged.

Studies of *Pneumocystis* have been substantially hampered by an inability to grow any species in culture for a sustained period. Thus, the life cycle of *Pneumocystis* is unknown, although putative life cycles based on morphologic studies have been proposed; there is accumulating evidence supporting a sexual phase in the life cycle. There are two easily recognized forms of the organism: trophic forms (≈2 to 6 μm in diameter) and cysts (≈6 to 8 μm in diameter), which can contain up to eight intracystic bodies; additional intermediate forms are also seen. Trophic forms, which have an amorphous shape, are estimated to outnumber cysts, which are spherical, by approximately 10:1 in an infected lung. β-1,3-Glucan is found in the cyst form only, where it contributes to the rigidity of the cell wall. The estimated genome size is 8 million base pairs. The most abundant surface protein of *Pneumocystis*, the major surface glycoprotein, is found on both cysts and trophic forms and is encoded by a multicopy gene family, only one of which is expressed in a given organism; this provides *Pneumocystis* with the potential for antigenic variability. Although, to date, only a single *Pneumocystis* species has been found that infects humans, recently developed molecular typing techniques have demonstrated a high level of diversity among human *Pneumocystis* isolates.

EPIDEMIOLOGY

Pneumocystis has a worldwide distribution. Serologic studies show a high prevalence of anti-*Pneumocystis* antibodies in all populations studied to date. In America and Europe, serologic studies have demonstrated that most humans develop antibodies to *Pneumocystis* by an early age, suggesting that this is a ubiquitous organism. In support of this, an autopsy study in infants younger than 1 year with no major underlying medical problems identified *Pneumocystis* infection in lung tissue by polymerase chain reaction (PCR) in 100% of cases.

Animal studies have demonstrated that *Pneumocystis* is transmitted by the respiratory route. Human infection is presumably transmitted in the same manner. There is no evidence that water or fomites play a role in transmission. A small number of animal studies and very limited human data suggest that transmission can occur transplacentally, although the clinical relevance is unknown.

Given the strict host specificity of *Pneumocystis*, the source of organisms infecting humans is presumably other humans, by either direct or indirect exposure. There is no evidence that *Pneumocystis* is a zoonosis. PCR-based studies have identified *Pneumocystis* DNA in environmental sources such as apple orchards; however, there are currently no data indicating that such sources play an important role in transmission. Because clinically apparent PCP is rare, and given the high penetration of infection into healthy human populations at a young age, *Pneumocystis* infection is likely acquired from apparently healthy humans, in whom subclinical infection (either asymptomatic or minimally symptomatic) must be quite common to allow such rapid and broad dissemination. The high frequency of detection in infants suggests an important role in transmission.

Although infection with *Pneumocystis* is widespread, in immunocompetent hosts, it does not appear to cause significant disease. Clinically significant PCP occurs exclusively in patients with severe levels of immunodeficiency that are usually associated with a high risk for other opportunistic pathogens. Populations at risk include those with congenital immunodeficiencies (Chapter 258), especially severe combined immunodeficiency (SCID) and hyper-IgM syndrome; patients with HIV infection (Chapter 392) and human T-lymphotropic virus-1–associated lymphoma (Chapter 386); patients receiving chemotherapy for the treatment of malignancies, especially lymphoma; transplant patients receiving immunosuppressive therapy; and patients being treated with prolonged courses of immunosuppressive drugs (Chapter 34), especially corticosteroids, for inflammatory diseases such as Wegener's granulomatosis or systemic lupus erythematosus. Among patients with HIV infection, the best predictor of the risk of developing PCP is the CD4 count: patients with CD4 counts less than 200 cells/mm^3, and especially those with CD4 counts less than 100 cells/mm^3, are at greatest risk. Patients with a prior history of PCP and those with unexplained fever, weight loss, or thrush are also at increased risk. Among other patient populations, laboratory parameters are not as useful in quantifying risk, although non-HIV patients with CD4 counts less than 200 cells/mm^3 may be at increased risk. Additional information on risk is provided in the section on prophylaxis.

For many years, development of PCP was thought to result from a reactivation of latent infection by organisms that remained viable following infection at an early age, similar to tuberculosis. However, recent molecular epidemiologic studies based on the detection of mutations in the dihydropteroate synthase (DHPS) gene of *Pneumocystis*, as well as single-nucleotide polymorphism and restriction fragment length polymorphism analysis of isolates from outbreaks of PCP in renal transplant patients, have provided convincing evidence that the infecting strain is often recently acquired. Molecular studies have further documented that in the majority of patients with PCP, more than one strain can be identified in respiratory samples. In patients who develop recurrent PCP, this recurrence can be due to relapse, especially for early recurrences, or to reinfection with a novel strain. Recurrent PCP occurs almost exclusively in HIV-infected patients, in whom the risk was greater than 50% early in the AIDS epidemic, before the availability of highly active antiretroviral therapy (HAART) and the broad use of anti-*Pneumocystis* prophylaxis.

PATHOBIOLOGY

Animal studies have provided important insights into the pathogenesis of *Pneumocystis* infection. Exposure for as little as 1 day to a *Pneumocystis*-infected animal results in transmission of infection. In healthy animals, an adaptive immune response develops by approximately 5 to 6 weeks, which leads to control and clearance before the organism burden produces

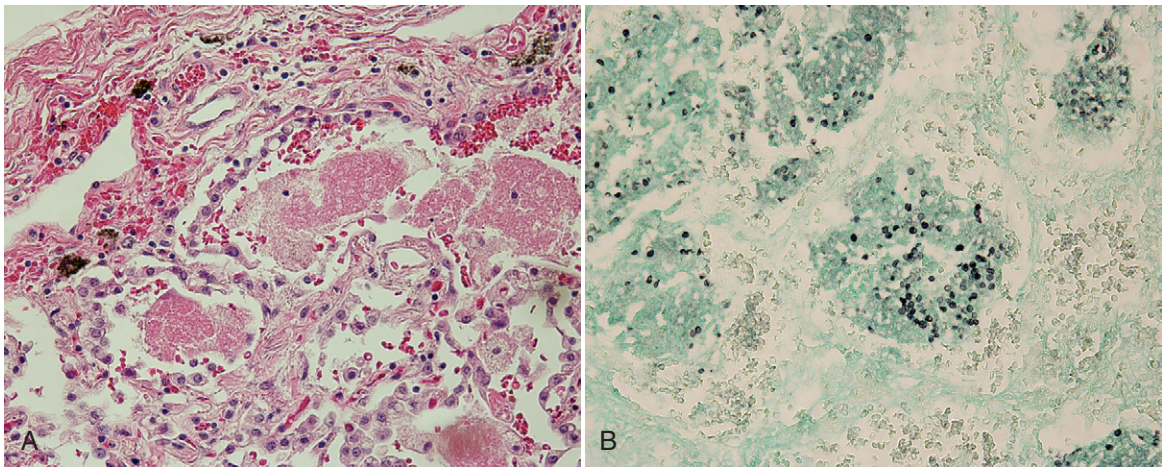

FIGURE 349-1. Histopathology of the lung of a patient who died from *Pneumocystis* pneumonia (PCP). A, The hematoxylin-eosin–stained section shows the characteristic acellular, eosinophilic, intra-alveolar exudate that is typical of PCP. **B,** Methenamine silver staining of lung tissue from the same patient demonstrates black-staining cysts scattered throughout the intra-alveolar exudates.

symptoms. CD4 cells are critical to this control, although other populations, including B cells and macrophages, also play important roles. In immunodeficient animal models, inability to control *Pneumocystis* replication leads to severe pneumonia by 2 to 3 months. Limited human data suggest a similar time course. Host inflammatory responses appear to play a critical role in the development of pulmonary symptoms. This may account for the development of symptoms of PCP in patients in whom corticosteroids are being tapered, as well as the exacerbation of hypoxia that develops approximately 4 days after the initiation of anti-*Pneumocystis* therapy (in the absence of concomitant corticosteroid therapy).

The lung pathology in patients with PCP is characteristic. Staining with hematoxylin-eosin demonstrates an acellular, foamy, eosinophilic, intra-alveolar exudate associated with mild interstitial inflammation (Fig. 349-1). With disease progression, hyaline membrane formation and interstitial as well as intraluminal fibrosis develop. Although methenamine silver stain highlights cysts scattered throughout the eosinophilic exudate, based on Giemsa staining of thin sections as well as electron micrographs, this exudate is composed almost entirely of *Pneumocystis* organisms. Atypical pathology, including noncaseating granulomas and intrapulmonary cystic changes, can also be seen.

CLINICAL MANIFESTATIONS

In non-immunosuppressed humans, no well-defined clinical syndrome is associated with *Pneumocystis* infection. *Pneumocystis* has been identified in infants by PCR and may be associated with a mild respiratory syndrome, but a postulated association with sudden infant death syndrome has not been supported by data from well-controlled studies. *Pneumocystis* has been detected by PCR in pulmonary samples from patients with chronic obstructive pulmonary disease (COPD), but what role, if any, it plays in the development or progression of COPD (Chapter 88) remains to be elucidated.

Pneumonia is the primary clinical manifestation of *Pneumocystis* infection in immunosuppressed patients. PCP typically presents with a fever, nonproductive cough, and shortness of breath that initially occurs only on exertion but, without therapy, inevitably progresses to dyspnea at rest. Only one or two of these symptoms may be present initially. Development of symptoms may be insidious, over the course of a few weeks, as is common in patients with HIV infection; a more rapid onset, over the course of only a few days, is more common in non-AIDS patients. Purulent sputum production is unusual, and chills and chest pain occur in a minority of patients. Patients with HIV infection may present with other manifestations of immunodeficiency, including weight loss and thrush.

In non-AIDS patients, corticosteroids are a common risk factor. Clinical manifestations may develop as corticosteroids are being tapered, which presumably represents the unmasking of an inflammatory response to the infection as immunosuppression is decreased.

Rarely, extrapulmonary disease can involve the skin, eye (choroiditis), central nervous system, bone marrow, thyroid, spleen, liver, gastrointestinal tract, lymph node, or multiple organs in disseminated disease. Extrapulmonary disease can occur with or without concurrent pneumonia. Use of aerosol pentamidine for prophylaxis has been associated with an increased risk of extrapulmonary disease in HIV-infected patients, but even in that circumstance, it remains extremely rare. Symptoms are related to the specific site involved and may be nonspecific; diagnosis is often made at autopsy.

DIAGNOSIS

Given the nonspecific symptoms, especially early in the disease process, clinicians must have a high index of suspicion for PCP even in patients not known to be immunosuppressed; many patients with HIV infection are unaware of their status until they present with an opportunistic infection. Knowledge of the most recent CD4 count is helpful in assessing HIV-infected patients because PCP is rare in those whose CD4 counts are above 200 cells/mm^3.

Physical examination and routine laboratory tests are usually not helpful in making the diagnosis because many pulmonary processes, both infectious and noninfectious, can present in a similar manner. Moreover, even though patients may be tachypneic and appear to be in respiratory distress, those presenting early in the disease course may have an entirely normal lung examination. Lymphopenia is common but is a manifestation of the underlying disease rather than PCP. Lactate dehydrogenase levels may be elevated but have poor specificity.

The initial evaluation should include a chest radiograph and assessment of arterial oxygenation, either by blood gas measurement or by pulse oximetry. The chest radiograph typically shows perihilar or diffuse bilateral interstitial infiltrates that progress to a diffuse alveolar pattern (Fig. 349-2). However, PCP has been associated with unilateral disease, focal disease, consolidation, nodules, cavities, pneumothorax, and, rarely, pleural effusions. In up to 30% of patients with HIV infection, the chest radiograph appears normal; in this situation, a computed tomography (CT) scan of the chest, especially high-resolution CT, is invariably abnormal, usually showing a patchy or diffuse ground-glass pattern (see Fig. 349-2).

Arterial oxygenation at rest is often abnormal, although in 30% or more of cases it is within normal limits. Exercise testing induces desaturation and an increase in the alveolar-arterial oxygen (A-a O_2) gradient in the majority of patients with PCP, even those with normal oxygenation at rest or a normal chest radiograph. An abnormal resting diffusing capacity is also common. However, although many of these tests have a high sensitivity for PCP, their specificity is poor because other respiratory processes show similar abnormalities. Gallium scans were frequently performed early in the AIDS epidemic, but they are no longer used owing to low specificity and the 2-day delay in diagnosis inherent with this test.

Serologic tests are not helpful in diagnosing PCP. Although antibody titers against recombinant *Pneumocystis* proteins such as major surface glycoprotein may be increased in patients with PCP, such tests have not shown utility for diagnosis in individual patients. Decreased plasma *S*-adenosyl methionine and increased serum β-D-glucan levels have been proposed as diagnostic tests, but to date, there are inadequate data from well-conducted trials to support their use.

Because *Pneumocystis* cannot be cultured, a definitive diagnosis of PCP requires detection of the organism in a pulmonary sample. This can be

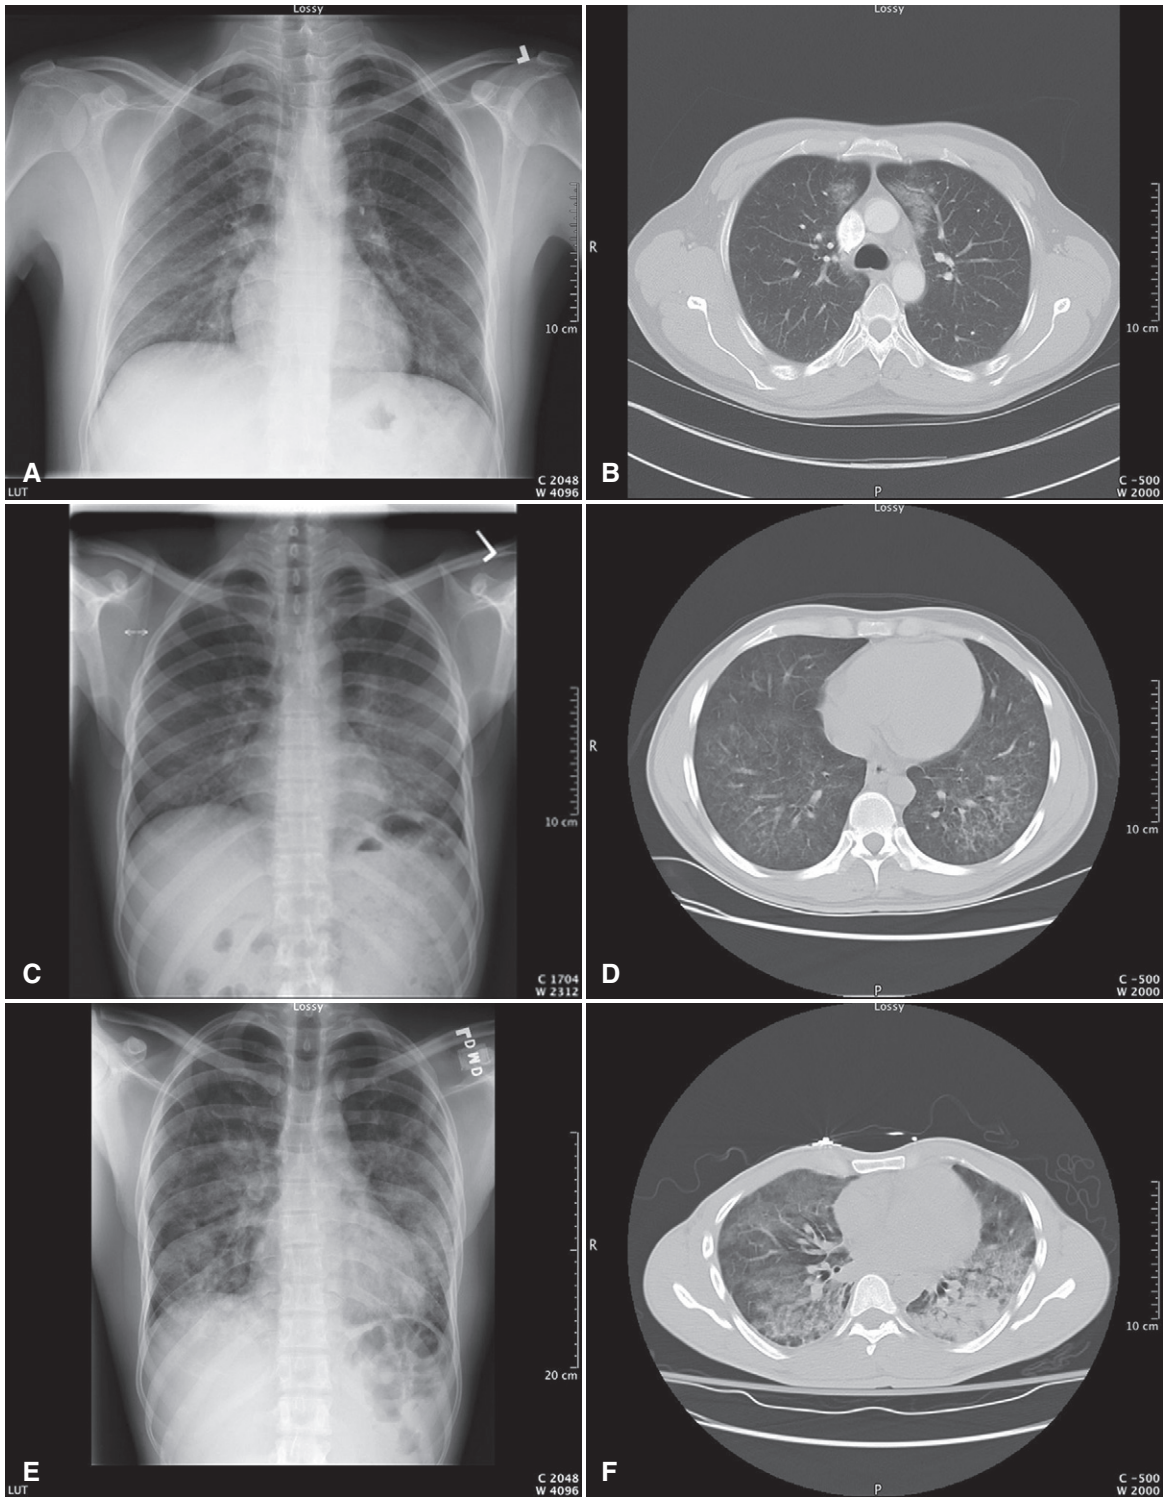

FIGURE 349-2. Chest radiographs (A, C, E) and corresponding computed tomography (CT) scans (B, D, F) from three HIV patients diagnosed with laboratory-confirmed *Pneumocystis* pneumonia. Patient 1 presented with no symptoms; had minimal abnormalities on an incidental chest x-ray (**A**), suggesting an interstitial process; and had focal infiltrates on CT (**B**). Patient 2 presented with fever and weight loss but no shortness of breath. Pulse oximetry demonstrated 99% saturation at rest, with a decrease to 89% with exercise. Chest x-ray (**C**) showed bilateral lower lobe infiltrates, and CT (**D**) showed bilateral lower lobe interstitial infiltrates with patches of ground-glass attenuation. Patient 3 presented with a 2-week history of fever, night sweats, shortness of breath, and weakness. His Pa_{O_2} at diagnosis was 67 mm Hg, and his (A-a) O_2 gradient was 53 mm Hg. Chest x-ray (**E**) showed bilateral mid and lower lung field infiltrates, and CT (**F**) showed bilateral infiltrates with lower lung consolidation.

accomplished by any number of colorimetric or immunologic stains or by molecular techniques. Until the development of anti-*Pneumocystis* monoclonal antibodies in the 1980s, colorimetric stains were routinely used, and they continue to be used at many centers owing to cost considerations. Such stains include Gomori methenamine silver, toluidine blue O, Gram-Weigert, and cresylecht violet, which stain the cyst wall of *Pneumocystis*, as well as Giemsa-type stains, including Diff-Quik, which can stain both trophic forms, the more abundant form of the organism, and intracystic bodies within cysts, but not the cyst wall. *Pneumocystis* can also be detected by calcofluor white, Papanicolaou, periodic acid–Schiff, and, rarely, Gram stain. None of the colorimetric stains are specific for *Pneumocystis*. Cyst wall stains such as Gomori methenamine silver and toluidine blue O can stain other fungi, and Giemsa-type stains also stain background cells and cellular debris. The latter requires substantial expertise for correct interpretation.

Immunofluorescent assays using anti-*Pneumocystis* monoclonal antibodies provide a number of advantages over colorimetric stains. They are specific for *Pneumocystis* and do not show cross-reactivity with other organisms, including fungi; they can be performed and interpreted rapidly; and they have

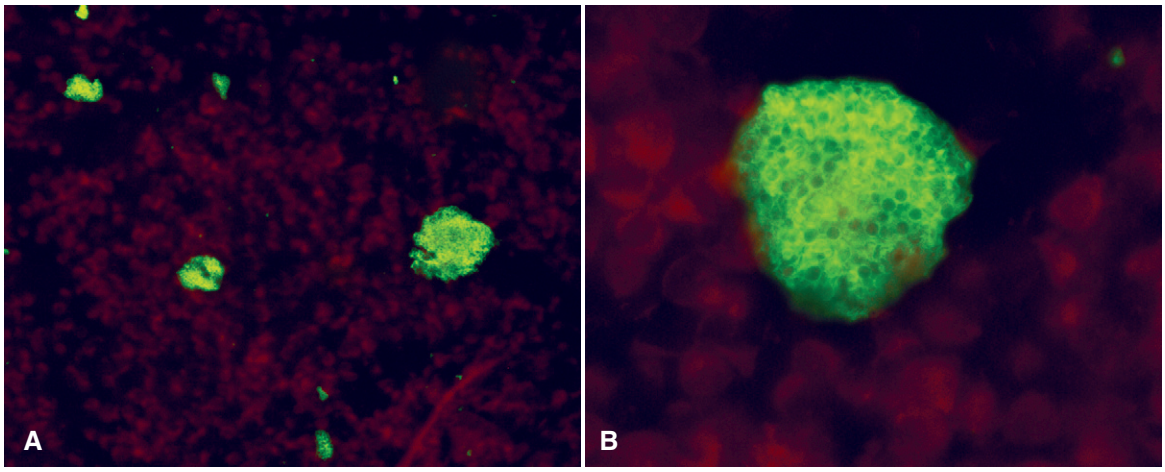

FIGURE 349-3. Immunofluorescent detection of *Pneumocystis* using a direct fluorescent antibody test to examine an induced sputum sample. A, Low power (100× original) allows visualization of multiple clusters or organisms staining bright green. **B,** Under high power (400× original), individual organisms can be seen within a single cluster.

increased sensitivity, especially when examining induced sputum samples (Fig. 349-3).

Molecular techniques, primarily PCR-based assays, have been extensively evaluated for diagnosing PCP. PCR assays are 10- to 100-fold more sensitive than stains for the detection of *Pneumocystis;* this may allow diagnosis using samples such as oral washes, which have a lower organism burden than induced sputum or bronchoalveolar lavage (BAL). This increased sensitivity, however, is associated with decreased specificity, because it allows the detection of organisms in patients ultimately shown not to have PCP. The latter situation presumably reflects colonization or subclinical infection that does not require specific anti-*Pneumocystis* therapy. PCR-based assays are currently not broadly used because of limited availability and the lack of a commercial product with Food and Drug Administration approval.

As detection methods for *Pneumocystis* improved, there was a parallel improvement in sample acquisition. Before the AIDS epidemic, open lung biopsy was required for diagnosis. During the 1980s, bronchoscopy, initially with brushings and biopsy, and subsequently with BAL, was shown to have a greater than 90% sensitivity for diagnosing PCP; BAL continues to be the primary diagnostic modality at many centers today. Although expectorated sputum has a low diagnostic yield, induced sputum, especially when combined with immunofluorescent staining, can have a sensitivity approaching 90%, although in many centers the diagnostic yield is much lower, likely due in part to variability in the methods used for induction and processing. Ideally, sputum induction should be the first step in diagnosis, followed by bronchoscopy with BAL (Fig. 349-4). Bronchoscopic or open lung biopsy is only rarely needed to make the diagnosis.

The differential diagnosis of pulmonary infiltrates in immunosuppressed patients is very broad and includes infections such as adenovirus, cytomegalovirus, tuberculosis, cryptococcosis, histoplasmosis, aspergillosis, and toxoplasmosis, as well as noninfectious processes such as tumor, congestive heart failure, pulmonary emboli, radiation- and chemotherapy-induced pneumonitis, and, especially in HIV-infected patients, nonspecific interstitial pneumonitis and Kaposi's sarcoma.

TREATMENT

Specific anti-*Pneumocystis* therapy should be initiated promptly when the diagnosis is suspected in a potentially susceptible patient. Dosing regimens with documented efficacy are listed in Table 349-1. Although there are no controlled studies defining the optimal duration of therapy, HIV-infected patients should be treated for 21 days, and non-HIV patients for 14 days. If the patient has moderate to severe disease (PaO_2 <70 mm Hg or A-a O_2 gradient >35 mm Hg), concomitant corticosteroid therapy should be administered. The diagnosis should be definitively confirmed by sputum induction or bronchoscopy as soon as possible; however, delaying such confirmation for a few days after the initiation of therapy will not decrease the diagnostic yield because organisms can be detected in clinical samples for more than 3 weeks after the initiation of therapy. Empirical therapy in the absence of a confirmed diagnosis runs the risk of delaying appropriate therapy for another infection, giving inappropriate therapy with known toxicities, and performing a definitive procedure such as bronchoscopy when the patient is failing therapy and consequently has more severe pulmonary compromise.

The treatment of choice for PCP or extrapulmonary disease, regardless of severity, is trimethoprim-sulfamethoxazole, which combines inhibitors of two enzymes in the folate synthetic pathway of *Pneumocystis*: sulfamethoxazole, an inhibitor of DHPS, and trimethoprim, an inhibitor of dihydrofolate reductase (DHFR). Trimethoprim-sulfamethoxazole is available in both oral and intravenous formulations. Oral therapy should be reserved for patients with mild to moderate disease in whom poor absorption is not a concern. Outpatient therapy should be reserved for patients with mild to moderate disease who will reliably return for follow-up.

The efficacy of trimethoprim-sulfamethoxazole for both the treatment and the prevention of PCP was first demonstrated in a pediatric cancer population in the 1970s; it has been the first-line therapy since then, when the only alternative was pentamidine. The high incidence of PCP during the early years of the AIDS epidemic led to the identification of a number of new agents with anti-*Pneumocystis* activity, and these were extensively evaluated in randomized controlled trials, primarily in HIV-infected patients. In patients with mild to moderate disease (A-a O_2 gradient <45 mm Hg), trimethoprim-sulfamethoxazole has superior efficacy compared with atovaquone and similar efficacy compared with trimethoprim-dapsone and clindamycin-primaquine.[1,2] In patients with moderate to severe disease (A-a O_2 gradient >30 mm Hg), it showed superior efficacy to trimetrexate, a potent inhibitor of *Pneumocystis* DHFR that is approved for the treatment of PCP but is no longer commercially available. In smaller, lower-powered studies, trimethoprim-sulfamethoxazole and pentamidine showed similar efficacy.[3]

The major toxicities associated with trimethoprim-sulfamethoxazole include fever, rash, neutropenia, thrombocytopenia, nausea, vomiting, and transaminase elevations. Hyperkalemia and crystalluria have also been reported, and hyponatremia is seen primarily in association with intravenous administration. Toxicities usually appear after the first week of therapy. Toxicities are much more common in HIV-infected patients, occurring in about 50 to 60%; 15 to 35% of these patients discontinue therapy because of these adverse events. Although folinic acid can decrease the toxicities associated with some DHFR inhibitors such as pyrimethamine, it should not be administered with trimethoprim-sulfamethoxazole; in one placebo-controlled trial, it did not decrease side effects but was associated with an increased risk of therapeutic failure and death.

Alternative regimens for patients with mild to moderate disease include trimethoprim-dapsone, clindamycin-primaquine, and atovaquone. Like sulfamethoxazole, dapsone is an inhibitor of *Pneumocystis* DHPS. Adverse reactions to trimethoprim-dapsone include rash, fever, nausea and vomiting, transaminse elevations, methemoglobinemia, anemia, and mild hyperkalemia. Approximately 20 to 30% of patients with adverse reactions to trimethoprim-sulfamethoxazole experience adverse reactions to trimethoprim-dapsone. Toxicities associated with clindamycin-primaquine include fever, rash, diarrhea, anemia, neutropenia, transaminase elevations, and methemoglobinemia. For both dapsone and primaquine and, to a lesser extent, sulfamethoxazole, glucose-6-phosphate dehydrogenase deficiency (Chapter 164) can increase the risk of hemolytic anemia and methemoglobinemia. In a randomized trial comparing trimethoprim-sulfamethoxazole, trimethoprim-dapsone, and clindamycin-primaquine in 181 HIV-infected patients with mild to moderate disease, response rates and toxicities were similar among the three arms, with an overall therapeutic failure rate of 9% by day 21 and a dose-limiting toxicity rate of 31%.[2] Serious transaminase elevations were more

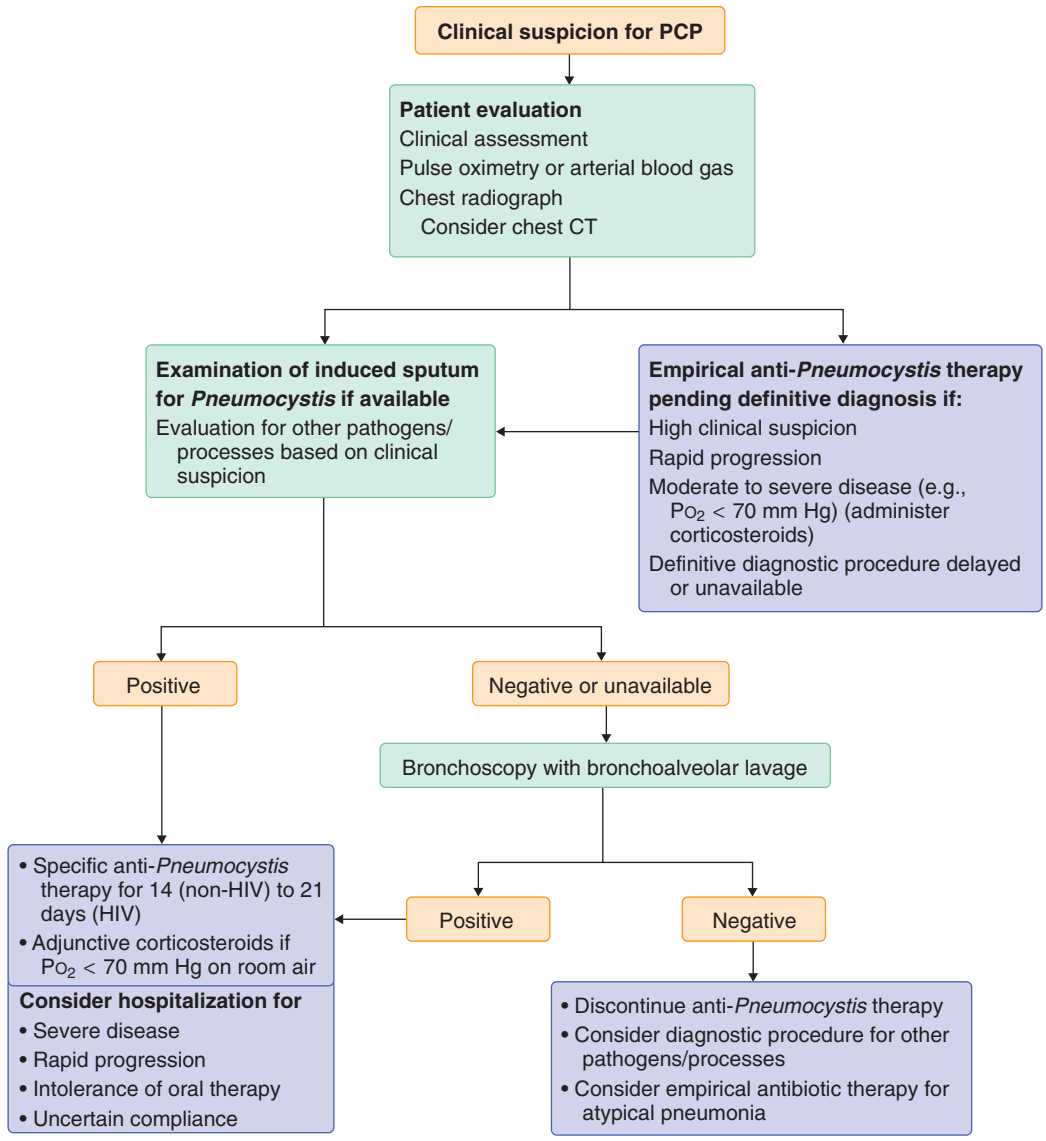

FIGURE 349-4. Algorithm for the evaluation of patients with suspected *Pneumocystis* pneumonia (PCP). CT = computed tomography; HIV = human immunodeficiency virus.

common in the trimethoprim-sulfamethoxazole group, and serious hematologic toxicities were more common in the clindamycin-primaquine group.

Atovaquone is a hydroxynaphthoquinone with activity against *Toxoplasma* and malaria as well as *Pneumocystis*. Atovaquone (tablet formulation) was less effective than trimethoprim-sulfamethoxazole in a randomized trial in HIV-infected patients with mild to moderate disease and showed a trend toward lesser efficacy when compared with pentamidine in another study.[1,4] Low serum atovaquone levels as well as preexisting diarrhea were associated with therapeutic failure. The current formulation is a suspension that has approximately 50% greater bioavailability than the tablet formulation, which may result in improved responses. Atovaquone should be taken with food because this increases its bioavailability, and it should be avoided in patients with potentially decreased gastrointestinal absorption (e.g., diarrhea). Toxicities of atovaquone include rash, fever, transaminase elevations, nausea, vomiting, diarrhea, neutropenia, and anemia.

Therapeutic alternatives to trimethoprim-sulfamethoxazole for patients with disease requiring parenteral therapy are limited to clindamycin-primaquine (but only clindamycin is available for intravenous administration) and pentamidine. Caspofungin and other echinocandins, which are β-1,3-glucan synthase inhibitors, cannot be recommended because there have been no clinical trials documenting their efficacy; β-1,3-glucan is present in the cyst but not in the trophic form of the organism.

Pentamidine was the first drug demonstrated to have anti-*Pneumocystis* activity. Available data suggest that trimethoprim-sulfamethoxazole and pentamidine have similar efficacy; trimethoprim-sulfamethoxazole is the preferred regimen because the toxicities associated with pentamidine are more frequent and potentially more severe.[3] Intravenous pentamidine was originally associated with severe hypotension, but a slow (>1 hour) infusion is usually well tolerated. Intramuscular administration is associated with a high frequency of sterile abscesses at the injection site. Toxicities associated with pentamidine, which occur in about 50 to 60% of patients and frequently result in discontinuation of the drug, include nephrotoxicity, hypoglycemia, hyperglycemia, fever, neutropenia, thrombocytopenia, hypotension, hyperkalemia, transaminase elevations, and pancreatitis. Hypoglycemia may be life-threatening and may precede the development of hyperglycemia; hyperglycemia may be irreversible. Torsades de pointes (Chapter 65) has also rarely been reported.

Adjunctive Corticosteroid Therapy

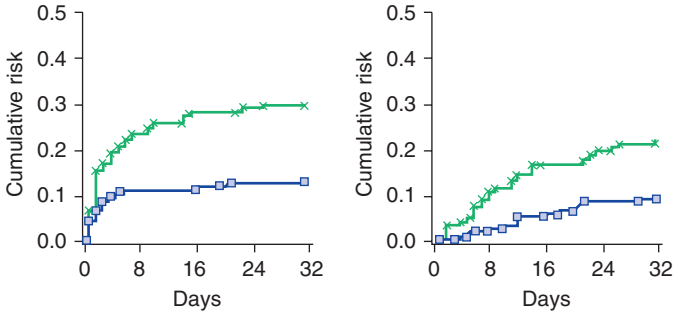
Initiation of specific anti-*Pneumocystis* therapy is associated with a deterioration in oxygenation after approximately 3 to 4 days; this likely results from a host inflammatory response to organisms damaged by therapy. Randomized controlled trials have demonstrated that the early addition of corticosteroids to specific anti-*Pneumocystis* therapy in HIV-infected patients can prevent this deterioration and improve survival, without a significant increase in opportunistic complications other than localized herpes simplex infection.[5] In the largest such study, corticosteroid therapy was associated with a 50% decrease in respiratory failure and mortality; this benefit was limited to patients with moderate to severe disease (E-Fig. 349-1). For HIV-infected patients, corticosteroids and specific anti-*Pneumocystis* therapy should be started at the same time; the addition of corticosteroids after 72 hours has shown no benefit, although it is reasonable to add them if patients exhibit deterioration after this time. Although the optimal regimen has not been defined by controlled trials, the tapering regimen from the largest study is most commonly used (see Table 349-1).

Data from controlled trials examining the benefit of corticosteroids are not available for non-HIV patients, who are often already taking corticosteroids,

TABLE 349-1 DRUG REGIMENS FOR THE TREATMENT OF *PNEUMOCYSTIS* PNEUMONIA*

INDICATION	REGIMEN PREFERENCE	DRUG	ROUTE	DOSE	COMMENTS
Mild PCP: PaO_2 >70 mm Hg or (A-a) O_2 gradient <35 mm Hg	Preferred	TMP-SMX	PO	2 double-strength (160 TMP + 800 SMX) tablets tid	
	Alternative	Trimethoprim +	PO	5 mg/kg tid (15 mg/kg/day)	
		Dapsone	PO	100 mg/day	If possible, test for G6PD deficiency before use
	Alternative	Clindamycin +	PO	450 mg qid or 600 mg tid	
		Primaquine	PO	30 mg/day (base)	If possible, test for G6PD deficiency before use
	Alternative	Atovaquone	PO	750 mg bid with food	
Moderate to severe PCP: PaO_2 <70 mm Hg or (A-a) O_2 gradient >35 mm Hg†	Preferred	TMP-SMX	IV†	TMP 5 mg/kg q6-8h (15-20 mg/kg/day) and SMX 25 mg/kg q6-8h (75-100 mg/kg/day)	May switch to oral therapy following clinical improvement
	Alternative	Pentamidine	IV	3-4 mg/kg/day	Infuse over >60 min
	Alternative	Clindamycin +	IV	600 mg q6h or 900 mg q8h	May switch to oral therapy following clinical improvement
		Primaquine	PO	30 mg/day (base)	No parenteral formulation is available
Adjunctive therapy for moderate to severe PCP: PaO_2 <70 mm Hg or (A-a) O_2 gradient >35 mm Hg	Preferred	Prednisone	PO	40 mg bid on days 1-5; 40 mg/day on days 6-10; 20 mg/day on days 11-21	Begin as early as possible and within 72 hr; efficacy has not been demonstrated if started later
	Preferred	Methylprednisolone	IV	30 mg bid on days 1-5; 30 mg/day on days 6-10; 15 mg/day on days 11-21	Use if parenteral therapy is necessary

*HIV-infected patients should receive 21 days of therapy; non-HIV-infected patients should receive 14 days of therapy.
†Moderate PCP ([A-a] O_2 gradient 35 to 45 mm Hg) can be treated with an oral regimen.
(A-a) O_2 gradient = alveolar-arterial oxygen gradient; G6PD = glucose-6-phosphate dehydrogenase; PaO_2 = arterial partial pressure of oxygen; PCP = *Pneumocystis* pneumonia; SMX = sulfamethoxazole; TMP = trimethoprim.



E-FIGURE 349-1. Cumulative risk of respiratory failure (left) or death (right) during a randomized trial of corticosteroid therapy in patients with HIV infection and *Pneumocystis* pneumonia. Cumulative risk of an unfavorable outcome over a period of 31 days. The risk of respiratory failure (left panel) was 0.14 in the corticosteroid group (X) and 0.30 in the standard-treatment group (□) (P = 0.004). The risks of death (right panel) were 0.11 and 0.23, respectively (P = 0.009). Corticosteroid therapy was associated with a significant decrease in both outcomes. (Modified from Bozzette SA, Sattler FR, Chiu J, et al. A controlled trial of early adjunctive treatment with corticosteroids for *Pneumocystis carinii* pneumonia in the acquired immunodeficiency syndrome. *N Engl J Med*. 1990;323:1451-1457. Copyright 1990, Massachusetts Medical Society. All rights reserved.)

possibly at tapering doses, at the time of PCP diagnosis. One retrospective analysis of 31 such patients suggested that increasing corticosteroids to a prednisone equivalent of 60 mg/day or more was associated with clinical benefit. It is reasonable to administer corticosteroids to non-HIV patients with moderate or severe disease using the same regimen as for HIV-infected patients; for patients already taking corticosteroids at lower doses, the dosage can be increased to those levels.

Initiation of Antiretroviral Therapy

Given that many patients with HIV infection who are diagnosed with PCP are not receiving antiretroviral therapy, an important issue is how soon to start HAART after a diagnosis of PCP. Retrospective and prospective studies have suggested that, in general, it is safe to initiate HAART while patients are being treated for PCP, and early HAART may be associated with an improved outcome. In a randomized 282-patient trial that examined early versus late initiation of HAART in patients with acute opportunistic infections, 63% of whom had PCP, the early initiation arm (HAART started a median of 12 days after starting therapy for the opportunistic infection) had a decreased rate of AIDS progression or death. Similar findings for tuberculosis in developing countries have emphasized the benefit of early initiation of HAART.

Major concerns about initiating HAART include the risk of adverse drug reactions, which may be confused with adverse reactions to anti-PCP therapy; the risk of overlapping toxicities, which may complicate management; and the risk of immune reconstitution. There are several reports describing apparent immune reconstitution syndrome (Chapter 402), which can be life-threatening, in patients who started HAART soon after being diagnosed with PCP. Thus, many clinicians initiate HAART during or immediately after completion of anti-*Pneumocystis* therapy, assuming the patient has shown clinical improvement, is able to tolerate oral medications, and accepts the commitment to lifelong therapy. However, the parameters for such an approach are difficult to precisely define. Patients who start HAART early should be closely monitored for a recurrence of symptoms that may represent immune reconstitution.

Treatment Failure

The optimal approach to the management of patients who are failing therapy has not been well defined. In patients with progressive respiratory deterioration, it is critical that the diagnosis of PCP be confirmed rather than presumptive and that other concurrent processes (e.g., other infections, congestive heart failure, pulmonary emboli) have been ruled out; bronchoscopy should be considered to facilitate these determinations. Parenteral therapy should be used to eliminate absorption concerns, and corticosteroid medications should be added if this has not already been done. Because patients who will ultimately respond can show clinical deterioration at 3 to 4 days, as noted earlier, it is reasonable to wait 5 to 8 days before considering a change in drug therapy.

Only trimethoprim-sulfamethoxazole and pentamidine are available in parenteral formulations. Parenteral clindamycin is available, but primaquine is available only as a tablet. No randomized trials have examined the relative efficacy of these agents in patients who are failing therapy. For patients who have not received trimethoprim-sulfamethoxazole, this should be the first choice as an alternative agent, assuming the patient did not have a life-threatening adverse reaction previously. Rapid desensitization (similar to penicillin desensitization), ideally in consultation with an allergy specialist, can be considered in patients with prior adverse reactions; however, patients with a history of Stevens-Johnson syndrome or toxic epidermal necrolysis should not be rechallenged. Although meta-analyses have found that clindamycin-primaquine is superior to pentamidine in patients failing a first-line regimen, there are potential biases in such analyses (e.g., severity of illness may have

affected the choice of salvage regimen). There are no data to recommend switching to an alternative agent rather than adding an alternative agent (if toxicity is not an issue); both approaches have been used.

Resistance

Although *Pneumocystis* cannot be cultured, molecular studies have identified mutations in genes that are the targets of anti-*Pneumocystis* therapy, and these mutations appear to represent the development of resistance by *Pneumocystis* to these agents. The best-characterized mutations have been identified in the DHPS gene of *Pneumocystis*, which is the target of sulfamethoxazole and dapsone. Two mutations at the active site of this enzyme, which can occur either individually or together, have been identified with greater frequency in patients receiving trimethoprim-sulfamethoxazole or dapsone for prophylaxis; in vitro studies suggest that these mutations confer resistance. The clinical relevance of these mutations remains uncertain; some studies have found worse outcomes in patients with these mutations, but others have found no such association. Most patients in whom these mutations were identified retrospectively were successfully treated with sulfa-containing drugs. In contrast to DHPS, there are very limited reports suggesting that the DHFR gene of *Pneumocystis*, which is the target of trimethoprim and pyrimethamine, has developed potential drug-resistant mutations.

Atovaquone presumably binds to the mitochondrial BC_1 complex of *Pneumocystis* and thus inhibits electron transport. Multiple mutations have been identified in the cytochrome B gene of *Pneumocystis,* which presumably represent resistance in patients receiving atovaquone for prophylaxis; these mutations have not, however, been associated with clinical outcome.

Because the presence of these mutations has not been definitively associated with worsening prognosis, clinical decisions should not be based on their identification. Methods for detecting these mutations are not readily available, and their presence should remain a research tool until their clinical relevance can be better defined.

PREVENTION

Although *Pneumocystis* is transmitted by the airborne route, the organism appears to be ubiquitous, making avoidance of exposure difficult. In animal models, it takes 2 to 3 months following exposure to develop a heavy infection. If the pattern of growth is similar in humans, clinical symptoms would develop only months after exposure to a source that is likely unknown. Currently, respiratory isolation of patients with active PCP is not required, although it is reasonable to avoid having a susceptible patient share a room with a PCP patient. Recent outbreaks in renal transplant patients strongly suggest a common source of infection; a better understanding of the patterns of transmission in these settings may lead to improved guidelines for preventing the spread of infection.

A major advance in the management of patients at risk for the development of PCP was the demonstration that trimethoprim-sulfamethoxazole was highly effective in preventing the disease in a susceptible pediatric population. Subsequent studies, primarily in HIV-infected patients, demonstrated that additional drug regimens were also effective. This has led to the broad use of anti-*Pneumocystis* prophylaxis in a wide range of susceptible populations.

Two important issues in administering prophylaxis are identifying populations at risk and defining the period of risk during which prophylaxis should be provided. AIDS patients are at especially high risk; before the use of prophylaxis or HAART, the lifetime incidence of PCP in this population was estimated at 60 to 80%. The most recent CD4 count is a validated surrogate marker for HIV-infected patients: patients with CD4 counts below 200 cells/mm^3 are at substantially increased risk for developing PCP, and prophylaxis is recommended for this group. Although 10 to 15% of patients who develop PCP have higher CD4 counts, the incidence is very low in this population, given the large number of patients who fall in this category. Patients with CD4 counts greater than 200 cells/mm^3 but a CD4 percentage of less than 14% or a history of an AIDS-defining illness are also candidates for prophylaxis. For pediatric patients with HIV infection, in whom the normal CD4 count changes with age, guidelines are based on age. Prophylaxis is recommended for children older than 6 years with CD4 counts below 200 cells/mm^3 or 15%, for children between 1 and 5 years old with CD4 counts below 500 cells/mm^3 or 15%, and for all children younger than 12 months.

Before the availability of HAART, once patients with HIV infection initiated prophylaxis, they were committed to continuing it for life because immunologic decline was irreversible. With HAART, however, control of HIV replication leads to an increase in the CD4 count, which is associated with a concomitant decrease in the risk of developing PCP. Multiple studies have shown that once the CD4 count has been above 200 cells/mm^3 for at least 3 months (ideally in the setting of controlled HIV replication), prophylaxis can be safely discontinued because the risk of developing PCP is no greater than in patients whose CD4 counts never fell below 200 cells/mm^3. In most of these studies, the median CD4 count was greater than 300 cells/mm^3, and HIV viral loads were below detection limits in the majority of patients.[6] Recent uncontrolled studies have suggested that prophylaxis can also be safely discontinued in patients with CD4 counts between 100 and 200 cells/mm^3 who have virologically suppressed HIV, but specific criteria for discontinuation (e.g., duration of viral suppression) were not defined in these studies.

Among non–HIV-infected patients, the CD4 count is not routinely measured, and it has not been shown to have the same predictive value for the development of PCP as in HIV-infected patients; however, CD4 counts below 200 cells/mm^3 do appear to increase their susceptibility. Recommendations for PCP prophylaxis in these populations are based on clinical parameters, including empirical identification of periods of risk and estimation of levels of immunosuppression. Very broad prophylaxis has not been implemented because of the side effects associated with these regimens; for example, there is concern that trimethoprim-sulfamethoxazole might cause bone marrow suppression that would interfere with engraftment or cause nephrotoxicity that would damage a transplanted kidney.

Risk factors for non–HIV-infected patients include underlying disease, use of immunosuppressive drugs, radiation therapy, graft-versus-host disease, and concomitant cytomegalovirus infection (Chapter 384). Patients with malignancies, especially hematologic malignancies, but increasingly solid tumors as well, are at risk for PCP primarily owing to the therapies they receive; the incidence can range from 1 to 43% in the absence of prophylaxis and is highly dependent on the intensity and duration of immunosuppression. In the absence of prophylaxis, the risk of developing PCP in transplant patients, whether hematopoietic stem cell or solid organ transplants, is reportedly about 5 to 15%, although lung and heart-lung transplant patients appear to have a higher incidence (up to 43%). Among patients with collagen vascular disease, the reported risk is less than 2% without prophylaxis, although patients with Wegener's granulomatosis (Chapter 278) reportedly have a risk up to 12%, presumably because of the use of more immunosuppressive treatment regimens. The current risk of developing PCP in non-HIV populations is difficult to quantify because of the widespread use of prophylaxis and because immunosuppressive regimens are evolving.

To facilitate the management of prophylaxis in at-risk populations, a number of guidelines have been developed by experts panels who have made recommendations based on the strength of the available data. HIV guidelines have already been summarized. For allogeneic stem cell transplant recipients, prophylaxis is recommended from the time of engraftment to at least 6 months after transplantation, and longer for patients who continue receiving immunosuppressive therapy or who have chronic graft-versus-host disease. For autologous stem cell transplant recipients, who have a lower risk of PCP, prophylaxis for 3 to 6 months should be considered if the degree of immunosuppression is substantial owing to underlying disease or therapy (e.g., patients with leukemia or lymphoma receiving intensive conditioning or immunosuppressive therapy).

For solid organ transplant patients, prophylaxis has not been universally adopted; it has been used primarily in centers with a known incidence greater than 3%. Guidelines recommend the administration of prophylaxis for 3 to 12 months in renal transplant patients and for longer periods, up to lifelong, in heart, lung, liver, and intestine transplant recipients. As noted earlier, a number of outbreaks of PCP have recently been reported in renal transplant centers, and many of those patients developed disease more than 1 year after transplantation. Changes in immunosuppressive therapy may have contributed to this apparent increase in incidence, given that some of these centers had seen very few cases in prior years.

For patients with inflammatory bowel disease (Chapter 143), who appear to be at increased risk as newer immunosuppressive agents are used, data are limited; however, consensus-based guidelines recommend prophylaxis for patients receiving triple immunomodulators that include either a calcineurin inhibitor or an anti–tumor necrosis factor agent. No consensus was reached for less intensive regimens. For patients with connective tissue disorders or vasculitis, there are currently no consensus guidelines.

Corticosteroid therapy (Chapter 34) is a well-described risk factor in non-HIV-infected patients, with approximately 90% of patients receiving such therapy before developing PCP in some studies. Higher dose and longer

TABLE 349-2 DRUG REGIMENS FOR THE PREVENTION OF *PNEUMOCYSTIS* PNEUMONIA

REGIMEN PREFERENCE	DRUG	ROUTE	DOSE	COMMENTS
Preferred	TMP-SMX	PO	1 double-strength tablet (160 mg TMP + 800 mg SMX) or 1 single-strength tablet (80 mg TMP + 400 mg SMX) daily	Also active in preventing toxoplasmosis
Alternative	TMP-SMX	PO	1 double-strength tablet (160 mg TMP + 800 mg SMX) 3 times/wk	Also active in preventing toxoplasmosis
Alternative	Dapsone	PO	100 mg/day or 50 mg bid	Test for G6PD deficiency before use
Alternative	Dapsone + Pyrimethamine + Leucovorin	PO PO PO	50 mg/day 50 mg once weekly 25 mg once weekly	Also active in preventing toxoplasmosis Should be administered with pyrimethamine to minimize toxicity
Alternative	Atovaquone	PO	1500 mg/day with food	Likely active in preventing toxoplasmosis
Alternative	Pentamidine	Aerosol	300 mg via Respirgard II nebulizer once monthly	Not active in preventing toxoplasmosis

Patients receiving pyrimethamine-sulfadiazine and atovaquone therapy for toxoplasmosis do not appear to need additional prophylaxis for PCP; patients receiving clindamycin-pyrimethamine therapy for toxoplasmosis need additional prophylaxis for PCP.
G6PD = glucose-6-phosphate dehydrogenase; SMX = sulfamethoxazole; TMP = trimethoprim.

duration increase the risk. Not all patients who receive corticosteroids are at risk, however; for instance, asthmatics receiving corticosteroid therapy are at low risk. Although there are no consensus guidelines on the use of prophylaxis for patients receiving corticosteroids, one reasonable approach is to provide prophylaxis to patients with an underlying immunosuppressive or inflammatory disease who receive at least 20 mg of prednisone or equivalent for longer than 1 month. Other immunosuppressive agents (Chapter 34), such as calcineurin inhibitors, sirolimus, tumor necrosis factor antagonists, and rituximab, also appear to increase the risk of developing PCP, primarily in the patient populations noted earlier.

Trimethoprim-sulfamethoxazole is the first-line agent for prophylaxis in all populations (Table 349-2). Alternatives include dapsone alone or combined with pyrimethamine plus leucovorin, atovaquone, and aerosol pentamidine administered by the Respirgard II nebulizer. In a randomized trial of 843 HIV-infected patients comparing trimethoprim-sulfamethoxazole with dapsone and aerosol pentamidine, no significant differences were seen on an intent-to-treat basis, but the lowest failure rates were seen while patients were receiving trimethoprim-sulfamethoxazole.[7] Conversely, trimethoprim-sulfamethoxazole was superior to aerosol pentamidine in another randomized study.[8] In other large randomized trials in HIV-infected patients, the following regimens showed similar efficacy: atovaquone suspension and dapsone, atovaquone suspension and aerosol pentamidine, and dapsone-pyrimethamine and aerosol pentamidine.[9-11] No randomized trials of these regimens have been conducted in non–HIV-infected populations, but clinical experience suggests that they are effective in these populations as well.

Although the combination of sulfadoxine and pyrimethamine is also efficacious, it is contraindicated in patients with sulfonamide allergies. Moreover, because Stevens-Johnson syndrome and other potentially life-threatening cutaneous reactions are more common with this combination than with trimethoprim-sulfamethoxazole, and because its long half-life results in slow clearance after the drug is discontinued, sulfadoxine plus pyrimethamine should probably not be used in sulfa-tolerant patients if trimethoprim-sulfamethoxazole is available.

HIV-infected patients with a prior history of a mild sulfa allergy (e.g., mild rash, excluding those with prior Stevens-Johnson syndrome or toxic epidermal necrolysis) can often be safely rechallenged with trimethoprim-sulfamethoxazole. Randomized trials have demonstrated that dose escalation over a 6- to 13-day period is associated with better tolerance than direct rechallenge with full-dose trimethoprim-sulfamethoxazole, and that up to 75% of patients can continue to receive trimethoprim-sulfamethoxazole for at least 6 months.[12,13]

PROGNOSIS

Mortality for untreated PCP approaches 100%. With therapy, the survival rate for HIV-infected patients with confirmed PCP is 80 to 90%; a poorer survival rate of 50 to 60% has been reported in patients without HIV infection. Risk factors for death in HIV-infected patients include greater hypoxia, older age, recurrent episodes of PCP, low hemoglobin, and presence of comorbid conditions. Although mortality for patients admitted to an intensive care unit is high, survival for HIV-infected patients has improved in recent years, approaching 50%.

350 MYCETOMA

DIMITRIOS P. KONTOYIANNIS

DEFINITION

Mycetoma (a tumor produced by fungi) was first described in 1842 in the Madura district of India, hence the terms "Madura foot," "maduromycosis," and "maduromycetoma." Mycetoma is a chronic, slowly progressive infection of diverse etiology that starts in subcutaneous tissue and spreads across tissue planes to contiguous structures. The offending organism is inoculated into subcutaneous tissue by trauma that typically involves soil contaminated with pathogens. The hallmarks of mycetoma are the presence of "grains" that consist of colonies of the infectious organism and chronically draining sinus tracts. (The term *pulmonary mycetoma* is used inappropriately to describe the fungus balls typically caused by *Aspergillus* species that colonize a preexisting lung cavity; the term *aspergilloma* [Chapter 347] is more appropriate for this entity, the pathogenesis of which is distinctly different from that of true mycetoma.)

The Pathogens

Two groups of soil-inhabiting pathogens, each of which accounts for approximately 50% of cases, cause mycetoma: (1) filamentous aerobic actinomycetes (Chapter 337), hence the term *actinomycetoma*, and (2) a wide range of saprophytic soil and woody plant fungi, hence the term *eumycetoma*.

A variety of *Nocardia* species (e.g., *Nocardia brasiliensis*, *Nocardia asteroides*), *Actinomadura* species (e.g., *Actinomadura pelletieri*, *Actinomadura madurae*), and *Streptomyces* species (e.g., *Streptomyces somaliensis*) have been reported to cause actinomycetoma. Even more numerous are the agents that cause eumycetoma, such as *Madurella* species, probably the most prevalent mycetoma-causing fungal species worldwide (e.g., *Madurella mycetomatis* causes 70% of all cases of eumycetoma), as well as *Fusarium* species, *Acremonium* species, *Pseudallescheria boydii*, *Exophiala* species, and *Curvularia* species. There is controversy about whether the various dermatophytes and *Aspergillus* species can cause mycetoma. Eumycetoma is often further characterized on the basis of the color of the grains; specifically, white to yellow grain mycetomas (white piedra) are typically caused by hyalohyphomycetes (e.g., *P. boydii*, *Fusarium* species, *Acremonium* species), and black grain eumycetomas (black piedra) are caused by *Madurella* species and other less common fungi. However, the geographic distribution of the fungi that cause black grain eumycetoma is variable.

EPIDEMIOLOGY

Although mycetoma has a broad worldwide distribution, it occurs primarily in the tropical and, to a lesser extent, the temperate zones. More specifically, the infection is quite prevalent in India, Mexico, Central America, South America, the Middle East, and especially sub-Saharan Africa (the "mycetoma belt"); Sudan in particular has a high burden of mycetoma. Indigenously acquired mycetoma is sporadic in North America and Europe. However, the globalization of tourism and the increase in immigration from countries with a high endemicity of mycetoma to Western countries necessitates awareness of this entity, even in the developed world.

The relative frequency of actinomycetoma and eumycetoma differs among geographic areas, with eumycetoma being more common in India and Africa and actinomycetoma more common in Latin America. Furthermore, the causative agents of mycetoma differ in their geographic distribution, as shown in Figure 350-1. The recent development of molecular typing procedures such as polymerase chain reaction and restriction fragment length polymorphism holds promise in expanding our knowledge on the environmental sources and pathogenesis of some agents of eumycetoma such as *M. mycetomatis*.

PATHOGENESIS

Local trauma (e.g., wood splinters) introduces a mycetoma-causing organism into the skin and subcutaneous tissue and initiates a chain of events that lead to chronic, suppurative granulomatous inflammation, tumefaction, formation of multiple fistulous tracts and sinuses, deep abscesses, fibrosis and scar formation, and extension to adjacent connective tissue across the lines of least resistance (fascia) and ultimately to bones, muscles, nerves, and tendon sheaths, thereby leading to gross anatomic distortion of the affected site. In addition, a chronic suppurative granuloma featuring reactive fibrosis and grains (sclerotia), which is a matrix consisting of vegetative aggregates of the etiologic agents and host-derived inflammatory response, is characteristic of mycetoma in histologic sections. This infection is not contagious, however. There may be differences in host susceptibility inasmuch as some affected persons have impaired or delayed hypersensitivity reactions. However mycetoma does not appear to be more common in immunocompromised hosts.

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

The clinical manifestations and natural history of mycetoma are variable and, to some degree, related to the pathogenic agent involved. For example, the progression of eumycetoma tends to be slower than that of actinomycetoma. In addition, eumycetoma lesions tend to be more confined and have less inflammation and fewer granulomas and fistulas but more fibrosis than actinomycetoma lesions do. Furthermore, male mycetoma patients predominate over female patients (5:1), and the disease is typically seen in rural areas and in persons susceptible to local trauma and contamination from soil (e.g., thorns). Hence, farmers, gardeners, wood cutters, herders, and people who work outside while barefoot are more susceptible to this infection. Not

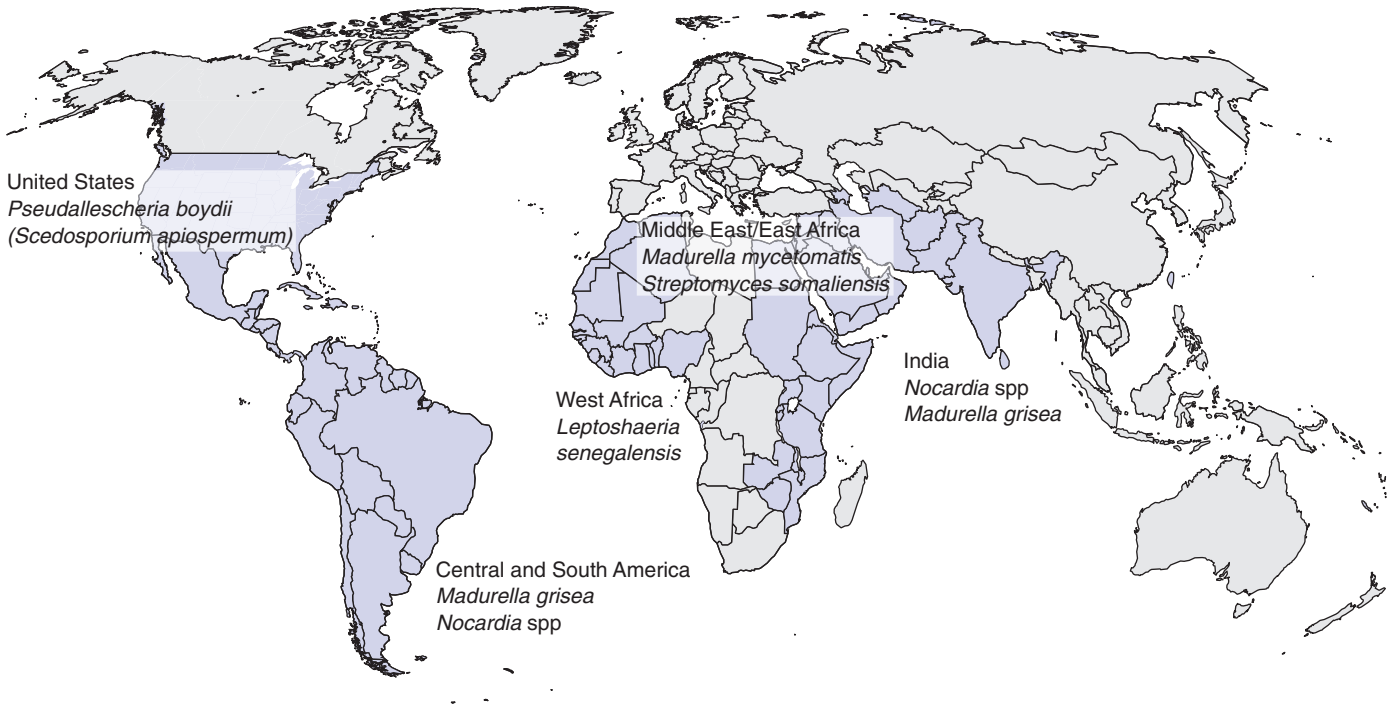

FIGURE 350-1. Predominant agents of mycetoma according to region.

FIGURE 350-2. Madura foot. A 40-year-old farmer from rural Venezuela with a 10-year history of foot edema and slowly progressive deformity following an injury caused by being struck by a hammer exhibited chronic crusted plaques, multiple confluent tender abscesses with fistulization, and release of black grains. The range of motion of the patient's ankle and foot joints was limited, but the joints were not painful. (Courtesy Dr. M. Mendoza, Instituto De Biomedicina, Laboratorio de Micología, San Jose Caracas, Venezuela.)

surprisingly, the foot is the most common site involved in mycetoma (Fig. 350-2), but any other part of the body, such as the hands, thighs, torso, and back of the head, may become involved. Location is typically solitary. Painless nodular or papular swelling (or both) is the most common early manifestation of mycetoma, which is followed by a slow evolution to painless, fixed woody induration. This infection typically runs a chronic, relentless course, sometimes spanning several decades. It is characterized by recurring, vicious cycles of suppuration, draining sinuses, bacterial superinfection, and scar formation. Old sinuses may close up, but new ones may occur, and satellite lesions may be seen. Constitutional symptoms are surprisingly rare. In particular, the presence of fever indicates bacterial superinfection. Bone involvement mimicking clinically chronic osteomyelitis with osteolytic cavitary bone lesions, periosteal reaction or sclerosis (seen on radiographs, computed tomography [CT], or magnetic resonance imaging [MRI]), and osteoporosis may occur; such involvement can be substantial. However, pathologic fractures are rare. In addition, because nerves are relatively spared from involvement, neuropathic manifestations are uncommon. Inexorable limb deformity and misuse because of destruction of deeper tissues may be seen in chronic, refractory, and advanced cases. Finally, because mycetoma does not spread hematogenously, visceral dissemination is not seen. However, because lymphatic spread may occur (typical incidence of 1 to 3% but more common with actinomycetoma and especially after surgery), regional lymphadenitis may develop.

DIAGNOSIS

Mycetoma, especially in its advanced forms, has rather characteristic findings. The classic triad of painless soft tissue swelling, draining sinus tracts, and extrusion of grains facilitates diagnosis with a high degree of accuracy, especially in endemic areas. For instance, the macroscopic and microscopic appearance of grains in pus-filled draining sinuses frequently allows presumptive diagnosis of the offending pathogen. However, basing the diagnosis on the presence of grains in tissue may be difficult because these grains might be composed of dead organisms. Furthermore, the grains may be contaminated by surface bacteria or fungi. Therefore, a deep tissue biopsy specimen is ideal for staining with hematoxylin and eosin, and appropriate selective bacterial and fungal cultures and stains are preferable for primary detection. Alternatively, aspiration of grains from unopened sinus tracts might provide material for culture.

The culture should be maintained for several weeks because some of the causative agents of mycetoma (e.g., *Nocardia* and *Streptomyces* spp) are slow growing and might take 4 to 6 weeks for growth. Histopathology differentiates eumycetoma from actinomycetoma; however, the multitude of fungi causing eumycetoma necessitates culture identification as agents of eumycetoma might respond differently to antifungal agents. Similarly, cross-reactivity, lack of standardization, and the many agents causing eumycetoma limit the practical value of serologic evaluation.

Differential Diagnosis

The specific manifestations of mycetoma are sometimes confused with those of other rare entities. For example, mycetoma must occasionally be distinguished from chronic cutaneous fungal infections such as sporotrichosis (mycetomatous lymphatic sporotrichosis) and dermatophytic mycetoma. The latter infection, which is typically seen in Africans and sometimes called pseudomycetoma, is a painless granulomatous induration of the skin and subcutaneous tissues caused by ringworm that may be associated with grains consisting of fungi. However, unlike mycetoma, dermatophytic mycetoma is confined to the skin and subcutaneous tissue and does not spread to fasciae or bone. Similarly, chronic severe botryomycosis (typically caused by gram-positive cocci) with purulent exudates, grains, and draining sinus tracts may be confused with mycetoma; however, the presence of visceral dissemination supports a diagnosis of (severe) botryomycosis. Actinomycosis, which is

caused by endogenous microaerophilic actinomycetes (part of the normal mucosal flora), also has a propensity for grains and the formation of draining sinus tracts, but unlike mycetoma, its location (neck, chest, pelvis) is rather characteristic. In addition, differentiation between mycetomas with bone involvement and chronic osteomyelitis or osseous tumors may be difficult. Ultrasonography has been used to reliably differentiate mycetoma from either tumor or osteomyelitis. The dot-in-circles sign seen on MRI (tiny hypodense foci, believed to be grains, within hyperintense spherical lesions, believed to be granulomas scattered by areas of fibrosis) might provide an early and specific diagnostic clue for mycetoma. Finally, in cases of mycetoma without draining sinus tracts, benign or malignant skin tumors, chronic granulomatous lesions (e.g., thorn granuloma, cutaneous tuberculosis), chromomycosis, and verrucous leishmaniasis are diagnoses that should be excluded. Unfortunately, delay in specific diagnosis by many months or even years is not uncommon, even in highly endemic areas.

TREATMENT

Rx

Therapy for mycetoma should be individualized. Optimal management has not been well defined, however, because the literature consists of rather heterogeneous and uncontrolled small studies. No single agent is effective against all causative agents of mycetoma. Hence, successful treatment necessitates a reliable diagnosis, differentiation between actinomycetoma and eumycetoma, assessment of the extent of the lesion, and identification of the causative agent. Specifically, the degree of tissue invasion, especially bone involvement (as determined by radiology studies), the site affected, and the specific etiologic diagnosis determine the type and intensity of therapy. Recent studies indicate that MRI and CT (more sensitive, particularly for mycetoma involving bone) are especially useful in "staging" the disease.

In general, in view of the refractoriness of eumycetoma to medical therapy, surgery plays a more prominent role. In contrast, with the satisfactory response of actinomycetoma to medical therapy (success rate of up to 90%) and recognized risk for lymphatic spread following surgery, chronic antibiotic administration is the mainstay of actinomycetoma management.

For actinomycetoma, treatment consists primarily of chronic antibiotic therapy (for at least 9 to 12 months) in conjunction with limited debulking surgery in selected cases; combination therapy designed for potential synergy is preferred. A variety of drugs (trimethoprim-sulfamethoxazole, tetracyclines, dapsone, streptomycin) have been used in different sequences and combinations according to the specific cause of actinomycetoma. Parenteral streptomycin is usually reserved for patients who do not respond to oral therapy. Responses to these drugs tend to occur slowly (within at least 1 month). In addition, relapse is not uncommon, and multiple cycles of therapy may be needed for chronically recurrent disease. Side effects and compliance issues after prolonged administration of antibiotics are common problems.

For eumycetoma, however, medical therapy has produced mixed results. The best results were obtained with prolonged (9 to 12 months) use of oral imidazoles (e.g., 200 to 400 mg/day of ketoconazole or itraconazole). The experience using newer triazoles (e.g., itraconazole, voriconazole, or posaconazole) or the allylamine terbinafine, though encouraging, is not as extensive. Posaconazole or voriconazole might prove to be especially useful for the treatment of eumycetoma caused by *P. boydii*, a fungus that is not susceptible to either ketoconazole or itraconazole. Also, intravenous amphotericin B and its lipid formulations have been used for refractory cases with rather disappointing results. Such results are not surprising because most eumycetoma-causing agents (e.g., *P. boydii*) are resistant to amphotericin B in vitro.

The need for and extent of surgery for mycetoma depend on the etiologic agent and, more important, the extent of the lesion. Early wide-margin surgery for early localized lesions is curative. Major disfiguring or mutilating surgery (e.g., amputation) is reserved for very advanced or refractory cases. Furthermore, primary reliance on surgery could result in recurrence or even spreading of the disease because of incomplete excision.

PROGNOSIS

The prognosis for mycetoma depends on the site and degree of tissue involvement (e.g., worse with involvement of the back because of poor healing or in the presence of bone destruction) and, more important, the timeliness of diagnosis and monitoring of recurrence and extension to other tissues, especially bone. CT and MRI are important modalities for early detection of bone involvement.

PREVENTION

Finally, because mycetoma represents a significant, yet frequently ignored socioeconomic burden for tropical and subtropical countries, every effort to prevent it should be made. Prompt recognition for early curative chemotherapy or surgery (or both) could lead to a better outcome of this difficult-to-manage, chronic infection.

351 DEMATIACEOUS FUNGAL INFECTIONS

PETER G. PAPPAS

DEFINITION

Dematiaceous fungi represent a large group of fungal organisms characterized by the presence of abundant melanin in the cell wall, which gives rise to a brown-black coloration on artificial culture media. A related term, *phaeohyphomycosis*, refers broadly to infection by these pigmented fungi. The two terms are often used interchangeably, but when dematiaceous fungi are reviewed, three distinct clinical conditions are encountered: eumycetoma (e.g., Madura foot) (Chapter 350), chromomycosis (also known as chromoblastomycosis), and phaeohyphomycosis. This chapter focuses on the latter two entities.

The Pathogens

More than 100 dematiaceous fungi causing colonization or disease have been isolated from humans. The more common organisms and their related conditions are listed in Table 351-1. The taxonomy of the dematiaceous fungi is somewhat confusing because these agents belong to different classes, including Hyphomycetes, Ascomycetes, Basidiomycetes, Coelomycetes, and

TABLE 351-1 DEMATIACEOUS FUNGI AND ASSOCIATED CONDITIONS

CLINICAL CONDITION	COMMON ETIOLOGIC AGENTS
Chromomycosis	*Fonsecaea pedrosoi* *Cladophialophora carrionii* *Phialophora verrucosa*

Central nervous system	*Cladophialophora bantiana* *Ochroconis gallopava* *Ramichloridium mackenziei*
Disseminated	*Wangiella dermatitidis* *Exophiala jeanselmei* *Bipolaris* sp *Ochroconis gallopava* *Phialophora* sp *Scedosporium prolificans*

Zygomycetes. The most common agents of phaeohyphomycosis include species in the following genera: *Bipolaris*, *Curvularia*, *Exophiala*, *Cladophialophora*, *Alternaria*, *Exserohilum*, *Ochroconis*, *Wangiella*, *Phialophora*, *Scedosporium*, and *Phaeoacromonium*. These agents are ubiquitous saprophytes of soil and decaying matter, and some are important plant pathogens. In tissue, these organisms exist as yeastlike cells, septated hyphae, or a combination of yeast and hyphae. Many have a histologic appearance similar to *Aspergillus* and *Fusarium* species, but they may be distinguished on the basis of positive melanin staining with the Fontana-Masson procedure.

Chromomycosis is a chronic skin and soft tissue infection that is observed most frequently in the tropics. Virtually all cases of chromomycosis are caused by three organisms: *Fonsecaea pedrosoi*, *Cladophialophora carrionii*, and *Phialophora verrucosa*. The distinctive histologic appearance is characterized by the presence of thick-walled, dark brown bodies known as *sclerotic cells* or *copper pennies*, which represent individual organisms and may be seen in clusters or as single cells. The etiologic fungi are indistinguishable on histologic examination of tissue.

EPIDEMIOLOGY AND PATHOBIOLOGY

The agents of chromomycosis and phaeohyphomycosis are found worldwide. Although there is no unique endemic area for most of these infections, some observations are relevant. Allergic fungal sinusitis associated with dematiaceous fungi appears to be more common in the southern portion of the United States. Chronic infections of the lower extremities are more commonly seen in men and in tropical areas. Chromomycosis is more prevalent in rural populations in the tropics and is hyperendemic in certain geographic areas such as Madagascar, where most infections are caused by *C. carrionii*.

Most cutaneous infections occur as a result of minor skin trauma and direct inoculation of the organism. In the nosocomial setting, infection from contaminated intravascular catheters and intravenous fluids has been reported. Other risk factors include intravenous drug abuse, chronic sinusitis, freshwater immersion, and chronic corticosteroid therapy.

In the developed world, phaeohyphomycosis is an important emerging fungal infection, particularly in immunocompromised patients such as solid organ and hematopoietic stem cell transplant recipients, patients with prolonged neutropenia, and other chronically immunocompromised individuals. Phaeohyphomycosis is reported in patients infected with human immunodeficiency virus but is far less common than other opportunistic fungal infections. Extracutaneous invasive disease occurs in otherwise normal patients but is much less common.

CLINICAL MANIFESTATIONS

Chromomycosis is manifested as a cutaneous or subcutaneous lesion that may range in size from a small papule to a large plaque. Single or multiple lesions may be seen, and ulceration may occur. Lesions may remain unchanged in size and consistency for months or years, although most tend to progress in the absence of specific therapy. Chronic lesions may become dry and crusted with a raised border, which may be smooth or irregular. Multiple lesions can coalesce to form larger plaques in which central scarring develops. Occasionally, lesions assume a verrucous, warty appearance. The differential diagnosis includes other fungal infections such as blastomycosis (Chapter 342), coccidioidomycosis (Chapter 341), sporotrichosis (Chapter 345), histoplasmosis (Chapter 340), and paracoccidioidomycosis (Chapter 343). Nocardiosis and cutaneous mycobacteriosis can also mimic the lesions of chromomycosis. Cutaneous lesions usually remain confined to one anatomic site, although nodular lymphangitis and autoinoculation resulting in multifocal cutaneous disease may occur. Common complications include local disfigurement because of scarring and extensive tissue involvement. Disseminated disease involving visceral organs may occur but is rare.

Phaeohyphomycosis is associated with several well-described clinical syndromes. *Superficial* infection is characterized by tinea nigra and black piedra. Tinea nigra is a darkening of the skin caused by growth of *Phaeoannellomyces werneckii* in the stratum corneum. Black piedra is associated with the development of focal thickening on the hair shaft and results from colonization of the shaft by *Piedraia hortae*. *Cutaneous* phaeohyphomycosis involves deeper skin structures and results in dermatomycosis and onychomycosis; it is frequently due to agents such as *Scytalidium* and *Phyllosticta* species.

Subcutaneous phaeohyphomycosis is relatively common and may be confused with chromomycosis. Patients have discrete subcutaneous nodules or cysts that result from direct inoculation or penetrating trauma. The most common organisms are *Exophiala jeanselmei*, *Wangiella dermatitidis*, and *Phialophora* spp. *Mycotic keratitis* as a result of infection with *Curvularia*, *Exophiala*, and *Exserohilum* species has occurred after corneal trauma or surgery.

Foreign body–related infections are seen in patients undergoing chronic ambulatory peritoneal dialysis in whom fungal peritonitis develops, in patients with indwelling intravenous catheters, and rarely with other devices such as breast implants.

Fungal sinusitis is commonly associated with dematiaceous fungi and can be manifested as allergic fungal sinusitis, a fungus ball (eumycetoma) in a sinus cavity, and invasive fungal sinusitis associated with extension into bone, soft tissue, and the central nervous system. This latter manifestation is indistinguishable from rhinocerebral zygomycosis or invasive *Aspergillus* sinusitis. *Bipolaris*, *Curvularia*, and *Alternaria* species are the most common organisms causing invasive fungal sinusitis.

Systemic phaeohyphomycosis may result from direct extension from a colonized area or dissemination from a distant source. Most patients with systemic disease have significant underlying immunosuppression, and the organisms have a proclivity for involvement of the brain, lungs, endocardium, and other visceral organs. Among patients with primary central nervous system disease, *Cladophialophora bantiana*, *Ochroconis gallopava*, and *Ramichloridium mackenziei* are the most common etiologic agents, and the majority of them occur in younger patients with no known underlying immunodeficiency.

DIAGNOSIS

The diagnosis of phaeohyphomycosis is suggested by direct examination of a clinical specimen treated with a 10% potassium hydroxide preparation or special stains to demonstrate pigmentation in the cell walls of these organisms. For patients with chromomycosis, the finding of sclerotic bodies or copper pennies on skin biopsy is characteristic, and special stains are usually unnecessary. For patients with other forms of phaeohyphomycosis, the Fontana-Masson stain is useful for distinguishing organisms with significant melanin content. Culture remains the "gold standard" by which a specific etiologic diagnosis is established, and the identity of the organism is largely based on colony and microscopic morphology. Serologic studies and molecular diagnostics are not generally available for these organisms.

TREATMENT

Rx

In many instances, surgical excision of a cutaneous or subcutaneous lesion is curative, although antifungal therapy is usually given in conjunction with surgery. Only limited clinical studies have assessed the efficacy of antifungal therapy for these conditions. Historically, 5-flucytosine (5-FC, 150 mg/kg/day) has been advocated for the oral treatment of chromomycosis based on moderate in vitro activity and clinical experience. Because of limited availability, the need for prolonged therapy, and the necessity of monitoring serum levels, 5-FC is uncommonly used for this purpose. Amphotericin B has only modest in vitro activity against most of the dematiaceous fungi and is most often reserved for patients with life-threatening or disseminated disease. The triazoles, including itraconazole (200 mg orally twice daily), voriconazole (200 mg orally twice daily), and posaconazole (400 mg orally twice daily), demonstrate the best in vitro activity, although clinical studies with these agents are limited. Among the triazoles, posaconazole offers the most potential in the clinical setting based on scattered reports from patients with central nervous system infection, but comparative clinical data are not available because of the relative rarity of these infections. Terbinafine (500 mg orally twice daily) has also been used successfully for the treatment of chromomycosis and is an effective alternative to azole therapy. The length of therapy with any of the oral antifungal agents for dematiaceous fungal infections is unclear, but treatment should probably be continued for at least 6 months or until 1 month after the resolution of all signs and symptoms of disease.

352

ANTIPARASITIC THERAPY

RICHARD D. PEARSON

Several factors, including the development of the global economy, international travel, and immigration, have drawn attention to the importance of parasitic diseases worldwide. A number of effective drugs are available to treat them. This chapter provides an overview of antiparasitic chemotherapy based on taxonomic relationships. Generalizations emerge from this approach that help in organizing an otherwise vast amount of information.

In considering chemotherapy, it is helpful to classify parasitic infections into those caused by helminths, multicellular worms with complex internal structures, and protozoa, single-celled organisms that multiply by cell division. Helminths are further divided into nematodes, or roundworms, which can be grouped into those that live in the gastrointestinal tract and those found elsewhere in the body, and platyhelminths, or flat worms, which are subdivided into cestodes, or tapeworms, and trematodes, or flukes.

The protozoa can be grouped into those that reside under anaerobic conditions in the gastrointestinal tract or vagina and those that live aerobically in the body. The most prevalent systemic protozoan infections are attributable to members of the Apicomplexa, which cause malaria, babesiosis, and toxoplasmosis, and the Kinetoplastida, which are responsible for Chagas' disease, human African trypanosomiasis (sleeping sickness), and leishmaniasis.

Many of the medications used to treat parasitic diseases are not well known by physicians practicing in the United States. They are the focus of this chapter. Some drugs with activity against parasites are also used for the treatment of bacterial or fungal infections and are discussed elsewhere (Chapters 295 and 339). Detailed descriptions of antiparasitic drugs are available in textbooks of infectious diseases and tropical medicine. An excellent compilation of therapeutic recommendations for parasitic diseases is available in tabular form in *The Medical Letter on Drugs and Therapeutics*, "Drugs for Parasitic Infections" (available at www.medicalletter.org). A number of antiparasitic drugs are readily available in the United States, whereas others can be obtained from the manufacturer, special pharmacies, or the Centers for Disease Control and Prevention (CDC) Drug Service. Many are approved by the Food and Drug Administration (FDA), but some are available only on an investigational basis.

TREATMENT OF HELMINTHS

Intestinal Roundworms (Nematodes)

Soil-transmitted intestinal roundworms (Chapter 365) are among the world's most prevalent parasites, and there are good therapeutic options for them. They are found in impoverished areas where sanitation is poor. *Ascaris lumbricoides*, the hookworms *Ancylostoma duodenale* and *Necator americanus*, and *Trichuris trichiura* each infect more than a billion people worldwide. Many residents of these areas harbor more than one soil-transmitted pathogen. Though frequently subclinical, infections can cause malnutrition, iron deficiency anemia, decreased growth, and poor performance in school or at work. *Strongyloides stercoralis* is less prevalent, but unique among common intestinal roundworms in its ability to produce autoinfection and persist for decades. Disseminated hyperinfection can occur in persons concurrently infected with human T-cell lymphotropic virus type 1 (HTLV-1), receiving corticosteroids, or immunocompromised by neoplasm, malnutrition, or other conditions. *Enterobius vermicularis*, the pinworm, infects children and occasionally adults worldwide.

Albendazole has a broad spectrum of activity against intestinal roundworms. It is active against *A. lumbricoides*, the hookworms, and *T. trichiura*. Administered as a single 400-mg dose, it has been used successfully in mass treatment programs in developing areas. However, reinfection is common and treatment is often repeated at 3- to 4-month intervals. Daily doses of albendazole for 3 days are recommended for those with heavy *T. trichiura* infection. Twice-daily doses of albendazole, 400 mg for 7 days, are used as an alternative to ivermectin for the treatment of *S. stercoralis* infections. Failures can occur with either drug, and they are often used together for longer periods to treat those with disseminated infection. Albendazole is effective against the pinworm *Enterobius vermicularis* in a single dose that is repeated in 2 weeks. It is used for cutaneous larva migrans, which is caused by migrating stages of *Ancylostoma braziliense* and other intestinal helminths of animals. It is the drug of choice for trichinosis, and it is an alternative for the treatment of *Trichostrongylus* species and *Capillaria philippinensis*.

Mebendazole, administered twice daily at a dosage of 100 mg orally for 3 days, has a similar spectrum of activity as albendazole against *A. lumbricoides*, hookworms, and *T. trichiura*. In this regimen it is more effective than a single dose of albendazole and is considered the treatment of choice for *T. trichiura*. A single 500-mg dose of mebendazole has been used in mass treatment programs. It is effective in treating pinworm when given at 100 mg orally in one dose followed by a second dose after 2 weeks. It is an alternative to albendazole for the treatment of trichinosis. Mebendazole is poorly absorbed and not effective against *S. stercoralis*.

Pyrantel pamoate is a relatively safe, poorly absorbed drug with activity against *A. lumbricoides*, hookworms, and pinworms, but it is not effective against *T. trichiura* or *S. stercoralis*. When used for pinworms, it is administered as an oral suspension at a dose of 11 mg/kg (to a maximum of 1 g), which is repeated after 2 weeks.

Ivermectin at an oral dose of 200 μg/kg daily for 2 days is considered the treatment of choice for *S. stercoralis*. It is also effective against cutaneous larva migrans and *A. lumbricoides*, but not hookworms. It is considered an alternative to mebendazole for the treatment of *T. trichiura*. Albendazole, mebendazole, pyrantel pamoate, and ivermectin replaced a number of older anthelmintics that were more toxic, such as piperazine and thiabendazole, or less effective for the treatment of intestinal roundworms.

Systemic Roundworms (Nematodes)

Diethylcarbamazine is the drug of choice for filarial infections (Chapter 366) caused by *Wuchereria bancrofti*, *Brugia malayi*, *Brugia timori*, and *Loa loa*, as well as for persons with tropical pulmonary eosinophilia. It promotes the host's killing of microfilariae of these species and also damages or kills the adult worms. Inflammatory side effects are common and due in part to the release of lipopolysaccharide from endosymbiotic *Wolbachia* bacteria within dying filaria. *Wolbachia* is necessary for filarial development, and it is a potential drug target. Long-term therapy with doxycycline has been shown to result in their elimination and decreased microfilariae. In heavy *L. loa* infections, encephalopathy may result following treatment with diethylcarbamazine. Apheresis or treatment with albendazole is used first to reduce the microfilarial burden in those heavily infected. Diethylcarbamazine can be used prophylactically for *L. loa*. Ivermectin has activity against the microfilariae of *W. bancrofti*, *Brugia* species, and *L. loa*, but it does not kill adult worms and is not recommended for these diseases.

Ivermectin is the treatment of choice for onchocerciasis. It is administered as a single dose of 150 μg/kg. It does not kill adult *Onchocerca volvulus*, but it decreases ova production and reduces microfilariae in the skin and eyes. Retreatment is usually necessary at 6- to 12-month intervals. Profits from the use of ivermectin for treatment of the dog heartworm *Dirofilaria immitis* have permitted the manufacturer to provide the drug free to persons with onchocerciasis in developing areas. Diethylcarbamazine should not be used for onchocerciasis. It kills the microfilariae of *O. volvulus* rapidly but can result in severe ocular and systemic inflammatory responses, known as the Mazzotti reaction. Ivermectin is associated with less rapid killing and less severe reactions.

Tapeworms (Cestodes)

Praziquantel has a broad spectrum of activity against tapeworms (Chapter 362) and flukes. It is the drug of choice for adult tapeworms in the human intestinal tract. It is effective against *Taenia solium* (pork tapeworm), *Taenia saginata* (beef), *Diphyllobothrium latum* (fish), and *Hymenolepis nana* (dwarf tapeworm) when administered as a single dose. Niclosamide, which is not absorbed, is an effective alternative for the treatment of *T. saginata* and *D. latum*. It also kills adult *T. solium*, but disintegration of the worm and release of viable ova into the intestinal lumen raise the theoretical possibility of autoinfection. In the case of *H. nana*, a dose of nitazoxanide, 500 mg daily for 3 days, provides an alternative to praziquantel. It also has activity against *T. saginata* and potentially other tapeworm species.

Neurocysticercosis caused by the larval or tissue phase of *T. solium* is a major cause of seizures and other central nervous system (CNS) abnormalities in residents of and immigrants from endemic areas in Latin America and elsewhere. Symptoms can result from the physical presence of cysticerci, but the inflammation elicited by the release of antigens from dying cysticerci is often more important. Both albendazole and praziquantel are capable of killing cysticerci in the brain; albendazole is the drug of choice

for pharmacokinetic reasons. Their use depends on the clinical syndrome. Corticosteroids are administered concurrently—and sometimes alone—to reduce the inflammatory response and the increase in intracranial pressure associated with it. Albendazole is administered for 8 to 30 days at 400 mg twice a day. Praziquantel is administered at 100 mg/kg in three divided doses the first day and then at 50 mg/kg in three divided doses for 29 days. The concurrent use of corticosteroids increases the serum level of albendazole but decreases that of praziquantel. Neither albendazole nor praziquantel should be used if cysticerci are present in the eye or spinal cord because the release of antigens can trigger a locally destructive inflammatory reaction.

Albendazole is the drug of choice for persons with echinococcosis. Administered at a dose of 400 mg twice daily for adults, generally for 1 to 6 months, albendazole can cure approximately a third of persons with uncomplicated *Echinococcus granulosus* liver cysts. Albendazole is also administered before ultrasound-guided percutaneous aspiration-injection-reaspiration (PAIR) of cysts or surgical approaches to prevent seeding of the peritoneum should the cyst's contents spill. Finally, albendazole is used for suppression of inoperable *E. granulosus* and *Echinococcus multilocularis* disease.

Flukes (Trematodes)

Praziquantel is the drug of choice for the treatment of all forms of schistosomiasis (Chapter 363), as well as intestinal, lung, and liver flukes (Chapter 364), with the exception of the liver fluke *Fasciola hepatica*. For schistosomiasis, two or three doses are given in 1 day depending on the species. The flukes are treated with three doses on 1 or 2 days, depending on the species. Oxamniquine is an alternative for *Schistosoma mansoni*, but it is more toxic and less effective. Higher doses of oxamniquine are recommended for *S. mansoni* infections acquired in areas of Egypt or equatorial Africa where the parasite is less susceptible. Either praziquantel or albendazole can be used to treat the liver fluke *Clonorchis sinensis*. *F. hepatica* responds to the veterinary agent triclabendazole. Bithionol, which is more toxic, and nitazoxanide are alternatives.

Drugs Used for Helminthic Infections

Albendazole is poorly soluble in water, but it is well absorbed when administered with a fatty meal. It undergoes rapid first-pass metabolism in the liver to albendazole sulfoxide, which has excellent anthelmintic activity. The serum half-life of albendazole sulfoxide is 8 to 9 hours. Elimination of albendazole sulfoxide and other metabolites is achieved primarily through the kidney. Albendazole binds to tubulin in susceptible parasites, inhibits microtubule assembly, and decreases glucose absorption. It does not affect human tubulin. It also inhibits fumarate reductase in helminths. Concurrent administration of dexamethasone, which is frequently given to prevent cerebral edema in persons with neurocysticercosis, increases serum levels by approximately 50%. The cerebrospinal fluid (CSF) concentration of albendazole is 40% of that in serum.

Albendazole is generally well tolerated when given as a single dose for the treatment of intestinal nematode infections, although gastrointestinal discomfort may develop or patients may experience migration of adult *A. lumbricoides* from the nose or mouth or in stool. Albendazole is contraindicated in persons with cysticerci in the eye or spinal cord, and corticosteroids are administered concurrently in those being treated for neurocysticercosis. High-dose, prolonged therapy with albendazole, such as that recommended for echinococcal disease, can be complicated by alopecia, bone marrow suppression, which is usually reversible after discontinuation of use of the drug, or hepatocellular injury. Albendazole is embryotoxic in animals and contraindicated during pregnancy.

Mebendazole is only slightly soluble in water and is relatively poorly absorbed from the gastrointestinal tract. This is advantageous for the treatment of intestinal parasites but limits its effectiveness against tissue-dwelling helminths. Absorbed drug is metabolized in the liver and excreted in urine. Mebendazole selectively binds to helminthic tubulin, blocks its assembly into microtubules, and inhibits glucose uptake, thereby leading to depletion of glycogen stores and ultimately death of the parasite. It is relatively well tolerated in the doses used to treat intestinal helminths. Transient abdominal pain and diarrhea occur in a small number of recipients. Mebendazole is contraindicated during pregnancy.

Ivermectin is a macrocyclic lactone produced by *Streptomyces avermitilis*. It has a broad spectrum of activity against helminths and arthropods, including *Sarcoptes scabiei*, the cause of scabies. It is well absorbed after oral administration. Ivermectin is highly protein bound, has a serum half-life of 12 hours, and accumulates in adipose tissue and the liver. It is subject to enterohepatic recirculation and ultimately eliminated in stool. Ivermectin activates the opening of gated chloride channels in susceptible helminths and arthropods. The result is an influx of chloride ions and paralysis of the pharyngeal pumping mechanism of helminths. Ivermectin is generally well tolerated in humans, although inflammatory reactions can result in response to antigens released from dying parasites.

Diethylcarbamazine, a piperazine derivative, is well absorbed orally and has a half-life of 8 hours. The parent drug and its metabolites are excreted through the kidney. Although the mechanism of action is uncertain, the piperazine moiety may result in paralysis of sensitive helminths. Diethylcarbamazine also alters the surface membranes of sensitive microfilariae, thereby resulting in destruction by the host's immune system. Side effects include those caused by the drug and those that result from release of the parasite's antigens and lipopolysaccharide from filaria-harbored, endosymbiotic *Wolbachia*. Adverse effects include nausea, vomiting, anorexia, headache, malaise, weakness, arthralgias, and rarely, acute psychotic reactions. In patients with lymphatic filariasis, localized swelling or nodules may develop along the lymphatics during treatment, or transient lymphedema or hydrocele formation may occur.

Praziquantel is well absorbed after oral administration. It undergoes extensive first-pass metabolism, and the metabolites, which are inactive, are excreted in urine. Praziquantel is approximately 80% protein bound, with a serum half-life of 4 to 6 hours. It is rapidly taken up by susceptible cestodes and trematodes. In the case of schistosomes, praziquantel damages the tegument, which results in intense vacuolation and increased permeability to calcium. Adult schistosomes are paralyzed and translocated to the liver through the portal circulation. Sequestered antigens are exposed on their surface, thereby permitting binding of antibodies and phagocytes and immune destruction. Praziquantel is an alternative to albendazole for the treatment of neurocysticercosis. The concurrent administration of corticosteroids, which are necessary to decrease inflammation and edema in the brain, reduces the serum concentration of praziquantel. Its concentration in CSF is approximately 15 to 20% of that in serum.

Praziquantel is frequently associated with mild, transient side effects, including headaches, lassitude, dizziness, nausea, vomiting, and abdominal discomfort, but they are seldom severe enough to interrupt therapy. Untoward reactions attributed to release of the parasite's antigens have been reported in patients treated for schistosomiasis and pulmonary paragonimiasis. Increased intracranial pressure resulting from release of cysticercal antigens is a potentially life-threatening consequence in patients receiving praziquantel for neurocysticercosis. Corticosteroids should be administered concurrently. Praziquantel is contraindicated in persons with cysticerci in the eye or spinal cord.

TREATMENT OF PROTOZOAL DISEASES

Intestinal and Vaginal Protozoa

Several major luminal pathogens, *Entamoeba histolytica* (Chapter 360), *Giardia lamblia* (Chapter 359), and *Trichomonas vaginalis* (Chapter 361), live in anaerobic conditions in the intestine or vagina and are susceptible to metronidazole and tinidazole. The latter has favorable pharmacodynamics and is generally better tolerated. Because neither metronidazole nor tinidazole reliably eradicates cysts of *E. histolytica*, either paromomycin or iodoquinol, which are active in the lumen of the bowel, is administered as well. Either one of these drugs or diloxanide furoate can be used alone to treat persons with asymptomatic cyst excretion.

Giardiasis can also be treated with nitazoxanide. It is well tolerated, and an oral formulation is available for children. Nitazoxanide is the only drug available for the treatment of cryptosporidiosis (Chapter 358). It is effective in immunocompetent persons, but not usually in those with acquired immunodeficiency syndrome (AIDS). Trimethoprim-sulfamethoxazole, which inhibits successive steps in the folic acid pathway, is the drug of choice for *Cystoisospora* (*Isospora*) *belli* and *Cyclospora cayetanensis*. Ciprofloxacin, a fluoroquinolone antibiotic, is an alternative. Tetracycline is the treatment of choice for *Balantidium coli*; metronidazole and iodoquinol are alternatives. Finally, albendazole is effective in the treatment of intestinal and disseminated microsporidiosis caused by *Encephalitozoon* (*Septata*) *intestinalis* and some, but not all other microsporidial species that cause disease in persons with AIDS.

Metronidazole, a nitroimidazole, is rapidly absorbed after oral administration and has a half-life of 8 hours. More than half of each dose is metabolized in the liver. The metabolites and remaining parent drug are excreted in urine.

Metronidazole is activated by reduction of its 5-nitro group through a sequence of intermediate steps involving microbial electron transport proteins of low redox potential. It is concentrated in susceptible anaerobic organisms and serves as an electron sink. Nausea, vomiting, diarrhea, and a metallic taste are often associated with the use of metronidazole. They are less common with the lower doses recommended for the treatment of giardiasis than with the higher doses used for amebiasis. Other untoward effects include headache, dizziness, vertigo, and numbness. Potentially severe disulfiram-like reactions occur in patients who ingest alcohol while taking metronidazole.

Tinidazole, another 5-nitroimidazole, has a similar mechanism of action and spectrum of activity as metronidazole, but more favorable pharmacodynamics, and is generally better tolerated. It has been used widely around the world for the treatment of giardiasis, intestinal amebiasis, and trichomoniasis. In comparison to metronidazole, it has a longer half-life, a shorter and less complicated dosing regimen, and fewer gastrointestinal side effects. It, too, can cause severe disulfiram-like reactions after alcohol ingestion.

Nitazoxanide, a 5-nitrothiazole salicylamide derivative, has a broad spectrum of activity against protozoa and helminths. It is formulated as a liquid for use in children. Nitazoxanide is well absorbed orally and hydrolyzed to its active metabolite tizoxanide, which undergoes conjugation to tizoxanide glucuronide. The parent compound is not detectable in serum. Maximum concentrations of the metabolites are observed in 1 to 4 hours. They are excreted in urine and bile. Tizoxanide is highly protein bound. Although its mechanism of action is uncertain, tizoxanide inhibits pyruvate:ferredoxin oxidoreductase–dependent electron transport reactions essential for the metabolism of susceptible anaerobic organisms. It is very well tolerated in children and adults.

Malaria: Prophylaxis and Treatment

As discussed in this section, a number of drugs are available for the prophylaxis and treatment of malaria. Most act against *Plasmodium* stages within erythrocytes. Only primaquine kills *Plasmodium vivax* and *Plasmodium ovale* hypnozoites in the liver. The antimalarial drug of choice depends on the geographic site visited and the *Plasmodium* species encountered (Chapter 353). Antimicrobial resistance is now widespread among *Plasmodium falciparum* isolates and well documented in *P. vivax* from some regions. Country-specific recommendations for prophylaxis and treatment are provided by the CDC at *www.cdc.gov/travel/* and in "CDC Health Information for International Travel 2010." Major recent additions to the therapeutic armamentarium in the United States include the fixed drug combination of artemether plus lumefantrine (Coartem), which is used for the oral treatment of acute malaria acquired in areas with chloroquine-resistant *P. falciparum*, and artesunate for intravenous administration in those with severe malaria who cannot take oral medications and for whom quinidine is contraindicated or not available. Artesunate can be obtained from the CDC on an emergency basis as an investigational new drug.

Chloroquine, a 4-aminoquinoline, has a bitter taste but is well absorbed from the gastrointestinal tract. Its half-life, which varies among persons, averages 4 days, thus permitting once-weekly administration for prophylaxis. Chloroquine is concentrated in the hemoglobin-containing digestive vesicles of asexual intraerythrocytic parasites. It inhibits the parasite's heme polymerase that incorporates ferriprotoporphyrin type IX complexes, which are potentially toxic to the parasite, into insoluble, nontoxic, crystalline hemozoin. Chloroquine-resistant strains of *P. falciparum* actively transport chloroquine out of the intraparasitic compartment. Although this action can be blocked by calcium-channel inhibitors in vitro, chloroquine resistance has not been effectively reversed in humans. Hydroxychloroquine (Plaquenil), which is used for rheumatologic diseases, is also effective against chloroquine-sensitive *Plasmodium* species.

Chloroquine is generally well tolerated when used at the doses recommended for the prophylaxis and treatment of malaria. Side effects include headache, nausea, vomiting, blurred vision, dizziness, and fatigue. Some Africans and African Americans experience pruritus, which responds to antihistamines. Rare side effects include depigmentation of hair, exacerbation of psoriasis, blood dyscrasias, seizures, neuropsychiatric effects, and reactions in persons with porphyria. Retinal damage has occurred in persons receiving chloroquine at high doses for the treatment of rheumatologic disorders, but it has not been documented as a problem in those taking it weekly over a period of many years for malaria prophylaxis. Cardiopulmonary collapse and death have occurred after accidental overdose and in adults attempting suicide. As little as 5 g of chloroquine can be fatal unless treatment is initiated with mechanical respiration, diazepam to control seizures, and blood pressure support.

Doxycycline taken daily provides effective prophylaxis against all *Plasmodium* species. It is begun 1 to 2 days before departure and continued during the time of exposure and for 4 weeks after leaving the malaria-endemic area. Doxycycline or tetracycline is also often administered with quinine for the treatment of acute chloroquine-resistant malaria, but neither drug acts rapidly enough to be used alone for treatment. Doxycycline is generally well tolerated, although it can cause gastrointestinal symptoms and "pill" esophagitis. To avoid the latter, it should be taken with a full glass of water, and the recipient should remain upright for an hour or more after ingestion. Other potential side effects include photosensitivity dermatitis, *Candida albicans* vaginitis, and antibiotic-associated colitis. Finally, tetracyclines should not be used in children younger than 8 years or during pregnancy.

Atovaquone plus ***proguanil*** (Malarone; adult tablets contain 250 mg of atovaquone and 100 mg of proguanil) is used for prophylaxis in areas with chloroquine-resistant *P. falciparum* and other *Plasmodium* species. Atovaquone is a highly lipophilic compound with low aqueous solubility. Administration with food enhances its absorption two-fold. Plasma concentrations do not increase proportionately with dose. Atovaquone is highly protein bound with a half-life exceeding 60 hours. It undergoes extensive enterohepatic cycling and is eventually excreted unchanged in feces. Atovaquone selectively inhibits electron transport in the mitochondria of susceptible *Plasmodium* species at the level of the cytochrome bc_1 complex, which results in collapse of mitochondrial membrane potential. It also affects pyrimidine biosynthesis, which is obligatorily coupled to electron transport in *Plasmodium*. Resistance develops rapidly when atovaquone is used alone to treat malaria. Atovaquone is generally well tolerated but can cause nausea, vomiting, diarrhea, rash, and pruritus.

Proguanil is absorbed slowly after oral administration. Its serum level falls to zero within 24 hours, so it must be administered daily. Its triazine metabolite, cycloguanil, inhibits dihydrofolate reductase in susceptible *Plasmodium* species. Resistance is well documented when proguanil is used alone. Proguanil also acts synergistically with atovaquone to collapse mitochondrial membrane potential in susceptible *Plasmodium* species.

The combination of atovaquone and proguanil (Malarone) is considered the best tolerated of the options for prevention of chloroquine-resistant malaria, but the most expensive. It is begun 1 to 2 days before departure and continued during the time of exposure and for 7 days thereafter. Higher doses are administered over a period of 3 days to treat acute, uncomplicated malaria. Potential side effects include abdominal pain, nausea, vomiting, diarrhea, headache, pruritus, and rash. Asymptomatic, transient elevations in liver enzymes have been observed with treatment doses.

Mefloquine, a quinoline methanol compound derived from quinine, was once used widely for the prophylaxis and occasionally treatment of chloroquine-resistant *P. falciparum* malaria. Concern about neuropsychiatric and other toxicities and the availability of better-tolerated alternatives have limited its use in recent years. Mefloquine is available for oral administration only. Slowly and incompletely absorbed, it is 99% protein bound. It has a variable half-life ranging from 6 to 23 days with a mean of approximately 14 days. It is metabolized and excreted slowly through bile and feces.

Considerable attention has been paid to the untoward effects of mefloquine. It is reasonably well tolerated in most recipients, although it can cause nausea, dizziness, vivid dreams, fatigue, and lassitude. Less common, but of substantial concern are neuropsychiatric reactions, including anxiety, depression, and acute psychosis. It can also cause seizures. Mefloquine is therefore contraindicated in persons with a history of epilepsy or psychiatric disorders. It can also depress atrioventricular conduction and should not be used in persons taking β-blockers for cardiac indications. It has antibacterial activity and can inactivate the live oral typhoid vaccine (*Salmonella typhi* Ty21a) if administered concurrently. Rare side effects include exfoliative erythroderma, agranulocytosis, and paresthesias. Mefloquine is not approved by the U.S. FDA for use during pregnancy or in children weighing less than 15 kg, but it has been used in situations in which potential benefits were judged to outweigh the risks.

Primaquine, an 8-aminoquinoline, eradicates the hepatic hypnozoite stage of *P. vivax* and *P. ovale* and is used at the end of treatment or for prophylaxis with other drugs to prevent late relapse in persons who are or may be infected with these *Plasmodium* species. It is also effective when used daily for prophylaxis for all *Plasmodium* species. It is begun 1 or 2 days before exposure and continued during and for 7 days after the traveler leaves the endemic area.

Primaquine is well absorbed orally and rapidly converted to carboxyprimaquine, which has a half-life of approximately 7 days. Primaquine is generally well tolerated, although some recipients experience abdominal cramps, epigastric distress, and nausea. The major concern is hemolysis in persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Chapter 164). The G6PD status of the recipient should be determined before it is administered. Rarely, primaquine causes neutropenia, methemoglobinemia, hypertension, or arrhythmias. Primaquine is contraindicated during pregnancy and in breast-feeding mothers because life-threatening hemolysis may occur if the fetus or baby is deficient in G6PD. Travelers should be warned not to give the drug to fellow travelers who have not been screened for G6PD deficiency.

Quinine sulfate, a cinchona alkaloid, is the oldest of the antimalarials. It has a very bitter taste. It is rapidly absorbed after oral administration and has a half-life of 16 to 18 hours in persons with malaria. Quinine has the poorest therapeutic-to-toxicity ratio of any antimalarial drug. The side effects, known collectively as cinchonism, include tinnitus, decreased hearing, headache, nausea, vomiting, dysphoria, and visual disturbances. They are dose related and reversible. Quinine has also been associated with severe hypoglycemia in persons with heavy *P. falciparum* infection as a result of the utilization of glucose by the parasites and release of insulin from the pancreas. Hypoglycemia can be prevented or treated by the intravenous administration of glucose. Rare complications with quinine include massive hemolysis in patients with heavy *P. falciparum* infection resulting in hemoglobinuria and renal failure (blackwater fever), cutaneous hypersensitivity reactions, agranulocytosis, and hepatitis. Quinine can cause respiratory paralysis in persons with myasthenia gravis. It stimulates uterine contractions and can produce abortions, but it has saved the lives of many pregnant women with *P. falciparum* malaria. Quinine dihydrochloride given intravenously can cause myocardial depression, peripheral vascular collapse, respiratory depression, and potentially death.

Quinidine gluconate, the stereoisomer of quinine, is recommended for the intravenous treatment of patients with acute malaria who cannot take quinine or other antimalarials orally. Quinidine gluconate was once widely used for the treatment of ventricular ectopy, but it has been replaced by newer antiarrhythmic agents, which has decreased its availability in many hospitals. Side effects include prolongation of the QT interval, arrhythmias, and hypotension, particularly if it is infused too rapidly. Persons receiving intravenous quinidine should be monitored in an intensive care setting, and therapy should be switched to an oral antimalarial medication as soon as possible.

Artemether, ***artesunate***, and other artemisinin derivates are sesquiterpene lactones derived from the wormwood plant *Artemisia annua*, from which qinghaosu, the Chinese herbal medication for malaria, is also derived. They are endoperoxide-containing compounds. In the presence of intraparasitic iron, they are converted into free radicals and other intermediates that alkylate specific malarial proteins and act rapidly to kill intraerythrocytic parasites. They have been used widely around the world for the treatment of acute malaria caused by chloroquine-resistant *P. falciparum*, as well as other *Plasmodium* species. The artemisinins are usually administered with a second antimalarial drug that has a different mechanism of action and longer half-life to prevent the development of resistance. The route of administration with artemisinins varies; some are well absorbed orally, whereas others are administered intravenously, intramuscularly, or by suppository. Their short half-lives preclude their use for prophylaxis. Adverse effects in humans are infrequent and usually mild. Neurologic toxicity and cerebellar dysfunction have been observed in dogs receiving chronic, high-dose therapy.

Artemether plus lumefantrine (Coartem), a fixed drug combination, was recently approved by the FDA for oral use in the United States. In addition, intravenous artesunate is available from the CDC as an investigational new drug for the treatment of acute malaria in persons who cannot take quinidine gluconate or in situations in which it is not available. Side effects with Coartem include headache, dizziness, anorexia, and weakness. Rare hypersensitivity reactions include urticaria, angioedema, and bullous eruptions. Lumefantrine inhibits CYP206 and can reduce the metabolism of medications that prolong the QT interval, so care must be taken in reviewing the recipient's medication list.

Toxoplasmosis and Babesiosis

Toxoplasma gondii (Chapter 357) and *Babesia* species (Chapter 361) are other important pathogens of the phylum Apicomplexa. Pyrimethamine and sulfadiazine are recommended for the treatment of toxoplasmosis. They inhibit sequential steps in the folic acid metabolic pathway. Pyrimethamine preferentially inhibits dihydrofolate reductase in susceptible parasites. It is well absorbed orally. The major side effect is macrocytic anemia, which can be prevented by the concurrent administration of leucovorin. Sulfonamides reduce the activity of dihydropteroate synthetase and the binding of *p*-aminobenzoic acid to it. In ocular toxoplasmosis with macular involvement, corticosteroids are indicated along with anti-*Toxoplasma* therapy to minimize the local inflammatory response. Clindamycin plus pyrimethamine and atovaquone plus pyrimethamine are therapeutic options in sulfonamide-intolerant patients. For prophylaxis in persons with AIDS and $CD4^+$ counts less than 100, options include daily trimethoprim-sulfamethoxazole, pyrimethamine plus dapsone, pyrimethamine plus atovaquone, or atovaquone alone. Spiramycin, a macrolide, is used for the treatment of toxoplasmosis during pregnancy. Two therapeutic regimens are available for babesiosis. The greatest experience has been with the combination of clindamycin plus quinine, but side effects are common. Atovaquone plus azithromycin is effective and better tolerated (Chapter 361).

CHAGAS' DISEASE, AFRICAN TRYPANOSOMIASIS, AND LEISHMANIASIS

The trypanosomes *Trypanosoma cruzi*, the cause of Chagas' disease, and *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*, the cause of human African trypanosomiasis (sleeping sickness), pose difficult therapeutic challenges. Nifurtimox and benznidazole orally are the only drugs available to treat *T. cruzi* (Chapter 355). Benznidazole has been used widely in endemic areas in Latin America and nifurtimox in the United States. They lower mortality and shorten the duration of acute Chagas' disease. Treatment is also recommended for asymptomatic children and younger adults with recent or indeterminate-stage *T. cruzi* infection. The percentage of those who are parasitologically cured has been debated. Neither benznidazole nor nifurtimox can reverse the manifestations of chronic Chagas' disease. Side effects are common with both drugs and increase in frequency and severity with age. Benznidazole is associated with allergic dermatitis, peripheral neuropathy, insomnia, and gastrointestinal symptoms, including anorexia and weight loss. Nifurtimox causes anorexia, nausea, vomiting, weight loss, headache, dizziness or vertigo, paresthesias, weakness, and polyneuropathy.

Suramin, pentamidine, eflornithine, and melarsoprol are used for the treatment of human African trypanosomiasis (Chapter 354). Suramin is recommended for the hemolymphatic stage of *T. brucei rhodesiense* infection, and melarsoprol is used in those with CNS involvement. Both drugs are associated with potentially severe side effects. Eflornithine, which is much better tolerated, is effective against both the hemolymphatic and CNS stages of *T. brucei gambiense* infection. It does not have activity against *T. brucei rhodesiense*. Unfortunately, eflornithine is costly and not available in many endemic areas, and supplies are limited. When eflornithine is not available, pentamidine, which has substantial untoward effects, is used for the hemolymphatic stage of *T. brucei gambiense* infection, with suramin being used as an alternative, and melarsoprol is used for CNS disease.

Liposomal amphotericin B (AmBisome) is the only drug approved for the treatment of visceral leishmaniasis (Chapter 356) in the United States. Amphotericin B deoxycholate is also effective. Liposomes deliver amphotericin to macrophages and are theoretically attractive because leishmaniae reside within them. Liposomal amphotericin is also better tolerated than the parent drug. Other lipid-associated amphotericin B preparations appear to be effective, but they have been less extensively studied and are not FDA approved for this indication. For many years two pentavalent antimony drugs, stibogluconate sodium and meglumine antimoniate, were used to treat visceral leishmaniasis, but resistance is now common among *Leishmania donovani* isolates in India, and therapeutic failures occur in other areas. Side effects increase with age and include gastrointestinal complaints, pancreatitis, myalgias, headache, malaise, elevated liver enzyme levels, and occasionally, bone marrow suppression. Nonspecific ST-T wave changes are common. Sudden death has been reported in persons receiving more than the recommended dose. Miltefosine, a phosphocholine analogue that was developed as an antineoplastic drug, has been used effectively for antimony-resistant visceral leishmaniasis in India and is being studied in other areas. It is the only antileishmanial drug that can be administered orally. There is concern that resistance will develop. Miltefosine is relatively well tolerated, but nausea, vomiting, and motion sickness occur, particularly at higher doses. Elevations in liver enzymes, blood urea nitrogen, and creatinine occur but usually resolve with continuation of the drug. Miltefosine is contraindicated during

pregnancy. Intravenously administered paromomycin has also been reported to be effective against antimony-resistant visceral leishmaniasis in India.

Treatment of cutaneous leishmaniasis depends on the size and location of the skin lesion or lesions, the infecting *Leishmania* species, and its propensity to cause mucosal disease. Consensus is lacking regarding optimal therapy. Stibogluconate sodium and meglumine antimoniate have been used widely. Miltefosine has been reported to be effective in limited studies and has the advantage of oral administration. Paromomycin has been used topically with methylbenzethonium chloride in soft white paraffin for the treatment of cutaneous leishmaniasis caused by *Leishmania major* and other species not associated with mucosal disease. The imidazole antifungals ketoconazole, itraconazole, and fluconazole vary in their activity against different *Leishmania* species but have been reported to be effective in some trials. Liposomal amphotericin B, amphotericin B deoxycholate, and pentamidine are effective, but more toxic alternatives. Other options include immunotherapy, cryotherapy, and local application of heat. Mucosal leishmaniasis is less responsive than cutaneous leishmaniasis to treatment, and relapses are common. Therapeutic options include stibogluconate sodium, meglumine antimoniate, amphotericin B, and miltefosine.

MALARIA

PHILIP J. ROSENTHAL AND MOSES R. KAMYA

DEFINITION

Malaria is caused by infection with protozoan parasites of the genus *Plasmodium,* all of which are transmitted by bites of infected anopheline mosquitoes. Malaria is typically characterized by an acute febrile illness, with parasites infecting large numbers of erythrocytes, and classically entails recurrent episodes of fever and chills. It was first described thousands of years ago and is named on the basis of the belief that it was caused by the bad air of the marshes surrounding Rome. Malaria is common, causing hundreds of millions of illnesses each year throughout most of the tropics. Severe disease can occur, primarily with *Plasmodium falciparum* infection, with the acute development of serious organ dysfunction or when chronic and repeated infection leads to severe anemia. Falciparum malaria kills about 1 million people each year, mostly children in sub-Saharan Africa.

The Pathogen

P. falciparum is responsible for most episodes of severe malaria. It is endemic in most malarious areas and is by far the predominant species in Africa. *Plasmodium vivax* is about as common as *P. falciparum,* except in Africa, but causes severe disease much less commonly. However, studies suggest that severe illness associated with *P. vivax* infection is more common than had previously been appreciated. *Plasmodium ovale* and *Plasmodium malariae* are much less common causes of disease and generally do not cause severe illness. It was recently shown that a fifth parasite causing human infections is *Plasmodium knowlesi*, a parasite of macaque monkeys that is a fairly common zoonosis in parts of Southeast Asia and has been responsible for malarial illnesses, including severe disease, in individuals exposed to macaque-biting vectors in forested areas.

EPIDEMIOLOGY

Malaria in Endemic Countries

Malaria is the most important parasitic disease of humans, causing hundreds of millions of illnesses and approximately a million deaths each year. The disease is endemic in most of the tropics, including many parts of South and Central America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, and Oceania. Transmission, morbidity, and mortality are greatest in Africa, where infection with *P. falciparum* predominates. In most other endemic areas, disease caused by both *P. falciparum* and *P. vivax* is common. In highly endemic areas, the group at greatest risk is young children, who suffer most episodes of disease and the most deaths. A second high-risk group is pregnant women, with high risks of maternal and fetal morbidity from falciparum malaria, including many deaths secondary to low birthweight. In highly endemic areas, in addition to extensive mortality, malaria exerts a massive toll through adverse effects on child development, contributions to school and work absenteeism, and, overall, billions of dollars in lost income among the poorest citizens of the poorest countries of the world. In areas of developing countries with lower levels of malaria transmission, malaria can be epidemic, with intermittent increases in transmission that cause major morbidity in relatively nonimmune populations.

Malaria in Travelers

Malaria is also common in travelers of any age from nonendemic areas to the tropics and may be manifested in those who have returned to nonendemic areas up to many months after travel. Indeed, malaria is the most common documented cause of febrile illness in travelers returning from the tropics to developed countries. Malaria is also rarely transmitted in areas considered nonendemic, including the United States, when imported parasites are transmitted by local anopheline mosquitoes, by blood products, or through congenital spread of infection.

Malaria Transmission

Malaria is transmitted by multiple species of mosquitoes of the genus *Anopheles,* which vary in geographic distribution, ecologic preferences, and susceptibility to mosquito control measures. Anopheline mosquitoes bite at night, and so personal mosquito control measures focus on avoidance of mosquito bites overnight. Levels of malaria transmission in endemic areas vary greatly, from areas where residents experience only rare infectious bites to regions of Africa where individuals may receive hundreds of infectious bites each year.

Recent Changes in the Epidemiology of Malaria

A major effort to eradicate malaria after World War II led to elimination of the disease in many areas, including the United States and Europe, but eventually failed to control the disease in most of the tropics. During the ensuing decades, improvements in malaria control were few, and malarial morbidity worsened in many areas, driven by the loss of enthusiasm for vector control, increasing resistance of mosquitoes to insecticides, and, in particular, resistance of parasites to commonly used antimalarial drugs. Some 50 years later, a new large effort to control and eventually to eradicate malaria has been initiated. Key control measures include indoor residual spraying of insecticides, distribution of insecticide-impregnated bed nets, prompt provision of effective drugs to those with malaria, and targeted intermittent use of drugs to prevent infection in high-risk groups. Recent efforts have led to documented decreases in levels of malarial morbidity and mortality in some areas, notably parts of Africa, Asia, and Oceania with relatively low levels of transmission

intensity. It is of great interest to learn whether recent advances due to intensified control efforts can bring significant improvements to those parts of the world most afflicted with malaria, in particular, highly endemic regions of Africa and Asia.

Malaria and Human Immunodeficiency Virus Infection

Malaria does not differ as markedly between those with human immunodeficiency virus (HIV) infection and others as is the case with typical opportunistic infections. However, several interactions between malaria and HIV infection have been established. First, HIV infection appears to disrupt the acquired immune response to malaria and thereby increases incidence and severity of malaria. Second, acute malaria elevates HIV viral load and so may increase the risk of HIV transmission. Third, HIV infection may be associated with reduced efficacy of antimalarial treatment, especially in the setting of severe immune suppression. Fourth, therapies for each infection may have an impact on the other, leading to unanticipated effects on drug efficacy or toxicity. Fifth, routine interventions for HIV infection may affect the incidence of malaria; notably, daily trimethoprim-sulfamethoxazole, a routine regimen in HIV-infected patients, offers partial protection against malaria. As both HIV infection and malaria are common in many areas, in particular sub-Saharan Africa, even modest associations are important. Thus, malaria coinfection in HIV-infected individuals may be an important factor in promoting the spread of HIV infection in Africa.

PATHOBIOLOGY

Parasite Life Cycle

Malaria is transmitted by the bite of infected female anopheline mosquitoes. During feeding, mosquitoes inject sporozoites, which circulate to the liver and infect hepatocytes, causing asymptomatic liver infection (Fig. 353-1). Merozoites are subsequently released from the liver, and they rapidly infect erythrocytes to begin the asexual erythrocytic stage of infection that is responsible for human disease. Multiple rounds of erythrocytic development, with production of merozoites that invade additional erythrocytes, lead to large numbers of circulating parasites and clinical illness. Each erythrocytic cycle lasts approximately 24 hours for *P. knowlesi*; 48 hours for *P. falciparum*, *P. vivax*, and *P. ovale;* and 72 hours for *P. malariae*. Some erythrocytic parasites also develop into sexual gametocytes, which are taken up by mosquitoes. In the mosquito, gametocytes mature to gametes, and after fusion of male and female gametes to produce zygotes, parasites develop into ookinetes, oocysts, and then salivary gland sporozoites that are infectious for humans, allowing completion of the life cycle and infection of others. *P. vivax* and *P. ovale* also cause a chronic liver infection, in which hypnozoites persist in hepatocytes in a dormant state not eradicated by most therapies for acute disease and subsequently can progress to erythrocytic infection and a relapse of clinical illness.

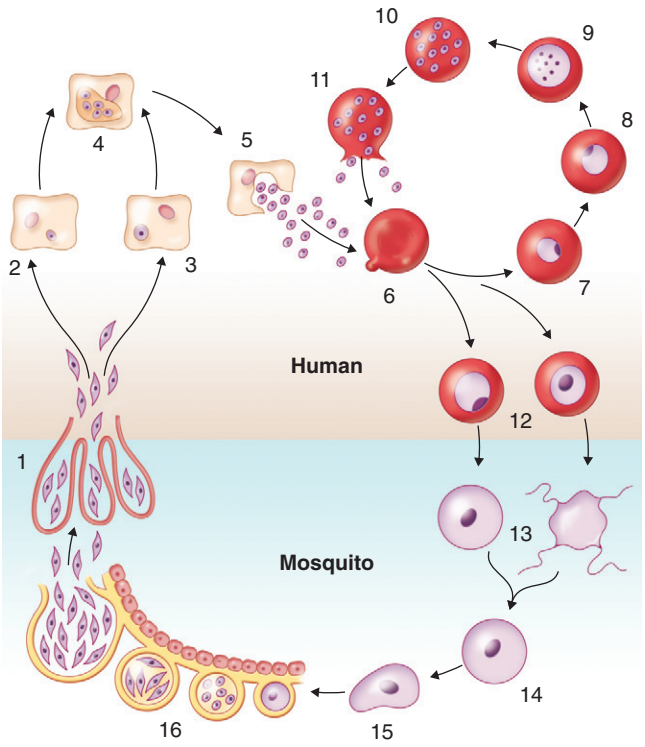

FIGURE 353-1. Life cycle of the malaria parasite. The *upper* and *lower* halves of the diagram indicate the human and anopheline mosquito parts of the cycle, respectively. Sporozoites from the salivary gland of a female *Anopheles* mosquito are injected under the skin (1). They then travel through the blood stream to the liver (2) and mature within hepatocytes to become tissue schizonts (4). Up to 30,000 parasites are then released into the blood stream as merozoites (5) and produce symptomatic infection as they invade and destroy red blood cells. However, in *Plasmodium vivax* and *Plasmodium ovale* infection, some parasites remain dormant in the liver as hypnozoites (3), which can later develop to tissue schizonts and merozoites, leading to relapse. Once within the blood stream, merozoites (5) invade erythrocytes (6) and mature to the ring (7, 8), trophozoite (9), and schizont (10) asexual stages. Mature schizonts lyse their host erythrocytes and release the next generation of merozoites (11), which invade previously uninfected cells. Some erythrocytic parasites differentiate to sexual forms (male and female gametocytes) (12). When taken up by a mosquito, the gametocytes mature to male and female gametes (13), fuse to form zygotes (14), and then develop into ookinetes that invade the gut of the mosquito (15) and develop into oocysts (16). Mature oocysts produce sporozoites, which migrate to the salivary gland of the mosquito (1) to allow another human infection. (From Krogstad DJ: Blood and tissue protozoa. In: Schaechter M, Medoff G, Eisenstein BI, eds. *Mechanisms of Microbial Diseases,* 2nd ed. Baltimore: Williams & Wilkins; 1993:600.)

Pathogenic Features of Malaria Parasites

The most common clinical feature of malaria is fever. Fever coincides with rupture of large numbers of schizont-infected erythrocytes at the completion of the erythrocytic cycle and with high circulating levels of tumor necrosis factor-α. Severe falciparum malaria is associated with very high levels of tumor necrosis factor-α and other inflammatory cytokines, but the specific roles of cytokines in pathogenesis are not well understood. *P. falciparum* infects erythrocytes of all ages, so it is capable of routinely causing high parasitemias, with infection of more than 1% of erythrocytes and more than 10^5 infected erythrocytes per microliter of blood. Non-falciparum parasites infect smaller numbers of erythrocytes, limiting the extent of infection and morbidity. Non-falciparum parasites are more likely to cause highly synchronous infections, leading if untreated to regular cycles of fever every 48 (*P. vivax* and *P. ovale*) or 72 (*P. malariae*) hours, often with minimal symptoms between fever episodes.

The contribution of parasite virulence determinants to the severity of malaria is poorly understood. A key biologic feature of *P. falciparum* infection is the ability of parasites to mediate the adherence of infected erythrocytes to a number of ligands on endothelial cells. By this mechanism, erythrocytes infected with the more mature stages of erythrocytic parasites do not circulate but rather adhere within small blood vessels in the brain and other organs. This phenomenon, termed cytoadherence, allows parasites to avoid passing through the spleen, where abnormal erythrocytes would be cleared. Cytoadherence is also likely to play a major role in mediating severe manifestations of falciparum malaria, with local inflammatory changes mediated by large numbers of adherent parasites leading to organ dysfunction. In particular, falciparum malaria can progress to cerebral malaria, including coma; noncardiogenic pulmonary edema, including severe respiratory compromise; and renal failure, severe anemia, acidosis, hypoglycemia, and other syndromes of organ dysfunction. Pregnancy selects for a subset of *P. falciparum* strains that specifically bind to ligands in the placenta. Pregnant women in endemic areas, in particular those in their first pregnancy who lack antibodies specific for placenta-binding parasites, are at high risk of morbidity, including anemia, from high parasite loads in the placenta and of poor fetal outcomes, including intrauterine growth retardation, spontaneous abortion, and low birthweight.

A common cause of death from falciparum malaria, in particular in children in endemic areas, is severe anemia. Anemia is caused by destruction of infected and uninfected erythrocytes, decreased hematopoiesis, and bleeding. In many endemic areas, most asymptomatic young children are infected with *P. falciparum,* with chronic infection contributing to chronic anemia. Other factors contributing to anemia are nutritional deficits and intestinal roundworm infections. With frequent malarial infections and chronic anemia, children are ill-equipped to manage acute worsening of the anemia due to acute malarial illness. With limited access to health care, children often present for medical care late in the course of illness if at all, and many deaths result.

P. falciparum parasites use antigenic variation to evade the host immune response. The principal protein that mediates the cytoadherence of infected erythrocytes to endothelial cells, *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1), is transported to the erythrocyte surface and is a target of host immune responses that limit infection. The PfEMP-1 family

comprises about 60 proteins, but only one PfEMP-1 variant is expressed on the surface of infected erythrocytes at a time. During the course of an infection, parasites frequently vary the expression of PfEMP-1s to stymie host responses. This factor and the high variability in sequence of many PfEMP-1 molecules present a broad repertoire of antigens and probably help explain the slow acquisition of protective antimalarial immunity. Antigenic variation and other aspects of immunologic diversity are poorly understood for non-falciparum malaria parasites, but each species appears capable of repeated infections.

Plasmodial parasites other than *P. falciparum* do not cause cytoadherence of infected erythrocytes, infect lower numbers of erythrocytes, and are much less commonly responsible for complicated and severe disease. However, recent reports suggest that *P. vivax* can cause severe disease, in particular respiratory compromise, more commonly than has previously been appreciated. *P. vivax* is also particularly prone to cause splenic rupture, although this complication can be seen with all malarial species. *P. malariae* most commonly causes a mild febrile illness, but chronic or repeated infection has been associated with an immune complex–mediated glomerulonephritis with nephrotic syndrome (Chapter 123). Recent reports indicate that *P. knowlesi* can cause severe illness, including deaths. The short (24-hour) erythrocytic cycle of *P. knowlesi,* which allows more rapid replication of these parasites compared with others, may partly explain the propensity of this zoonotic parasite to cause severe illness.

Host Immunity and Genetics

The nature of human immune responses to malaria remains poorly characterized, but protective responses require multiple infections and apparently humoral and cell-mediated responses. Where falciparum malaria is common, disease occurs primarily in children. After some protection during the first few months of life, probably due to protective effects of maternal antiplasmodial antibodies and fetal hemoglobin, young children are infected frequently, suffer repeated febrile malaria illnesses, and are at high risk of severe disease. With repeated episodes of malaria, children develop partial immunity. Immunity develops gradually, with some protection against severe malaria after only a few infections, increasing protection against symptomatic illness in children, and eventually strong protection against infection. Thus, in highly endemic areas, young children experience frequent episodes of malaria, especially at about age 6 months to 5 years; older children are frequently infected but uncommonly symptomatic, and adults experience identifiable malarial parasitemia only uncommonly. However, antimalarial immunity is not complete; malaria can occur in individuals of any age. In addition, immunity requires boosting by repeated infections, and so adults are at increased risk of disease if they return to a highly endemic site after an extended stay in a nonendemic area.

A number of human genetic polymorphisms offer protection against malaria. The best characterized is sickle hemoglobin (Chapter 166). Hemoglobin S heterozygotes are partially protected against severe falciparum malaria, leading to a balanced polymorphism in which the survival advantage of the polymorphism allows persistence of sickle cell disease in homozygotes. Other erythrocyte polymorphisms that also are likely to offer protection against malaria include hemoglobin C and E, thalassemias (Chapter 165), glucose-6-phosphate dehydrogenase deficiency (Chapter 164), and ovalocytosis (Chapter 164). The Duffy antigen, an erythrocyte chemokine receptor of uncertain function, is the principal receptor on human erythrocytes for attachment and subsequent invasion of *P. vivax*. Most Africans lack the erythrocyte Duffy antigen, explaining the nearly complete absence of vivax malaria in most of Africa.

CLINICAL MANIFESTATIONS

Uncomplicated Malaria

Most malarial episodes, even with *P. falciparum* infection, are uncomplicated. The incubation period after an infectious bite is usually 10 to 14 days for *P. falciparum* and about 2 weeks for other species, but this can be much longer, especially in non-falciparum malaria and in individuals with prior immunity. The hallmark of malaria is fever, often with a nonspecific influenza-like prodrome including headache and fatigue, followed by a classic malarial paroxysm including chills, high fever, and then sweats. Patients may be remarkably well between febrile episodes. Fevers are typically irregular early in the illness but without therapy may become regular, with 48-hour (*P. vivax* and *P. ovale*) or 72-hour (*P. malariae*) cycles, especially with non-falciparum disease. Headache, malaise, myalgias, arthralgias, rigors, confusion, cough, chest pain, abdominal pain, anorexia, nausea, vomiting, and diarrhea are common. Seizures are often simple febrile convulsions, especially in young children, but they also may represent evidence of severe neurologic disease. Physical findings may be absent or include signs of anemia, jaundice, splenomegaly, and mild hepatomegaly. Rash and lymphadenopathy are not typical in malaria and thus suggestive of another cause of fever. Laboratory studies commonly show anemia, thrombocytopenia, and liver and renal function abnormalities.

Severe Falciparum Malaria

Severe malaria can be defined as presentation with signs of severe illness or organ dysfunction (including prostration, impaired consciousness, convulsions, respiratory distress, shock, acidosis, severe anemia, excessive bleeding, hypoglycemia, jaundice, hemoglobinuria, and renal impairment) or a high parasite load (generally peripheral parasitemia >5% or >200,000 parasites/μL). Cerebral malaria, the most common severe complication in children, is generally defined as altered consciousness in the setting of falciparum malaria. Seizures are common, and deep coma, abnormal posturing, focal neurologic findings, and abnormal respiratory patterns can be seen. Mortality is 15 to 25%, with about 10% with persistence of neurologic sequelae, but many patients do remarkably well with appropriate therapy.

Severe anemia is a common presentation, particularly in young children. Transfusions are avoided when possible but play a key role in management of those with severe compromise. Respiratory failure is caused by noncardiogenic pulmonary edema and is more common in adults than in children. Mechanical ventilation can be life-saving, if available. Acute renal failure is also more common in adults and generally due to hypoperfusion and acute tubular necrosis; hemofiltration and hemodialysis are valuable, if available. Blackwater fever, including intravascular hemolysis and hemoglobinuria, has an uncertain etiology but can be caused by quinine. Hepatic dysfunction, including jaundice, can be seen; jaundice may also be due to hemolysis. Splenic enlargement is common, and splenic rupture can be seen. Hypoglycemia is common because of glucose consumption by parasites, increased demand, impaired gluconeogenesis, and quinine-induced insulin secretion; blood glucose levels should be observed closely, with replacement as needed. Metabolic acidosis due to lactic acidosis and other factors is common; the value of specific therapies for acidosis or aggressive fluid resuscitation is uncertain. Electrolyte derangements can be seen. Coagulopathy, caused by consumption of clotting factors, and marked thrombocytopenia, due to increased platelet turnover, can lead to significant bleeding. Bacterial infection and sepsis can coexist with malaria; presumptive use of antibiotics is warranted when signs of sepsis are seen.

Complications of Non-Falciparum Malaria

The large majority of infections with non-falciparum parasites are uncomplicated both in endemic areas and in nonimmune travelers. Nonetheless, *P. vivax* infection is common in many areas, and studies from a number of sites in Asia and Oceania have shown that it makes up about a quarter of children hospitalized with severe malaria, with a mortality of about 1%. Important features of severe vivax malaria include severe anemia and respiratory distress. All malarias, but in particular *P. vivax* infection, can be complicated by splenic rupture. Chronic malaria infections can be complicated by hyperreactive malarial splenomegaly, with massive splenomegaly and findings of hypersplenism. Chronic infections can also lead to the nephrotic syndrome, particularly with *P. malariae* infection.

DIAGNOSIS

Clinical Features

In individuals with febrile illness and malaria risk, it is essential to make a diagnosis promptly and also important to distinguish the different species that infect humans as management differs according to the infecting species. Malaria is the most common cause of febrile illness in many areas, and with limited diagnostic capabilities, it is frequently diagnosed based only on presentation with a febrile illness. However, formal diagnosis is preferred. In travelers returning from endemic areas with fever, historical details can aid in the diagnosis. Malaria is most likely in individuals who failed to use measures to prevent infection and in travelers to the most highly endemic areas, such as rural sub-Saharan Africa. Falciparum malaria generally has a fairly short incubation period in nonimmune individuals and so presents within 1 to 2 months of return in more than 90% of travelers. Infection with the other malarial species can present a number of months and uncommonly more than a year after exposure.

Blood Smears

The standard means of diagnosis in malaria-endemic areas is by thick blood smear. In this procedure, a drop of blood is allowed to dry on a slide, erythrocytes are lysed, and parasites are then stained with Giemsa. Parasites are easily identified by trained microscopists, and parasite density can be estimated on the basis of counts relative to those of leukocytes. However, thick blood smears do not allow consideration of erythrocyte morphology, which is helpful in species diagnosis, and are difficult for those with limited training. Giemsa-stained thin blood smears offer an improved means of characterizing parasite morphology, but the process is much less efficient than for thick smears. Thus, thick smears are the standard means of diagnosis in highly endemic areas, and thin smears are preferred where malaria is uncommon and where laboratory personnel have ample time to examine multiple microscopic fields. It is important to distinguish infecting species of malaria parasites. In *P. falciparum* infection, generally only ring-form asexual parasites are seen. Trophozoites of *P. vivax* and *P. ovale* are present in enlarged (and ovoid in the case of *P. ovale*) erythrocytes that contain inclusions known as Schüffner's dots. Intraerythrocytic *P. malariae* and *P. knowlesi* trophozoites are often elongate in shape. Sexual stage gametocytes (which have a characteristic oblong shape in *P. falciparum*) are also seen on blood smears; most treatments do not eradicate gametocytes, so persistence of these forms for a few weeks is not a sign of treatment failure.

Antigen Detection

An important new means of malaria diagnosis is antigen detection. Multiple simple tests are now available, incorporating colorimetric detection of one or two antigens in an assay that requires limited training and only a few minutes. The most used assays in Africa use histidine-rich protein-2, a protein that is abundant and long-lived but expressed only by *P. falciparum*. Other assays identify plasmodial lactate dehydrogenase and aldolase, which are produced by all human malarial species. Some tests use two antigens to separately identify *P. falciparum* and all-species plasmodial infection. Rapid diagnostic tests have recently become a standard component of many malaria control programs. One test is approved in the United States. However, with many different tests available around the world, standardization is not optimal, and the specific role of rapid antigen tests for the diagnosis of malaria in different epidemiologic settings is not yet established.

Other Diagnostic Tests

Serologic tests are available to identify prior malaria infection, but responses develop slowly and persist for an extended period, so these tests have limited clinical value, unless it is helpful to diagnose the cause of a febrile illness retrospectively in an individual without prior history of malaria. Malaria parasites can be identified readily with polymerase chain reaction (PCR) using primers encoding genus- and species-specific sequences. These tests are convenient for research purposes as they can be conducted on DNA extracted from blood spotted onto filter paper in field settings. PCR is more sensitive than other diagnostic modalities. It is not practical for routine diagnosis because of the time required to complete an assay, the uncertain significance of a positive test result in endemic areas where low-level parasitemia may be common and clinically insignificant, and the cost and logistical requirements of the procedure in developing countries.

TABLE 353-1 TREATMENT OF MALARIA*

CHLOROQUINE-RESISTANT *P. FALCIPARUM*, RESISTANT *P. VIVAX*, OR SPECIES UNIDENTIFIED	
Uncomplicated Disease	
Coartem (artemether 20 mg, lumefantrine 120 mg)	4 tablets orally twice daily for 3 days
or	
Malarone (atovaquone 250 mg, proguanil 100 mg)	4 tablets daily for 3 days
or	
Quinine	650 mg quinine sulfate 3 times daily for 3-7 days
plus	
Doxycycline	100 mg twice daily for 7 days
or plus	
Clindamycin	600 mg twice daily for 7 days
or	
Mefloquine	1250 mg (15 mg/kg) once or 750 mg followed by 500 mg in 6-8 hr; can also be given as a single 1250-mg dose, although less well tolerated
Complicated *P. Falciparum* Malaria or Unable to Tolerate Oral Medications†	
IV artesunate‡	2.4 mg/kg every 12 hr on day 1, then daily for 2 additional days
or	
IV quinidine gluconate§	10 mg/kg over 1 to 2 hr, then 0.02 mg/kg/min *or* 15 mg/kg over 4 hr, then 7.5 mg/kg over 4 hr every 8 hr
or	
IV quinine dihydrochloride§,¶	20 mg/kg over 4 hr, then 10 mg/kg every 8 hr
or	
IM artemether¶	3.2 mg/kg IM, then 1.6 mg/kg/day
CHLOROQUINE-SUSCEPTIBLE *P. FALCIPARUM* AND OTHER SPECIES	
Chloroquine phosphate	1 g, followed by 500 mg at 6, 24, and 48 hr *or* 1 g at 0 and 24 hr, then 0.5 g at 48 hr
plus (for *P. vivax* and *P. ovale* only)	
Primaquine¶	30-mg base (52.6 mg primaquine phosphate) daily for 14 days

*Dosages refer to salts unless indicated and are for adults. For pediatric dosing and full CDC recommendations, see *http://www.cdc.gov/malaria/pdf/treatmenttable.pdf*. For the CDC malaria hotline, call 770-488-7788.
†IV regimens should be given until the patient can tolerate oral agents, then followed by a course of oral therapy (doxycycline, clindamycin, or full treatment courses of other drugs, as listed) when patients can tolerate this.
‡Available in the United States on an investigational basis through the CDC (phone 770-488-7788 or 770-488-7100).
§Cardiac monitoring should be in place during IV administration of quinidine or quinine.
¶Not available in the United States.
¶Use primaquine only after demonstrating normal levels of glucose-6-phosphate dehydrogenase.

TREATMENT

The treatment of falciparum malaria has been challenged by drug resistance for many years and has changed dramatically recently, with recommendations for artemisinin-based combination therapy in nearly all countries endemic for falciparum malaria (Table 353-1). Non-falciparum malaria is still generally treated with chloroquine, although chloroquine resistance is increasing in *P. vivax*.

Chloroquine and Other Aminoquinolines

Chloroquine has been widely used to treat malaria for more than 60 years. It remains the treatment of choice for non-falciparum malaria and falciparum malaria in the few areas where resistance has not been seen (primarily Central America and the Caribbean) and is generally rapidly effective and well tolerated. For *P. vivax* and *P. ovale* infections, primaquine must also be given to eradicate dormant liver forms and thereby prevent subsequent relapse. Chloroquine remains effective as weekly chemoprophylaxis to prevent malaria in areas without resistance. Amodiaquine and piperaquine probably share mechanisms of action with chloroquine, but they are routinely active against chloroquine-resistant parasites because of increased potency compared with chloroquine and some differences in mechanisms of resistance. Monotherapy with either drug is discouraged, but each is now a component of a leading artemisinin-based combination therapy (Table 353-2). Amodiaquine is somewhat less well tolerated than other aminoquinolines. It is generally safe with short-term use but can cause rare serious toxicities, including hepatic and bone marrow toxicity, especially with chronic use, and so it is not recommended for chemoprophylaxis. Piperaquine was well tolerated during extensive use in China a few decades ago; although resistance was reportedly common in China, it does not appear to be a problem at present.

Mefloquine, Halofantrine, and Lumefantrine

Mefloquine offers effective therapy and chemoprophylaxis for most chloroquine-resistant strains of *P. falciparum* and for other species. Resistance to mefloquine is uncommon but has been seen in parts of Southeast Asia. Mefloquine is now used to treat falciparum malaria in combination with artesunate and is one of three drugs recommended for chemoprophylaxis against *P. falciparum* by the Centers for Disease Control and Prevention (CDC). Tolerability of chemoprophylactic and especially treatment doses of

TABLE 353-2 RECOMMENDATIONS FOR THE TREATMENT OF FALCIPARUM MALARIA IN DEVELOPING COUNTRIES*

REGIMEN	NOTES
Artemether-lumefantrine (Coartem, Riamet)	First-line therapy in many countries; FDA approved
Artesunate-amodiaquine (ASAQ)	First-line therapy in many African countries; efficacy limited by resistance to amodiaquine in many areas
Artesunate-mefloquine	Standard therapy in parts of Southeast Asia
Artesunate-sulfadoxine-pyrimethamine	Efficacy low compared with other regimens in most areas
Dihydroartemisinin-piperaquine	Newer regimen; highly effective in studies in Asia and Africa
Amodiaquine-sulfadoxine-pyrimethamine	Recommended as an interim option when efficacy established and newer regimens are not available

*Recommendations modified from World Health Organization. *Guidelines for the Treatment of Malaria.* Geneva: World Health Organization; 2010. ISBN 9789241547925.

mefloquine is often limited by neurologic and gastrointestinal toxicity. Halofantrine is an effective drug, but its use is limited by uncommon but dangerous cardiac rhythm disturbances. Lumefantrine is a related drug that does not share this toxicity and offers effective therapy in combination with artemether as Coartem.

Quinine and Quinidine

Quinine has been used to treat malaria for hundreds of years. It offers rapid action against all species, with limited known resistance except in Southeast Asia, where failures against falciparum malaria are fairly common. Quinine can be used to treat uncomplicated malaria, but gastrointestinal and other nonspecific toxicities lead to difficulty in tolerating a full 7-day treatment course. This problem is circumvented by combining a 3-day course of quinine with other agents. For severe disease, intravenous quinine or, in the United States, intravenous quinidine has been standard therapy for many years; therapy should be accompanied by cardiac monitoring because of cardiac toxicities of the drugs.

Primaquine

Primaquine is the only available drug to eradicate dormant liver forms of *P. vivax* and *P. ovale* that are not cleared by other drugs and can lead to relapses after therapy with chloroquine and other agents. Primaquine is also an alternative agent for chemoprophylaxis against *P. falciparum* and other species. Primaquine use is limited principally by hemolysis or methemoglobinemia (Chapter 161) in individuals with deficiency in glucose-6-phosphate dehydrogenase (Chapter 164). Testing for deficiency should ideally be performed before use of the drug.

Inhibitors of Folate Metabolism

Inhibitors of two parasite enzymes involved in folate metabolism, dihydrofolate reductase and dihydropteroate synthase, are used in fixed-dose combination regimens for the treatment and prevention of malaria. For treatment, sulfadoxine-pyrimethamine (Fansidar) was heavily used to treat uncomplicated falciparum malaria, but resistance has increased markedly in most endemic areas. The dihydrofolate reductase inhibitor proguanil is combined with atovaquone in Malarone (see later). For chemoprophylaxis, sulfadoxine-pyrimethamine is no longer recommended because of drug resistance and rare life-threatening dermatologic toxicities. However, less frequent dosing in intermittent preventive therapy regimens has been well tolerated and has decreased malaria in high-risk African groups, in particular, pregnant women and young children. Daily trimethoprim-sulfamethoxazole, a common prophylactic to prevent opportunistic infections in individuals with HIV infection, has offered some protection against malaria in Africa.

Artemisinins

Artemisinin, the active component of an herbal medicine from China, and a number of analogues offer rapid elimination of circulating malaria parasites and also activity against gametocytes to limit disease transmission. The drugs are all short-acting, leading to frequent recrudescences of infection after short-course monotherapy. For this reason and to prevent selection of resistance, artemisinins are now used in combination with longer acting drugs to treat malaria in 3-day regimens. A number of these combinations have become the standard therapies for falciparum malaria in most endemic countries (see Table 353-2). Leading regimens are artemether-lumefantrine, artesunate-amodiaquine, artesunate-mefloquine, and dihydroartemisinin-piperaquine. Of these, artemether-lumefantrine is most widely advocated, is now approved in the United States, includes a partner drug that has never been available as monotherapy, but requires twice-daily therapy. The other regimens offer once-daily therapy but have potential problems with resistance to partner drugs. Resistance to artemisinins is a recent concern, with evidence for prolonged times to parasite clearance in Southeast Asia suggestive of diminished drug responsiveness of *P. falciparum*. Artemisinins also have an increasing role for the treatment of severe malaria. Intravenous artesunate has been shown to be superior to quinine for the treatment of severe malaria in a mostly adult population in Asia. Most recent evidence clearly supports the superiority of parenteral artesunate over quinine for the treatment of severe malaria in both adults and children and in different regions of the world. For settings with limited infrastructure, intramuscular artemether and intrarectal artesunate have also shown good efficacy. Intravenous artesunate should now be considered the first-line therapy for severe malaria in the United States, where it is available from the CDC. Artemisinins are generally very well tolerated, with minimal toxicity.

Atovaquone-Proguanil (Malarone)

This fixed-dose combination of a dihydrofolate reductase inhibitor and atovaquone, which has a unique antimalarial mechanism, has excellent efficacy against most *P. falciparum* infections. It is approved for both treatment and chemoprophylaxis of falciparum malaria and other species in the United States, where it is now widely used for both indications. Malarone offers excellent efficacy with minimal toxicity. Adverse effects may include gastrointestinal symptoms, elevations in liver enzymes, headache, and rash. Widespread use in developing countries is limited by high cost and concerns about resistance, as resistance to each component drug is readily selected.

Antibiotics

A number of antibacterials are slow-acting antimalarials. Tetracyclines and clindamycin should not be used alone to treat malaria but are combined with quinine to allow a shorter duration of therapy with that drug. In addition, doxycycline is effective in chemoprophylaxis of most falciparum malaria and is recommended for this purpose by the CDC, in particular for travelers to regions of Southeast Asia with high-level resistance to other drugs. Macrolides also have antimalarial activity and are currently under study for treatment and prophylaxis.

Treatment of Severe Malaria

Severe malaria is a medical emergency and requires parenteral therapy. With appropriate prompt therapy and supportive care, rapid recoveries may be seen even in very ill individuals. As noted before, standard therapy for severe malaria has been intravenous quinine or quinidine, with continuous cardiac monitoring if possible. However, intravenous artesunate showed superior efficacy and decreased toxicity and although it is not yet available in most endemic areas, this is likely to become the worldwide standard to treat severe malaria. In the United States, intravenous quinidine is not available in all hospitals, and intravenous artesunate must be obtained from the CDC; treatment should be with whichever treatment is most rapidly available. Appropriate care of severe malaria includes close nursing care; maintenance of fluids and electrolytes, including glucose; respiratory and hemodynamic support; and consideration of blood transfusions, anticonvulsants, antibiotics for bacterial infections, and hemodialysis or hemofiltration. Aggressive fluid resuscitation, blood transfusion for moderate anemia, exchange transfusion, and specific treatment of acidosis are of uncertain value. After the acute illness, parenteral quinine, quinidine, or artesunate should be followed with oral longer acting drugs, typically doxycycline, clindamycin, Malarone, mefloquine, or a full course of an oral artemisinin-based combination therapy.

PREVENTION

Recent years have been marked by a dramatic increase in interest and investment in the control of malaria. Key malaria control interventions in malaria-endemic regions are control of mosquito vectors by indoor residual spraying of insecticides; personal protection against mosquito bites with insecticide-impregnated bed nets; routine use of artemisinin-based combination therapies, which offer prompt control of malaria infections and activity against gametocytes to limit transmission to mosquitoes; and selected use of intermittent preventive therapies to decrease malarial incidence in high-risk groups. No vaccine to prevent malaria is yet available, but extensive research on potential vaccines including multiple clinical trials is under way. A fully protective malaria vaccine is not expected in the near future, but vaccines that offer significant decreases in malarial incidence for children and other high-risk groups in endemic areas may be available soon.

Preventive Measures for Travelers to Malaria-Endemic Regions

It is important for nonimmune travelers (Chapter 294) to endemic areas to be protected against potentially lethal malaria. Travelers should decrease exposure to night-biting anopheline mosquitoes by use of insecticide repellants

TABLE 353-3 CHEMOPROPHYLAXIS OF MALARIA*

AREAS WITH CHLOROQUINE-RESISTANT *P. FALCIPARUM*	
Malarone	1 tablet (250 mg artesunate/100 mg proguanil) daily
Mefloquine	250 mg weekly
Doxycycline	100 mg daily
Primaquine†	30 mg daily during exposure (chemoprophylaxis) or 30 mg daily for 14 days (terminal prophylaxis against *P. vivax* and *P. ovale*)
AREAS WITHOUT CHLOROQUINE-RESISTANT *P. FALCIPARUM*	
Chloroquine phosphate	500 mg weekly

*Recommendations may change on the basis of drug resistance patterns. For additional details and pediatric dosing, see CDC guidelines *(http://www.cdc.gov)* or call 770-488-7788 or 770-488-7100. Begin 1 to 2 weeks before travel for mefloquine and 2 days before for doxycycline, Malarone, and primaquine; continue for 4 weeks after leaving the endemic area (1 week for Malarone; 2 weeks for primaquine). All doses refer to salts unless indicated.
†Use primaquine only after demonstrating normal levels of glucose-6-phosphate dehydrogenase.

and sleeping in rooms that are screened or equipped with insecticide-impregnated bed nets. Standard advice for travelers to endemic areas is also to use low doses of preventive drugs chosen on the basis of the resistance profile of the particular region. Chloroquine is still recommended for malaria endemic regions of Central America and the Caribbean. For nearly all other areas, the CDC recommends use of daily Malarone, weekly mefloquine, or daily doxycycline; details of dosing vary, but it is important to continue therapy after return from travel to eliminate parasites as they emerge from the liver (Table 353-3). For areas with high risk of vivax malaria, some authorities recommend a full treatment course of primaquine after travel to eliminate dormant liver stages. For all chemoprophylaxis, it is important to appreciate that no mosquito avoidance methods or drug regimens are fully protective, and so consideration of malaria as a cause of fever in returned travelers is essential (Chapter 294).

PROGNOSIS

Patients with malaria due to *P. vivax, P. ovale,* or *P. malariae* generally respond well to chloroquine and make an uneventful recovery. Chloroquine-resistance is increasing with *P. vivax* from many areas; failures of initial treatment are usually not dangerous but should be followed by treatment with another regimen, such as an artemisinin-based combination therapy, Malarone, or mefloquine. Falciparum malaria also generally responds well to prompt therapy as long as the disease is not overly advanced at presentation. The mortality rate in uncomplicated falciparum malaria is about 0.1%. Key contributing factors to most deaths from falciparum malaria are probably delay between the appearance of symptoms and presentation for definitive therapy and the use of suboptimal therapies. Presentation with high-level parasitemia (>200,000 parasites/μL or >5% parasitemia) or signs of severe malaria are predictive of poor outcome. However, with aggressive support, even individuals with severe disease can often experience complete recoveries.

354 AFRICAN SLEEPING SICKNESS

WILLIAM A. PETRI, JR.

DEFINITION

Human African trypanosomiasis (HAT), commonly known as sleeping sickness, is a vector-borne parasitic disease transmitted to humans and animals by the bite of the tsetse fly (genus *Glossina*). Infection is caused by protozoa of the genus *Trypanosoma* and species *brucei*. In humans, there are two forms of illness caused by two distinct subspecies that are morphologically identical but differ in their geographic range and clinical presentations. *Trypanosoma brucei gambiense* is typically found in west and central Africa and *Trypanosoma brucei rhodesiense* in east Africa. *T. b. gambiense* has a more chronic course, and *T. b. rhodesiense* causes a rapid disease course; both have late stages marked by meningoencephalitis, resulting in coma and death if untreated. There is a third subspecies, *Trypanosoma brucei brucei,* known to cause chronic infection called nagana in cattle; however, humans are not susceptible to this organism.

The Pathogen

As an extracellular microbe, the parasite must evade immune clearance to establish a persistent infection. The surface of the blood stream form of the trypanosome is covered by a dense, homogeneous coat of variant surface glycoproteins (VSGs). VSGs are immunodominant, whereas invariant antigens, such as nutrient receptors, are protected from host antibody recognition by strict localization to a membrane subdomain hidden at the base of the flagellum. Each individual trypanosome expresses only one VSG at a time but possesses more than 1000 different silent copies of the VSG gene, and switching to a new VSG occurs at a frequency of about 1×10^{-6} parasites. Hence, the trypanosomes expressing a given VSG will eventually be cleared by the host antibody response, but any individual trypanosome that has switched to a new VSG will evade immune clearance, resulting in a new peak of parasitemia. Recombination between VSG alleles ensures a virtually limitless repertoire of new VSGs; therefore, antibody-mediated parasite eradication is impossible.

EPIDEMIOLOGY

Although considered one of the "neglected tropical diseases," HAT is relatively less of a problem now than it has been in the prior century, in part because of cyclic epidemics in the past as well as recent increases in public health efforts for control. However, it remains a looming threat to an estimated 60 million people living in tsetse fly–inhabited areas among 36 countries of sub-Saharan Africa and causes significant morbidity, accounting for 1.5 million disability-adjusted life years in Africa as a whole.

The causative organism was first identified during the latter half of the 19th century, roughly corresponding to the first of three epidemics occurring during the past century. The first epidemic occurred in the Congo basin and Uganda between 1896 and 1906, driven in part by various natural disasters that decimated populations of livestock and regional droughts as well as changes in population distribution influenced by colonialism. The second

epidemic occurred in numerous endemic countries in the 1920s; control was achieved after major efforts to systematically screen and treat individuals, followed by extensive vector control programs, including bush clearing and insecticide spraying. These acts were nearly successful in halting transmission by the 1960s; however, the independence of many African nations around this time hindered the sustainability of prevention and control programs. The incidence began to rise by the 1970s and surged a decade later, leading to the third epidemic of this century. However, in the past 15 years, increased access to at-risk populations for diagnosis and treatment has led to a 68% reduction in the incidence of reported cases.

Despite increased surveillance efforts during the past 15 years, there are still at-risk areas that lack active monitoring programs, and many people are thought to die of HAT without an accurate diagnosis. The World Health Organization recently reported an annual incidence of 12,000 cases in 2007, a dramatic decrease from the estimated incidence of 300,000 cases a decade ago. It is estimated that 300,000 to 500,000 people are infected, contributing to approximately 100,000 deaths each year. More than 90% of reported cases are due to *T. b. gambiense,* the majority being from the Democratic Republic of the Congo.

The geographic distribution includes areas where the vector, parasite, reservoir hosts, and human hosts cohabit (Fig. 354-1). In general, these include focal areas on the African continent within 15° North and 15° South latitude, with a predilection for rural areas. Humans at greatest risk for infection are those who rely on animal husbandry, agriculture, fishing, and hunting for their livelihoods. Often, disease is concentrated among foci of rural areas, having significant socioeconomic impact on affected villages. With a few exceptions, this infection is never found in urban areas. There have been fewer than 50 cases reported annually outside of Africa, usually the result of travel by North Americans or Europeans to African game reserves.

T. b. gambiense is transmitted by tsetse flies from the *Glossina palpalis* group, which are typically found along riverbanks among wooded areas in the more tropical regions of central and west Africa. The reservoir hosts for *T. b. gambiense* and the focus of public health campaigns are mainly humans. Because of this, *T. b. gambiense* is not generally considered a zoonotic disease; the role of the animal reservoir for this organism remains undetermined, although natural infections have been reported in domestic animals such as dogs, sheep, cattle, and pigs.

T. b. rhodesiense is transmitted by tsetse flies belonging to the *Glossina morsitans* group, which are commonly found among woodland and savannah areas of east and central Africa. *T. b. rhodesiense* is a zoonotic disease with numerous wild and domestic species of animals acting as reservoirs. With this infection, the animal reservoir serves an important role in the cycle, sustaining parasite transmission and human infections. Domestic species, especially cattle, have the potential to drive outbreaks and, not surprisingly, have served as the focus of successful prevention campaigns.

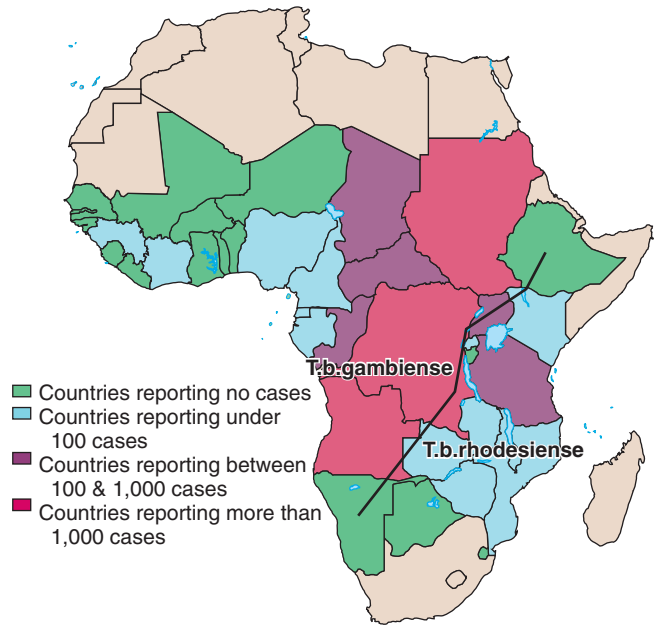

FIGURE 354-1. Map of human African trypanosomiasis. These 36 sub-Saharan African countries are considered endemic for HAT. *Shaded areas* represent the reported incidence from 1997 to 2006. The *black line* roughly represents the dividing line for the two parasites, although some overlap may already occur.

PATHOBIOLOGY

After the bite of a tsetse fly carrying metacyclic trypomastigotes, a local reaction (chancre) may form at the inoculation site. This symptom is seen with *T. b. rhodesiense* infection and is more frequently observed in travelers but is rarely seen with *T. b. gambiense* infection. Parasites subsequently disseminate into the blood and lymphatic systems in what is considered stage I of the disease. Spread of the parasites into the central nervous system (CNS) defines stage II of the disease, which is invariably fatal if untreated. The parasite appears to remain extracellular throughout the course of infection.

Peaks and waves of parasitemia occur during stage I disease and result in the classic symptom of intermittent fever. These bouts of fever correspond to a type 1 inflammatory response (Chapter 47), in which classically activated macrophages produce high levels of tumor necrosis factor and nitric oxide. This helps in the control of parasitemia but also contributes to tissue damage. Type 2 inflammatory responses with high interleukin-10 production may subsequently occur, which limit tumor necrosis factor and nitric oxide production once initial parasitemia has been controlled. Antibody responses are directed to VSGs and other trypanosome antigens (e.g., antigens from lysed parasites), but autoantibodies are also produced. Generalized febrile episodes are observed together with lymphadenopathy and myocardial and pericardial inflammation. Cardiac involvement is typically more severe with *T. b. rhodesiense* infection. Anemia, thrombocytopenia, disseminated intravascular coagulation, and renal disease may also be observed.

In stage II of the disease, parasites cross the blood-brain barrier and invade the CNS. Acute meningoencephalitis develops, with a variety of inflammatory cells infiltrating the brain, including macrophages, lymphocytes, plasma cells, Mott cells, and morular cells. These inflammatory cells are found in the meninges, which become thickened, as well as in the perivascular spaces and neuropil. Edema, hemorrhage, and granulomatous lesions are often present; thrombosis and neuronal degeneration may also be observed.

CLINICAL MANIFESTATIONS

The clinical manifestations of HAT differ on the basis of the infecting organism. *T. b. gambiense* is more of a chronic disease, with an estimated average duration of 3 years; infection with *T. b. rhodesiense* progresses much more rapidly, leading to coma and death within weeks to months. However, infection with *T. b. gambiense* has been known to cause rapid decline. Other similarities exist, including an early hemolymphatic stage (stage I) and a late stage characterized by prominent CNS disease including meningoencephalitis (stage II).

West African Sleeping Sickness

Infection starts after the bite of a fly infected with *T. b. gambiense*. At the site of inoculation, a painful, indurated, and erythematous trypanosomal chancre may develop 1 to 2 weeks after the bite and resolves spontaneously after several weeks. On occasion, the chancre may ulcerate. However, these features are rarely seen at the time of clinical presentation and sometimes are not known to have occurred on history; thus, many develop disseminated disease without awareness of a localized infection.

The hemolymphatic stage, when parasites disseminate throughout the body, may not be manifested clinically until weeks or months after the initial bite. Typical symptoms include intermittent spiking fevers, occasionally accompanied by headaches and malaise. These features may persist for weeks or months because of the cyclic nature of parasitemia and antibody production against the various antigens sequentially expressed by the parasite.

Lymphadenopathy (Chapter 171) is a common finding in West African sleeping sickness. Whereas regional lymphadenopathy may develop after the initial bite, generalized lymphadenopathy around the head and neck is often found as chronic illness develops. Enlargement of nodes in the posterior cervical triangle, commonly known as Winterbottom's sign, is the classic finding; but other cervical and supraclavicular nodes may also be involved. Affected nodes are discrete, movable, rubbery nodes that are nontender to palpation; over time, they may become more indurated because of fibrosis.

Other symptoms reported include pruritus, occasionally accompanied by rash, arthralgias, and periarticular swelling as well as by transient edema of the extremities and face. Less common symptoms include features consistent with neuroendocrine dysfunction: loss of libido and impotence, amenorrhea

and infertility, alopecia, and gynecomastia. Signs of disease include hepatomegaly and splenomegaly, cardiac dysfunction including tachycardia, electrocardiographic abnormalities like prolonged QTc intervals and repolarization changes, and, less commonly, pericarditis or myocarditis. Hemolytic anemia and derangements in liver function test results may occur.

Months or even years after the initial infection, stage II disease develops and is characterized by headaches, daytime somnolence, and neuropsychiatric features. Behavioral changes, including irritability, confusion, inability to concentrate, and lassitude, are among the first signs of CNS disease; psychosis has also been described. Neurologic findings are numerous and include a variety of motor and sensory disturbances, including extrapyramidal features, dysesthesias, and visual impairment. Disruption of the normal circadian rhythm has allowed its common name of sleeping sickness and is manifested by daytime somnolence and nocturnal irritability. Late-stage disease is marked by cerebral edema and meningoencephalitis. Progressively, a loss of neurologic function can lead to paralysis, and many may succumb to aspiration pneumonias or malnutrition; otherwise, coma leads to death in the absence of treatment.

East African Sleeping Sickness

In comparison to Gambian sleeping sickness, East African sleeping sickness is more rapidly progressive. The infective bite is more frequently associated with the development of a chancre, although some studies report this in only 20% of patients. An incubation period lasting days to weeks is needed before symptoms are demonstrated. Initial symptoms include severe intermittent fevers that may resemble those found with malaria infection. Lymphadenopathy is not as common with this infecting organism; Winterbottom's sign is typically absent. Skin changes are more prominent, and rashes in the early stage of infection are particularly common in expatriates with the infection. In addition, cardiac manifestations are more commonly and clinically relevant; tachycardia, arrhythmias, myocarditis, and congestive heart failure have been documented and may be severe enough to cause death before the development of severe CNS disease. Hematologic abnormalities include anemia, thrombocytopenia, and disseminated intravascular coagulation. CNS disease mirrors that of West African sleeping sickness, but the onset occurs earlier and the rate of deterioration is more rapid. Death may ensue after weeks or months without treatment.

DIAGNOSIS

Epidemiologic clues and clinical findings may together suggest the diagnosis of HAT, but definitive diagnosis relies on demonstration of the parasite. In the early stage of disease, light microscopy and Giemsa stain may be employed to visualize the highly motile parasites directly from fresh specimens of fluid expressed from chancres or lymph node aspirates. Peripheral blood smears, including Giemsa-stained thick and thin smears and bone marrow aspirates, have been successful. Blood smears have increased sensitivity when they are performed during stage I disease, when parasitemia is high (Fig. 354-2); the threshold for visualization of parasites by thick smear is approximately 5000 parasites/mL. Performance is superior with *T. b. rhodesiense* infection, given the higher parasite load. If the initial smear analysis is negative, subsequent examinations should be pursued. Concentration techniques including buffy coat analysis should be employed when technically feasible. Culture of any of these fluids may yield higher sensitivity than smear preparations.

Cerebrospinal fluid (CSF) must also be analyzed to determine the most appropriate treatment. Abnormalities in CSF analysis often start with increased cell counts and progress to include an elevated opening pressure and total protein levels with an increased polyclonal IgM. Stage II disease is defined by the presence of more than 5 white blood cells/μL, the presence of trypanosomes, or an elevated total protein count (>370 mg/L) in the CSF. Newer diagnostic methods including polymerase chain reaction analysis of CSF and a latex-agglutination test for CSF IgM hold promise but require validation to determine outcomes after treatment of patients with positive test results.

Serology tests are also available for diagnosis of *T. b. gambiense* infection. The card agglutination test for trypanosomiasis with *T. b. gambiense* (CATT) is commonly used by screening programs; the sensitivity ranges from 87 to 98%, depending on the population under study, and the specificity may be as high as 95%. There are no serology tests available for *T. b. rhodesiense* infection.

Allocation of resources to this neglected tropical disease in recent years has allowed slow but exciting progress in the field of HAT diagnostics. The genomes of *T. brucei* species have been mapped, and molecular assays have been developed that can distinguish between species of HAT with a single polymerase chain reaction test. Novel uses of mass spectrometry have been developed that employ proteomic signature analysis to identify specific fingerprints of HAT with the host. In contrast to these highly technical and expensive methods, other tests suitable for the field are being validated, including the dot-ELISA test, which would be able to provide information on stage of disease.

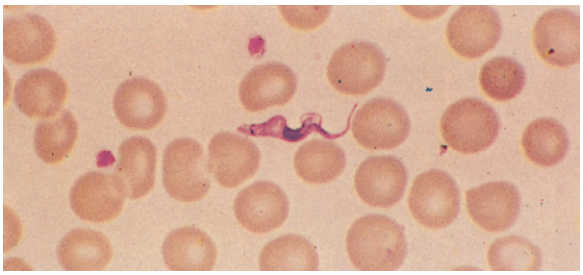

FIGURE 354-2. ***Trypanosoma rhodesiense*** **in peripheral blood.** It has a nucleus, posterior kinetoplast, undulating membrane, and flagellum (×1500).

TREATMENT Rx

There are very few drugs for treatment of HAT, and those that are commonly used are quite toxic (Table 354-1). Treatment is dependent on the infecting organism and the stage of disease. For stage I disease with *T. b. gambiense* infection, pentamidine is the drug of choice. The standard regimen consists of daily parenteral administration for 1 week; however, studies are ongoing to determine the efficacy of shortening therapy to three doses.

Suramin is also used for stage I disease with *T. b. rhodesiense*. This medication is complex to mix and to administer. The drug must be administered in a slow intravenous infusion periodically during 3 weeks. Although anaphylaxis is rare (approximately 1:20,000 patients), a test dose is recommended before full treatment is initiated. There are a number of side effects that require close monitoring, the most important being nephrotoxicity. Urinalysis is recommended before each dose, and the drug should be discontinued if proteinuria persists and casts are seen in the urine sediment.

Melarsoprol is a highly effective but impressively toxic drug used for stage II disease with either organism. The side effects are numerous, but the most important is the life-threatening encephalopathy that may develop from the arsenic (highly fatal) or as an inflammatory reaction. Concomitant steroid use is helpful in reducing the risk of encephalopathy and mortality without compromising the efficacy of melarsoprol. Gradual increase in the first round of treatment between 2 and 3.6 mg/kg in divided doses three times daily during 3 days has also been shown to reduce the risks of encephalopathy. Melarsoprol has been replaced by eflornithine for *T. b. gambiense* infection but remains the only agent available for the treatment of stage II *T. b. rhodesiense* infection.

Developed more than 20 years ago, eflornithine is the newest agent and drug of choice for treatment of stage II disease with *T. b. gambiense*. Unfortunately, it is not effective as monotherapy for *T. b. rhodesiense* because of reduced susceptibility of this organism to the drug. Eflornithine requires frequent intravenous administration, and up to 40% of patients may report some adverse effects. The drug is much more tolerable than its predecessor melarsoprol and is associated with a reduced mortality, comparatively.

PREVENTION

To date, there is no vaccine against HAT. The mainstays of prevention include active case finding with early treatment and vector control. Given the nature of each infection, active case surveillance is more suitable for infection with *T. b. gambiense*, whereas vector control is more effective for prevention of infection with *T. b. rhodesiense.* The goal of active case finding is to identify infected individuals who may still be in the asymptomatic stage or early stage. This approach, which is more suited for disease from *T. b. gambiense*, typically consists of a screening examination for lymphadenopathy followed by a CATT test. If results are positive for both, the patient should undergo further evaluation with lymph node aspirate and blood testing. If trypanosomes are found, the patient should be treated. Vector control measures include tsetse fly traps and insecticide-impregnated screens; the traps are easily maintained by locals, whereas the screens require regular re-treatment and thus are more labor intensive and costly to maintain. Mass spraying, once a successful

TABLE 354-1 DRUGS USED TO TREAT HUMAN AFRICAN TRYPANOSOMIASIS

DRUG	CLASS	STAGE	ROUTE	ADULT DOSE	ADVERSE EFFECTS
TRYPANOSOMA BRUCEI GAMBIENSE					
Pentamidine	Aromatic diamidine	I	Intramuscular or intravenous	4 mg/kg daily for 7 days	Pain, gastrointestinal symptoms, hypoglycemia or hyperglycemia, electrolyte abnormalities, leukopenia, thrombocytopenia
Eflornithine	Ornithine carboxylase inhibitor	II	Intravenous	100 mg/kg every 6 hr for 14 days	Gastrointestinal symptoms, bone marrow toxicity, seizures
Melarsoprol (alternative option)	Trivalent arsenical	II	Intravenous	2.2 mg/kg daily for 10 days (maximum daily dose is 180 mg)	Encephalopathic syndromes, peripheral neuropathy, paralysis, cardiac dysrhythmias, gastrointestinal symptoms, rash, pruritus, thrombophlebitis
TRYPANOSOMA BRUCEI RHODESIENSE					
Suramin	Polysulfonated naphthylamine derivative of urea	I	Intravenous	1 g IV on days 1, 3, 7, 14, and 21 (after test dose of 100-200 mg)	Anaphylaxis, nephrotoxicity, fever, rash, pruritus, arthralgias, reversible peripheral neuropathy and bone marrow toxicity
Melarsoprol	Trivalent arsenical	II	Intravenous	1.2 mg/kg every 8 hr for 3 consecutive days each week for 3 weeks (maximum daily dose is 180 mg)	Encephalopathic syndromes, peripheral neuropathy, paralysis, cardiac dysrhythmias, gastrointestinal symptoms, rash, pruritus, thrombophlebitis

method until the 1960s, is no longer practiced. However, if an epidemic does occur, ground or aerial spraying combined with disruption of the animal reservoir's habitat may be the most effective in achieving rapid vector control.

Travelers to endemic areas should be aware of this disease and should employ basic protective measures. Protective clothing of at least medium weight should be worn; neutral colors are most effective, as flies are attracted to bright and dark colors. Tsetse flies are attracted to moving vehicles but rest in the shade or bushes. Although use of insect repellant is prudent for other vector-borne illnesses that may be endemic in these areas, it has not been proven to substantially reduce the risk of tsetse fly bites. There is no recommended chemoprophylaxis for travelers.

CHAGAS' DISEASE

LOUIS V. KIRCHHOFF

DEFINITION

Chagas' disease, or American trypanosomiasis, is caused by the protozoan parasite *Trypanosoma cruzi*. The terms *Chagas' disease*, *American trypanosomiasis*, and *T. cruzi infection* are synonyms.

The Pathogen

Several dozen species are included in the genus *Trypanosoma*, but only the African trypanosome *Trypanosoma brucei* (subspecies *T.b. gambiense* [West African] and *T.b. rhodesiense* [East African]) (Chapter 354) and the American trypanosome *T. cruzi* cause disease in humans. Many species of triatomine insects, also called *kissing bugs*, act as vectors for *T. cruzi*, and many species of wild and domestic mammals, as well as humans, are involved in the complex life cycle of this fascinating organism. The vectors become infected by ingesting blood from mammals that have parasites in their blood stream. The parasites then multiply in the gut of the insects and are ultimately discharged in the feces of the vector. Transmission to a new mammalian host occurs when parasite-laden vector feces contact vulnerable surfaces such as the mucosae of the mouth or nose, the conjunctivae, or breaks in the skin. Once in contact with tissues of the new host, the contaminating parasites enter local cells, multiply intracellularly, and as parasitized cells rupture, are released into the lymphatics and blood stream. The circulating organisms enter new cells at distant sites and in this manner maintain an endless process of asynchronous multiplication. The life cycle is completed as parasites are swept up in blood meals taken by vectors. In addition to vector-borne transmission, *T. cruzi* can be transmitted by blood or organs donated by infected persons, from mother to unborn child, by the ingestion of contaminated food or drink, and in laboratory accidents.

EPIDEMIOLOGY

Epizootiology of *T. cruzi*

The triatomine vectors that transmit *T. cruzi* are found in the Americas from southern Argentina through the southern half of the United States. The parasite has been isolated from more than 100 species of domestic and wild mammals, which for the most part probably become infected when they eat infected vectors. Armadillos, wood rats, raccoons, and opossums are typical wild mammalian reservoirs, and these and other species that harbor *T. cruzi* can be found in large numbers in the southern and western parts of the United States.

Typically, humans acquire *T. cruzi* infection when they live in houses in enzootic areas where the sylvatic cycle of transmission is active. The process begins when vector species adaptable to living in human dwellings take up residence in niches in the primitive wood, mud, and stone houses that are typical in many regions of Latin America. These vectors become domiciliary and they then take blood meals, mostly at night, from the humans who occupy the dwellings that they have invaded, as well as from domestic animals that sleep there, particularly dogs. Thus, Chagas' disease is primarily a public health problem among poor people who live in rural areas.

Epidemiology of Chagas' Disease in Latin America

Chagas' disease is a zoonosis that is endemic in Mexico and all countries of Central and South America. None of the Caribbean islands are endemic. In 2006 the Pan American Health Organization estimated that 8 million people are chronically infected with *T. cruzi* and that up to 14,000 deaths result from Chagas' disease annually. In 2000 the total annual cost of the morbidity and mortality related to Chagas' disease was estimated to be more than U.S. $8 billion. This harsh reality makes Chagas' disease the most important parasitic disease burden in Latin America. Despite this burden, however, the current situation related to transmission of *T. cruzi* is much more positive. Since 1991 a major international vector control program in the southern cone countries of South America (Chile, Argentina, Paraguay, Brazil, Bolivia, and Uruguay) has achieved a marked reduction in transmission of *T. cruzi* through housing improvement, education of people at risk for acquiring the infection, and spraying of residual insecticides. Substantial reductions in prevalence rates in school-aged children and in blood donors constitute clear evidence of the success of the program. Uruguay, Chile, and Brazil were certified as being free of vector transmission in 1997, 1999, and 2006, respectively. Marked reduction in transmission has been achieved in Argentina as well. Similar programs have been initiated in Central America and the Andean countries. In parallel with the vector control programs, donor screening has been implemented throughout almost the entire endemic range, and with the notable exception of Mexico, transmission of *T. cruzi* by transfusion has largely been eliminated. Nonetheless, much remains to be done before transmission of *T. cruzi* can be eliminated entirely. In 2005 an estimated 41,200 new cases of vector-borne *T. cruzi* infection occurred, as well as 14,385 instances of congenital transmission, which occurs in 2 to 10% of infants born to chronically infected mothers. The barriers standing in the way of elimination of *T. cruzi* transmission to humans are political and economic, and no scientific or technical breakthroughs are required for its completion.

Epidemiology of Chagas' Disease in the United States

As noted, the sylvatic cycle of *T. cruzi* exists in much of the southern and western regions of the United States, but only six cases of autochthonous transmission have been reported: three in Texas and one each in Tennessee, Louisiana, and California. Moreover, the nationwide blood donor screening that started in January 2007, in which more than 35 million units have been tested, has uncovered only a small number of *T. cruzi*–infected donors, who appear to have acquired the infection autochthonously. In the past 30 years only about 15 laboratory-acquired and imported cases of acute Chagas' disease have been reported to the Centers for Disease Control and Prevention (CDC). None of the latter infections occurred in tourists returning to the United States, but three such instances have been reported in Europe. Thus, acute Chagas' disease is extremely rare in the United States.

In contrast to the improving Chagas' disease situation in most endemic countries, because of immigration, the number of persons in the United States with chronic *T. cruzi* infection has increased enormously in recent decades. Census data indicate that including illegal and legal immigrants, 23 million persons born in countries endemic for Chagas' disease currently live in the United States. Roughly 17 million of these individuals are from Mexico, where the overall prevalence of *T. cruzi* infection is thought to range from 0.5% to 1.0%. Moreover, more than half of the non-Mexican immigrants have come from Central America, a region where the prevalence of *T. cruzi* infection is relatively high (e.g., 3.4%, 3.1%, and 2.0% in El Salvador, Honduras, and Guatemala, respectively). A recent estimate puts the number of *T. cruzi*–infected persons currently living in the United States at 300,000. Several studies done before blood donor screening began in 2007 identified *T. cruzi*–infected persons in the donor pool, and seven instances of transmission by transfusion in the United States and Canada were described.

The question of how to avoid transmission of *T. cruzi* by transfusion most effectively in the United States has been debated for decades. Until December 2006 there was no Food and Drug Administration (FDA)-approved donor screening test, so serologic identification of infected donors was not an option. Common sense suggested that if screening for Chagas' disease was warranted in the endemic countries from which the millions of immigrants living here had come, they should be screened at the time of blood donation in the United States. When the Ortho *T. cruzi* ELISA (enzyme-linked immunosorbent assay) Test System (Ortho-Clinical Diagnostics, Raritan, NJ) received FDA approval in late 2006, blood industry and governmental authorities adopted this view and shortly thereafter nearly universal screening began. To date, more than 35 million units have been screened and roughly 1200 *T. cruzi*–infected donors have been identified and permanently deferred from donation. The confirmed rate of *T. cruzi* infection in donors is about 1 in 29,000. With the goal of reducing the enormous cost of universal screening ($100 to $200 million per year), a selective screening protocol based on previous negative test results is being implemented in some regions.

The transplantation in the United States of organs from three persons with undiagnosed chronic *T. cruzi* infection resulted in acute Chagas' disease in five recipients, one of whom died of the infection. To date, no instances of congenital transmission of *T. cruzi* here have been reported.

PATHOBIOLOGY

In acute Chagas' disease, an inflammatory lesion, called a *chagoma*, may appear at the site of entry of the parasites. Local histologic changes include intracellular parasitism of muscle and other subcutaneous tissues,

lymphocytic infiltration, interstitial edema, and hyperplasia of lymph nodes that drain the area. As the parasites spread systemically through the lymphatics and blood stream, muscles, including the myocardium, are the most heavily parasitized tissues, but the organisms can invade essentially any tissue. Myocarditis may develop in association with focal areas of infected cardiomyocytes, inflammation, and necrosis. The characteristic pseudocysts seen in sections of *T. cruzi*–infected tissues are actually host cells filled with multiplying forms of the parasite (Fig. 355-1). In some patients parasites can be seen in cerebrospinal fluid (CSF).

In persons with chronic Chagas' disease, the heart is the organ most commonly affected. Hearts obtained at autopsy from patients who died of Chagas' cardiomyopathy usually have a global appearance reflecting biventricular enlargement and thinning of ventricular walls (Fig. 355-2). Mural thrombi are frequently present, and an apical aneurysm of the left ventricle is typical with advanced disease. At the cellular level, the process that underlies these gross pathologic abnormalities is a chronic inflammation with mononuclear cell infiltration, diffuse interstitial fibrosis, and atrophy of myocardial cells. The chronic inflammation affects the conduction system as well and causes a variety of rhythm disturbances, including atrial bradyarrhythmias and fibrillation; premature ventricular contractions; bundle branch blocks, often of the right bundle; ventricular tachycardia; and third-degree atrioventricular block. Parasites are rarely seen in diseased tissues by conventional histologic methods, but several studies using polymerase chain reaction (PCR) assays found a correlation between the intensity of inflammation and the presence of parasites. Evidence accumulated to date implicates the persistence of parasites and the resulting chronic inflammation in affected tissues—rather than autoimmune mechanisms—as the basis for the pathogenesis in patients with chronic *T. cruzi* infection.

The dilation and hypertrophy observed on gross examination of the esophagus or colon of a patient with chronic Chagas' disease of the digestive tract (megadisease) is striking. Focal inflammatory lesions with lymphocytic infiltration are seen on microscopic examination of affected tissues. In addition, the number of neurons in the myenteric plexus is reduced, and periganglion and intraganglion fibrosis with Schwann cell proliferation and lymphocytosis is present. In most patients the clinical consequences of this parasympathetic denervation are limited to the esophagus or colon (or to both), but the ureters, biliary tree, and other hollow viscera can be affected as well.

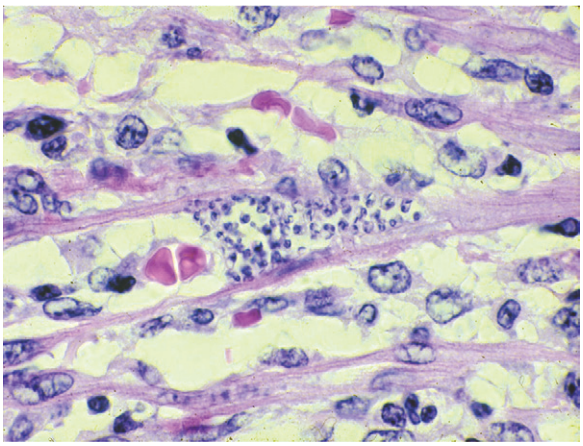

FIGURE 355-1. *T. cruzi* in cardiac muscle of a child who died of acute Chagas' myocarditis. An infected myocyte containing several dozen *T. cruzi* amastigotes is in the center of the field (hematoxylin-eosin staining, ×900).

FIGURE 355-2. Chest radiograph of a patient from Bolivia with chronic *T. cruzi* infection, rhythm disturbances, and cardiomyopathy. Pacemaker wires can be seen in the area of the left ventricle.

CLINICAL MANIFESTATIONS

Acute Chagas' Disease

Acute Chagas' disease is usually an illness of children but can occur at any age. Symptoms are typically mild and nonspecific. When the parasite has entered through a break in the skin or the site of a vector's puncture, as noted, a chagoma may appear with local lymphadenopathy. The Romaña sign, the classic finding in acute Chagas' disease, consists of painless edema of the palpebrae and periocular tissues and may appear when the conjunctiva is the portal of entry. These initial local signs can be followed by fever, malaise, anorexia, and edema of the face and lower extremities. Generalized lymphadenopathy and hepatosplenomegaly may also be present. Severe myocarditis may develop as well, and most deaths are due to the resulting congestive heart failure. Meningoencephalitis is a rare complication. In untreated patients the acute illness resolves spontaneously over a period of 6 to 8 weeks as the patient enters the indeterminate phase of Chagas' disease, which is characterized by subpatent parasitemia, absence of associated signs and symptoms, and easily detectable antibodies to *T. cruzi*.

Chronic Chagas' Cardiopathy

As noted, in only 10 to 30% of persons chronically infected with *T. cruzi* does clinically manifested disease develop, which most often involves rhythm disturbances or cardiomyopathy. Symptoms of cardiac Chagas' disease can develop insidiously years and often decades after the initial infection. Clinical findings reflect the rhythm disturbances, congestive heart failure, and thromboembolism that characterize the illness. Dizziness, syncope, and even seizures can result from a wide variety of arrhythmias. The cardiomyopathy often leads to biventricular failure, and right-sided heart failure can predominate in patients with advanced disease. A validated risk score assessment tool has been developed to gauge prognosis. Chronic Chagas' disease is an independent risk factor for stroke.

Chronic Gastrointestinal Chagas' Disease (Megadisease)

The esophagus and colon are the segments of the gastrointestinal tract most commonly affected in persons with chronic *T. cruzi* infection. In patients with megaesophagus, the symptoms are similar to those of idiopathic achalasia (Chapter 140) and may include cough, dysphagia, odynophagia, and regurgitation. Hypersalivation and consequent salivary gland hypertrophy develop in some patients with advanced esophageal dysfunction. Aspiration can occur, especially during sleep, and in untreated patients, repeated episodes of aspiration pneumonitis are common. Weight loss and even cachexia in patients with severe megaesophagus can combine with pneumonitis to cause death. Patients with chagasic megacolon suffer from intermittent abdominal pain and chronic constipation and in advanced cases can go for several weeks between bowel movements. Rarely, acute obstruction, occasionally with volvulus, can lead to perforation, septicemia, and death.

Immunosuppression and Transplantation in Patients Infected with *T. cruzi*

When persons with chronic carriage of *T. cruzi* become immunosuppressed, reactivation of the infection can occur, sometimes with an intensity that is atypical of acute Chagas' disease in immunocompetent persons. The overall incidence of reactivation in immunosuppressed persons who harbor the parasite chronically is not known. Reactivation after renal transplantation has been reported, and in two of the patients described the central nervous system was involved. The consensus view is that Chagas' disease should not

be a contraindication to kidney transplantation. In *T. cruzi*–infected patients who do undergo the procedure, periodic monitoring for signs and symptoms of acute Chagas' disease should nonetheless be carried out, including careful neurologic evaluation, and parasitologic tests for the parasite should be done when acute illnesses occur postoperatively.

Reactivation of *T. cruzi* infection can also occur in persons coinfected with the parasite and human immunodeficiency virus (HIV). Dozens of such patients have been described, one of whom was an immigrant from El Salvador living in the United States. It is striking that in many of these patients *T. cruzi* brain abscesses developed, which do not occur in immunocompetent patients with chronic Chagas' disease. It has been shown that HIV viral loads increase in the context of reactivated acute Chagas' disease. Calculations based on the overlapping epidemiologies of HIV and *T. cruzi* infections in the endemic countries suggest that the incidence of reactivation of the latter in coinfected persons is quite low.

DIAGNOSIS

Acute Chagas' Disease

The first step in considering the diagnosis of acute Chagas' disease is establishing that a person is at risk for *T. cruzi* infection. Risk factors include recent residence or blood transfusion in an endemic area, birth to a mother with geographic- or transfusion-associated risk in the case of a newborn, or a laboratory accident involving the parasite. Definitive diagnosis of acute Chagas' disease can be made only by detecting parasites. Serologic assays for *T. cruzi*–specific IgM are not accurate enough to justify their use. In immunocompetent persons suspected of having acute Chagas' disease, the most productive approach is examination of wet preparations of anticoagulated blood or buffy coat for the highly motile blood stream parasites. They can be seen in Giemsa-stained smears as well. In infected immunocompromised patients, moreover, parasites can sometimes be found in other specimens such as lymph node aspirates, biopsy specimens of skin lesions, bone marrow, endomyocardial tissue, CSF, and pericardial fluid.

When these direct methods fail to detect organisms in an at-risk person, samples should be tested with a PCR assay (see later). PCR assays have been shown to be more sensitive than the direct methods described earlier for detecting *T. cruzi*. Another method is to culture blood or other samples in specialized liquid medium, but the usefulness of this approach is limited by low sensitivity (50 to 70% for hemoculture) and by the fact that cultures take a minimum of 2 weeks before turning positive. In newborns whose blood is negative both by direct examination and in a PCR assay right after birth, serologic evaluation for *T. cruzi*–specific IgG should be performed 6 to 9 months later, by which time maternal antibodies will have disappeared.

Chronic Chagas' Disease

Chronic *T. cruzi* infection is usually diagnosed by detecting IgG antibodies that specifically bind to the parasite's antigens, and in almost all instances isolation of the organism is not necessary. More than 30 serologic assays for diagnosing Chagas' disease are currently available commercially in endemic countries, where they are used widely for testing clinical specimens and screening blood donors. Even though these tests usually have good sensitivity and reasonable specificity, false-positive reactions do occur, typically with specimens from people who have other infectious diseases or autoimmune conditions. The World Health Organization has recommended that testing be done with two assays based on different formats. A number of assays based on recombinant antigens are available commercially or are in development and may offer improved diagnostic accuracy. Two FDA (510[k])-approved assays are available in the United States for clinical testing but are not approved for screening donated blood (Chagas Kit, Hemagen Diagnostics, Inc., Columbia, MD; Chagatest ELISA Recombinante v3.0, Wiener Laboratories, Rosario, Argentina). In addition, two tests are now approved by the FDA for screening donated blood (Ortho *T. cruzi* ELISA Test System, Ortho-Clinical Diagnostics, Raritan, NJ; Abbott Prism Chagas, Abbott Laboratories, Abbott Park, IL). The Ortho ELISA is also approved for clinical testing. A Clinical Laboratories Improvement Act (CLIA)-approved radioimmune precipitation assay (Chagas RIPA) is used for confirmatory testing of donor samples that are positive in the screening tests (Quest Diagnostics Nichols Institute, Chantilly, VA) and is also available in my laboratory for testing clinical and research specimens.

The potential usefulness of PCR assays for detecting *T. cruzi* infection has been studied since the late 1980s. In 1989, Moser and coworkers described a PCR assay in which a 188–base pair nuclear repetitive DNA sequence (≈100,000 copies per genome) is amplified with primers named TCZ1 and TCZ2. In acutely and chronically infected mice the TCZ1-TCZ2 assay was much more sensitive than microscopic examination of blood. In another PCR assay described by Sturm and colleagues, a 330–base pair segment of the *T. cruzi* kinetoplast minicircle (≈120,000 copies per genome) is amplified with primers called S35-S36. In the three studies published to date that directly compare the sensitivities of these two assays, the TCZ1-TCZ2 assay appeared to be somewhat more sensitive. PCR assays based on several other primer pairs have been described, but none appears to be more sensitive than assays based on TCZ1-TCZ2 or S35-S36.

Since the publication in 1989 of two reports describing the use of PCR tests to detect *T. cruzi*, well over 100 articles dealing with this approach have appeared. In human studies the sensitivity of the PCR assays ranged from 44.7 to 100%, with most being higher than 90%. It is generally accepted that the level of sensitivity of these assays is not high enough to justify their use for confirmatory testing of serologically positive donor samples. In contrast, PCR assays may be useful in persons who have borderline serologic results, in patients suspected of having congenital or acute Chagas' disease in whom parasites are not detected microscopically, and in infected patients who have received specific treatment. In all such persons, because of the sensitivity issue, only positive PCR results can be taken as being truly indicative of infection status.

TREATMENT Rx

Antiparasitic Drugs (also see Chapter 352)

The two drugs currently available for treating Chagas' disease are unsatisfactory, and the need for a parasitologically curative drug regimen is the most important current challenge in Chagas' disease research. Nifurtimox (Lampit, Bayer 2502, Leverkusen, Germany) is a nitrofuran derivative that has been used for more than 3 decades. Nifurtimox reduces symptoms and decreases mortality in patients with acute Chagas' disease, approximately 70% of whom are cured parasitologically. Nifurtimox also can cure a substantial portion of children in the indeterminate phase, but unfortunately, cure rates may be less than 10% in adults with long-standing chronic *T. cruzi* infection.

Disadvantages of nifurtimox include its long course of treatment and occasionally bothersome side effects, including gastrointestinal complaints such as anorexia, nausea, vomiting, weight loss, and abdominal pain. Patients taking the drug may also have neurologic symptoms such as insomnia, restlessness, paresthesias, twitching, polyneuritis, and even seizures. Nifurtimox is available in 30- and 120-mg tablets. For adults, the recommended oral dosage is 8 to 10 mg/kg body weight per day. For adolescents, the dose is 12.5 to 15 mg/kg/day, and for children 1 to 10 years of age, it is 15 to 20 mg/kg/day. The drug should be given each day in four divided doses, and treatment should be continued for 90 to 120 days. Nifurtimox can be obtained from the CDC Drug Service (404-639-3670).

The second drug for treating *T. cruzi* infection is the nitroimidazole derivative benznidazole (Rochagan, Radinil, Roche 7-1051; LAFEPE, Pernambuco, Brazil). Cure rates are similar or perhaps a bit higher than those achieved with nifurtimox. A cure rate higher than 90% in babies with congenital infection has been observed with benznidazole. Side effects can include rash, peripheral neuropathy, and granulocytopenia. Benznidazole is considered the drug of choice by most Latin American experts. The recommended oral dosage of benznidazole is 5 to 10 mg/kg body weight per day for children and 5 mg/kg body weight per day for adults, in both cases for 60 days.

There is broad agreement among experts that treatment is indicated in all patients with acute or congenital infections, as well as in chronically infected children up to 18 years old. This recommendation is supported by several studies showing that a majority of such patients can be cured parasitologically. By extension, it would be reasonable to treat anyone 18 years or older known to have acquired *T. cruzi* infection within the past 17 years. There is also broad agreement that persons with advanced symptomatic *T. cruzi* infection should not be given specific treatment. The remaining question, then, is whether adults with long-standing indeterminate-phase infections, who by far constitute the largest group of *T. cruzi*–infected persons, should be treated. This is a thorny question because the burden of taking a full course of either drug can be substantial and also because parasitologic cure rates are so low. Importantly, there is no clear evidence from randomized controlled trials that therapy with either drug delays the onset of symptoms or the progression of pathology or reduces mortality in adults with chronic *T. cruzi* infection. In 2006 a panel of experts convened at the CDC recommended that adults 19 to 50 years old in the indeterminate phase or with mild symptoms be offered treatment. A large randomized trial (the BENEFIT multicenter trial) designed to assess the clinical and parasitologic efficacy of benznidazole in patients with Chagas' disease 18 to 75 years old without advanced disease is being conducted in Colombia, Bolivia, Brazil, and Argentina. Initial findings will not be available until 2012. An additional important question is whether specific treatment given before pregnancy will reduce the probability of subsequent

congenital transmission. To date, only one limited study has addressed this issue, and the findings suggest a protective effect.

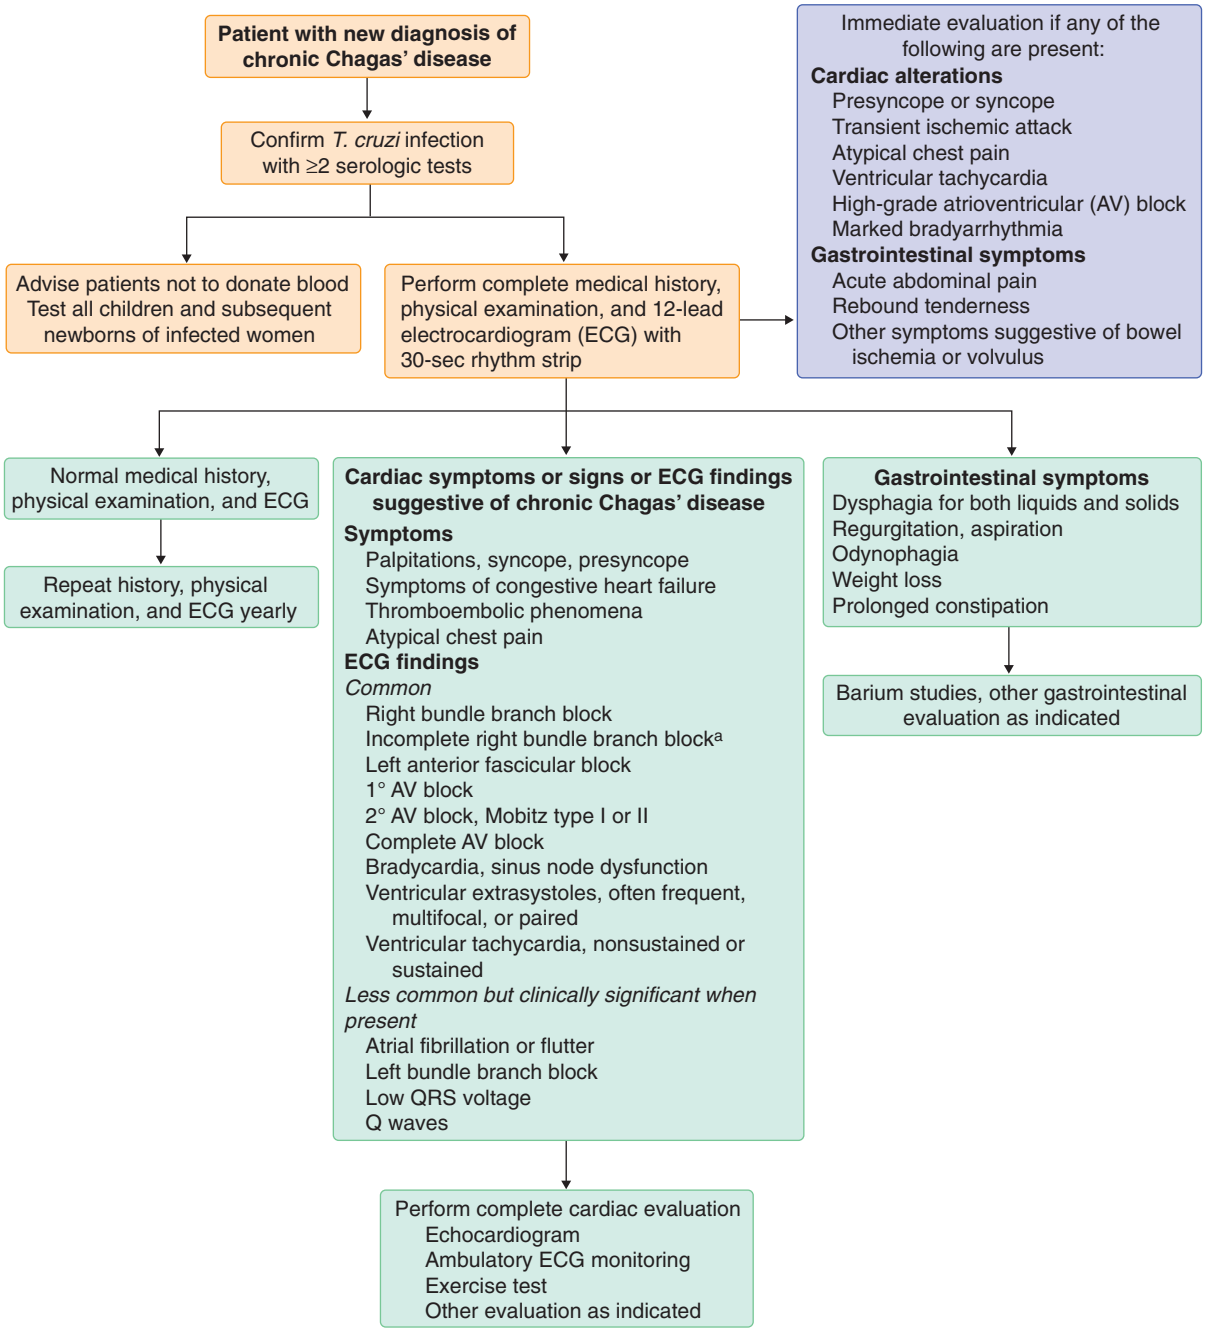
Management of Symptomatic Chagas' Disease

An algorithm for the evaluation of persons with newly diagnosed Chagas' disease has been developed (Fig. 355-3). *T. cruzi*–infected patients in whom symptomatic cardiac or gastrointestinal disease develops should be referred to appropriate subspecialists. Beyond the possible use of nifurtimox or benznidazole, treatment of acute and chronic Chagas' disease is symptomatic. In patients with symptomatic chronic Chagas' cardiac disease, treatment should be directed at managing symptoms with the anticoagulants and cardiotropic drugs used in patients with cardiomyopathy of other cause. Pacemakers are useful in patients with ominous arrhythmias. Studies of the usefulness of autologous bone marrow cells in improving heart function in patients with Chagas' cardiomyopathy are under way.

Heart transplantation (Chapter 82) is an option in patients with end-stage Chagas' cardiac disease, and more than 150 such patients have undergone the procedure in Brazil and the United States. As is the case with other *T. cruzi*–infected patients who are immunosuppressed, reactivation is a risk but is manageable. The usefulness and side effects of long-term prophylaxis for reactivation with either benznidazole or nifurtimox in *T. cruzi*–infected patients after heart transplantation have not been evaluated. The long-term survival of Chagas' patients with heart transplants appears to be longer than that in patients undergoing cardiac transplantation for other reasons, probably because the lesions of *T. cruzi*–associated pathology affect mostly the heart.

Chagas' megaesophagus should be treated as normally done for idiopathic achalasia (Chapter 140), which usually responds to balloon dilation of the lower esophageal sphincter when symptoms are mild. Surgical treatment may be required in patients who do not respond to repeated attempts at balloon dilation. Laparoscopic myotomy is being used with increasing frequency to treat Chagas' megaesophagus, as is the case with achalasia. Injection of botulinum toxin into the lower esophageal sphincter is being evaluated as an alternative to myotomy.

Chagas' megacolon in its early stage can be treated with a high-fiber diet and occasional laxatives or enemas. Fecal impaction requiring manual disimpaction can occur, and toxic megacolon requires surgery. In patients with



[a]QRS interval of 0.10 to 0.11 seconds in adults. Criteria based on the *Minnesota Code Manual of Electrocardiographic Findings* with modifications from Maguire et al. Different criteria may be required for ECGs in children.

FIGURE 355-3. Algorithm for baseline evaluation of a patient with newly diagnosed chronic *T. cruzi* infection. (From Bern C, Montgomery SP, Herwaldt BL, et al. Evaluation and treatment of Chagas disease in the United States: a systematic review. *JAMA*. 2007;298:2171-2181.)

advanced megacolon, volvulus (Chapter 144) can develop when an enlarged and lengthened sigmoid colon twists and folds on itself; volvulus causes a constellation of symptoms and in many cases requires immediate surgery. Even if the symptoms associated with volvulus are resolved without operative intervention, however, surgical treatment is usually ultimately necessary because the volvulus tends to recur. Several surgical procedures are used to treat advanced Chagas' megacolon, all of which include resection of the sigmoid and removal of part of the rectum.

PREVENTION

Reducing human contact with triatomine vectors through education of at-risk persons, housing improvement, and spraying of residual insecticides in endemic countries has resulted in reduction or elimination of vector transmission of *T. cruzi* in a major part of the endemic range, and progress in this regard is expected to continue. Serologic screening of donated blood has essentially eliminated transfusion-related transmission of the parasite. Outbreaks of acute Chagas' disease through oral transmission can be avoided by the implementation of better food safety standards. Drug treatment of *T. cruzi*–infected women before pregnancy may reduce the likelihood of congenital transmission, but this issue needs further study. No protocols have been defined and validated for preventing reactivation of *T. cruzi* infection in chronically infected persons who are immunosuppressed iatrogenically or by HIV. A treatment regimen that reliably results in parasitologic cure is needed to prevent the onset or progression of chronic symptomatic Chagas' disease.

PROGNOSIS

The prognosis for patients with acute Chagas' disease is generally excellent because most acutely infected persons have only mild symptoms that resolve spontaneously, even without specific treatment. The occasional patient who has symptomatic acute Chagas' myocarditis should generally do well if treated early. In persons with chronic *T. cruzi* infection, the lifetime risk for the development of related cardiac or gastrointestinal dysfunction is only 10 to 30%. A validated risk score assessment tool has been developed to gauge prognosis. It has not been determined in randomized controlled trials whether this rate of progression to clinical disease or overall mortality is significantly affected by treatment with nifurtimox or benznidazole.

LEISHMANIASIS

SIMON L. CROFT AND PIERRE A. BUFFET

DEFINITION

Leishmaniasis is caused by protozoan parasites of the genus *Leishmania* that are transmitted between mammalian hosts by female phlebotomine sandflies. The disease has a number of clinical manifestations ranging in severity from self-curing, limited cutaneous lesions to disseminated, potentially fatal visceral disease. The parasite exists as an extracellular flagellated form, the promastigote, in the sandfly gut and as an intracellular form, the amastigote, that survives and multiplies in a phagolysosomal compartment of macrophages in the mammalian host.

This disease complex is caused by 17 species of *Leishmania*, which are widely distributed in Europe, Asia, Africa, and South and Central America. The characteristics of the main *Leishmania* species are summarized in Table 356-1. There are an estimated 1.5 to 2.0 million new cases each year, with up to 70,000 deaths, although this is probably an underestimate because leishmaniasis is a reportable disease in only 40 of the 88 countries in which it is known to occur. Many *Leishmania* infections are either asymptomatic or misdiagnosed.

Because leishmaniasis is a disease complex, clinical aspects are considered under separate sections for visceral leishmaniasis (VL) and cutaneous leishmaniasis (CL).

EPIDEMIOLOGY

Infection is established in the mammalian host following a bite of the female sandfly belonging to either *Phlebotomus* spp in Europe, Asia, and Africa or *Lutzomyia* spp in the Americas. Different species of sandfly are associated with transmission of different *Leishmania* species. Most species that cause CL have a zoonotic (acquired from a vertebrate animal) transmission cycle, with the exception of *Leishmania tropica*, which is sometimes anthroponotic (transmitted from a human being). VL is either anthroponotic (in the case of *Leishmania donovani*) or zoonotic (in the case of *Leishmania infantum*). The predominant mammalian hosts (the reservoirs) are associated with different *Leishmania* species in diverse ecosystems (Fig. 356-1).

VL is caused by either *L. donovani* or *L. infantum* (which is identical to *Leishmania chagasi* in South America). These species have different geographic distributions, with the highest incidence found in the poorest communities in six countries (Bangladesh, Nepal, India, Sudan, Ethiopia, Brazil), and it is potentially fatal if untreated. An estimated 1 in 5 to 1 in 50 infections are asymptomatic, depending on the parasite species and host immunity. Since 2005 there has been a regional program to eliminate VL (reducing annual incidence to <1 per 10,000) in the Indian subcontinent.

CL, which undergoes self-cure in more than 90% of patients within 3 to 18 months, is widely distributed, but its prevalence is difficult to estimate because of underreporting. Prevalence is associated with age, possibly related to the acquisition of immunity and risk factors, including the presence of domestic animals in some cases or rodent hosts. Ecologic conditions for sandflies, including shaded and humid habitats in crevices and mammal burrows, have been identified.

Urbanization and deforestation have resulted in changing patterns of disease, with transmission occurring in peridomestic cycles. Other forms of transmission, such as via intravenous needles shared by drug users, have been reported in Spain.

TABLE 356-1 CHARACTERISTICS OF THE MAIN *LEISHMANIA* SPECIES

LEISHMANIA SPP	*LEISHMANIA* SUBGENUS	DISTRIBUTION: OLD WORLD	DISTRIBUTION: NEW WORLD	PRIMARY FORM	SECONDARY FORMS	ANTHROPONOTIC: AREAS OF TRANSMISSION	ZOONOTIC: RESERVOIR	ALTERNATIVE NAME
L. donovani	*Leishmania*	Indian subcontinent E. Africa		VL	PKDL CL, ML OIVL	Indian subcontinent E. Africa		Kala-azar
L. infantum (*L. chagasi*)	*Leishmania*	Europe Asia	S. & C. America	VL	CL, ML OIVL		Canid	
L. major	*Leishmania*	Asia N. & E. Africa Europe		CL			Rodent	
L. tropica	*Leishmania*	Asia Europe		CL	Recidivans	Syria Afghanistan	Rodent	Aleppo boil
L. aethiopica	*Leishmania*	Ethiopia		CL	DCL		Hyrax	
L. mexicana	*Leishmania*		C. America	CL			Rodent	Chiclero's ulcer
L. amazonensis	*Leishmania*		C. & S. America	CL	DCL		Rodent	
L. braziliensis	*Viannia*		S. America	CL ML	DissCL Lymph		Rodent, marsupial	ML-espundia
L. panamensis	*Viannia*		C. & S. America	CL	ML Lymph		Edentate rodent	Ulcera de bejuco
L. guyanensis	*Viannia*		S. America	CL	ML Lymph		Rodent, edentates	Pian bois
L. peruviana	*Viannia*		S. America	CL			Canids	Uta

CL = cutaneous leishmaniasis; DCL = diffuse cutaneous leishmaniasis; DissCL = disseminated cutaneous leishmaniasis; Lymph = nodular lymphangitis; ML = mucosal leishmaniasis; OIVL = opportunistic infection with VL in HIV-infected patients; PKDL = Post–kala-azar dermal leishmaniasis; VL = visceral leishmaniasis.

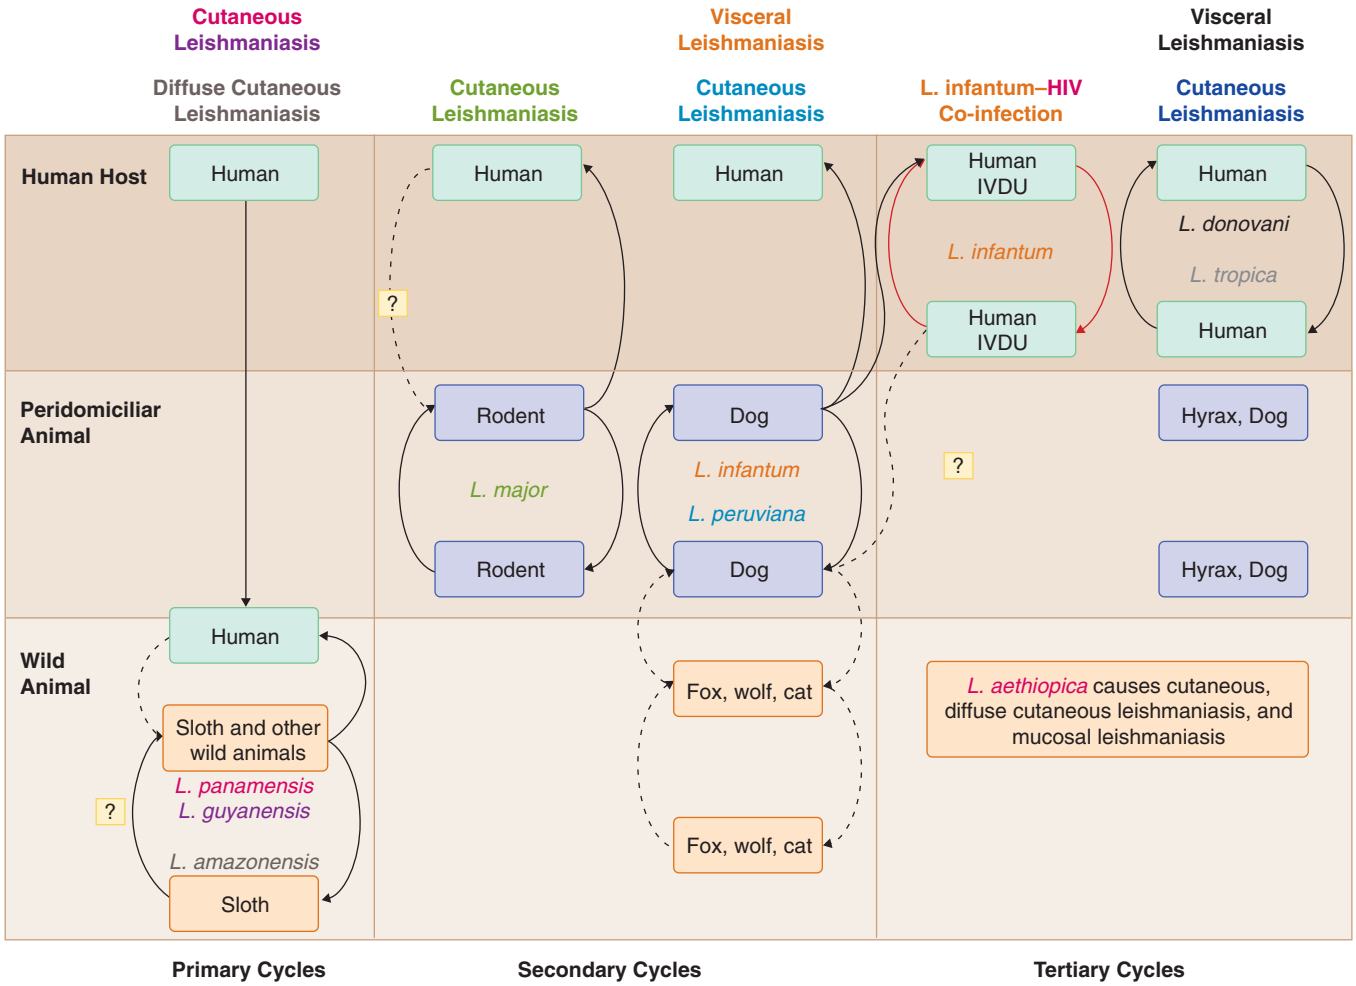

FIGURE 356-1. Old World and New World zoonotic and anthroponotic life cycles of the main species of *Leishmania*. Leishmaniasis is often referred to as a "disease complex" because different forms of disease can be caused by the same parasite species and similar forms of disease can be caused by different parasite species. IVDU = intravenous drug use.

PATHOBIOLOGY

The infection is initially established in the skin after the inoculation of infective metacyclic promastigotes by the sandfly. These infective forms have a glycoprotein coat (a lipophosphoglycan) that enables them to resist complement and attach to and invade host cells. Peptides in sandfly saliva (e.g., maxadilan) cause vasodilation and erythema and help establish infection in the dermal layer of the skin. Early responses to infection involve neutrophil infiltration and invasion of resident macrophages. Progress of the disease depends on the parasite species and host responses. For both VL and CL, disease progression depends on maintenance of a parasite-specific immunosuppressive state. Host cell macrophages are in a deactivated state, but cure follows when macrophages become activated and kill the parasites, which are sensitive to nitric oxide and oxygen radicals in the phagolysosomal compartment. Resolution of disease following the activation of macrophages is mediated by a T-helper cell T_H1 response after interaction between antigen-presenting cells (e.g., dendritic cells) with $CD4^+$ and $CD8^+$ T cells and subsequent secretion of pro-inflammatory cytokines (e.g., interleukin-1 [IL-12], interferon-γ, tumor necrosis factor-α). However, in clinical forms such as active VL or diffuse CL, a T_H2 cell response predominates whereby down-regulation of macrophage activity follows the production of cytokines such as IL-4, IL-10, IL-13, and transforming growth factor-β. This profile has been defined in experimental models, mainly inbred mice, and ongoing clinical studies generally support the notion of a similar profile in human infection.

In patients with VL, the absence of a T-cell–specific immune response to leishmanial antigens is associated with uncontrolled progression of infection. This is related to elevated levels of IL-10 and decreased production of interferon-γ. Genetic susceptibility to *L. donovani* in Sudan has been associated with a solute carrier family (formerly NRAMP1) that regulates macrophage activation and with a polymorphism in the IL-4 gene. In localized simple CL, patients show a T_H1-type response and a delayed-type hypersensitivity (DTH) response. DTH is frequently measured by a Montenegro skin test, which can also be used in epidemiologic prevalence studies. Chronic infections show a T_H2-type response, most predominantly in patients with diffuse CL, in whom there is complete anergy to leishmania antigen and no DTH response. Patients with mucosal leishmaniasis (ML) have both T_H1 and T_H2 cell responses and a strong DTH response.

VISCERAL LEISHMANIASIS

CLINICAL MANIFESTATIONS

The onset of VL, often referred to as kala-azar when caused by *L. donovani*, occurs weeks to months after the initial infection. Clinical signs and symptoms do not distinguish VL from hyperreactive malarial splenomegaly or other infectious or hematologic conditions. Anemia, leukopenia, thrombocytopenia, systemic inflammation, or polyclonal hypergammaglobulinemia, either isolated or combined, suggests but does not confirm the diagnosis. Parasitologic tests are therefore indispensable before making a therapeutic decision.

DIAGNOSIS

Parasitology

Microscopic visualization of amastigotes in samples from the lymph nodes, bone marrow, liver, spleen, or other organs is usually the first step. Because spleen aspiration causes life-threatening complications in approximately 0.1% of patients, it should be performed only in trained facilities and only if other, lower-risk methods cannot be used. It is still used in the field because of the higher cost, logistic constraints, and lower sensitivity of bone marrow aspiration. Polymerase chain reaction (PCR) is more sensitive than microscopic examination and has become the first-line test in several referral hospitals and research centers. Quantitative PCR with validated thresholds allows accurate diagnosis with venous blood samples, thereby avoiding bone marrow aspiration.

Serology

Serologic tests based on indirect fluorescent antibody (IFA), enzyme-linked immunosorbent assay (ELISA), or Western blot display high performance but require equipment that is poorly adapted to field settings. The field-friendly direct agglutination test (DAT) and immunochromatography using the rK39 antigen have high diagnostic accuracy and can be used in peripheral health centers. Whatever the serologic test used, specific antibodies remain detectable for several years after cure or asymptomatic infection.

Antigen Detection Tests

A latex agglutination test that detects a heat-stable, low-molecular-weight carbohydrate antigen in the urine of patients with VL showed good specificity but low to moderate sensitivity in East Africa and the Indian subcontinent. Further optimization is expected.

Complex Manifestations of Visceral Leishmaniasis

Visceral Leishmaniasis–Human Immunodeficiency Virus Coinfection

Although the clinical manifestations in VL patients infected with human immunodeficiency virus (HIV) without severe immunosuppression are similar to those in immunocompetent patients, atypical clinical features can be found in patients with low $CD4^+$ T-cell counts (<200/μL). In the latter group, physicians may order investigations for VL even in the absence of classic signs (e.g., lack of splenomegaly). A substantial proportion of HIV-VL–coinfected patients may have other opportunistic infections that complicate the clinical diagnosis. The parasitic load is usually higher and parasites may be found in unusual sites, especially in severely immunosuppressed patients. Therefore, the sensitivity of microscopic examination, culture, or PCR of blood (plain blood or buffy coat) or bone marrow aspirates is higher than that in immunocompetent VL patients. *Leishmania* parasites can occasionally be found in biopsy samples from the skin, gastrointestinal tract, or lungs. Limited data have also shown high sensitivity of the latex agglutination test in the urine of HIV-VL–coinfected patients. In contrast, the sensitivity of serologic tests is decreased in coinfected patients, although study results are equivocal and depend on several factors such as the test's format, region of endemicity, and level of immunosuppression. For example, the DAT has shown high sensitivity in Ethiopia. Increased sensitivity can be achieved by using a sequential combination of different serologic tests.

Post–Kala-azar Dermal Leishmaniasis

After successful treatment of visceral disease, a proportion of patients progress to disseminated cutaneous disease. This is reported in up to 20% of patients in Sudan and 0.5% in India. Studies in India have shown that smears are more likely to show amastigotes if taken from nodular lesions rather than papular or macular lesions. Serologic tests such as the DAT, ELISA, and rK39 immunochromatography are of limited value because a positive finding may be the result of persistent antibodies following the past episode of VL. Nevertheless, serology can be helpful when a previous history of VL is uncertain.

TREATMENT Rx

General Principles

The clinical response to antileishmanial agents depends on the clinical form and the infecting species or even the subspecies (zymodeme). Many antileishmanial agents are either toxic, expensive, or difficult to administer in field conditions. No single satisfactory option for treating most of the clinical forms or species has been validated. Although therapeutic decisions and follow-up have become relatively simple for the treatment of VL in nonendemic countries—based on the powerful, well-tolerated agent liposomal amphotericin B—more complexity persists for the treatment of VL in endemic countries and for CL or ML everywhere.

Visceral Leishmaniasis in Immunocompetent Patients

Single-Agent Therapies

Pentamidine is efficient in treating VL only when high doses (more than seven injections of 4 mg/kg) are used. These are toxic, and pentamidine is no longer used for the treatment of VL. Lower doses (fewer than four injections of 4 mg/kg) induce much less adverse events and are still used for the secondary prophylaxis of VL in HIV-infected patients and in those with CL caused by *Leishmania guyanensis* or *Leishmania panamensis*.

Pentavalent antimonials (sodium stibogluconate, meglumine antimoniate) are still prescribed as first-intention drugs in many areas. In the Indian subcontinent (mainly in northern Bihar), *L. donovani* is resistant to pentavalent antimonials. Their efficacy has decreased from 90% to less than 40% over the past 40 years. In other VL foci, failure rates of initial treatment do not exceed 10% as long as the dosage is respected (20 mg of pentavalent antimony per kilogram per day for 28 days). In an endemic country, mortality in treated patients may exceed 10%, with toxicity positively correlating with age. Pentavalent antimonials are contraindicated in patients with heart, kidney, or liver disease

or advanced age and in pregnant women. Generic formulations have demonstrated activity and tolerance identical to that of sodium stibogluconate.

Miltefosine is an alkyl phosphocholine. The oral form (2.5 mg/kg/day for 28 days) is very effective for VL in India. In Ethiopian patients with VL (28% with HIV infection), there was significantly higher mortality with sodium stibogluconate (generic) than with miltefosine (9.7 vs. 2.1%) despite the lower parasitologic efficacy of miltefosine (92.1 vs. 99.3%). Miltefosine is contraindicated in pregnant women or those who may become pregnant. Because of persistent levels of the drug, contraceptive measures must be observed for months after therapy.

Paromomycin (aminosidine sulfate) (15 mg/kg in sulfate form equivalent to 11 mg of base per kilogram intramuscularly for 21 days) is highly effective in India, where it has been available since 2006. In East Africa, its efficacy is lower. Similar to the situation with miltefosine, the longevity of the product would probably be better preserved in combination than as a single-agent therapy.

Amphotericin B (cumulative dose of 7 to 15 mg/kg) cures more than 98% of patients in India, whereas treatment of visceral infection with *L. infantum/chagasi* requires at least 14 mg/kg.

Liposomal amphotericin B achieves very high cure rates in India with lower cumulative doses than needed with the deoxycholate formulation. In preliminary studies in East Africa, the doses of liposomal amphotericin B required to cure VL (about 30 mg/kg cumulatively) are markedly higher than those used in India. Liposomal amphotericin B is associated with less infusion-related fever and chills, less renal toxicity, and a reduction in the number of infusions and length of hospitalization. The better renal tolerance of liposomal amphotericin B is especially beneficial in patients with renal failure or a kidney graft and in those with an increase in serum creatinine during amphotericin B deoxycholate therapy. Liposomal amphotericin B is the antileishmanial agent with the best benefit-risk ratio. It is now the first-line option in most nonendemic countries, both in children and in adults. The very high cost of liposomal amphotericin B has been reduced for use in endemic countries, but wider implementation would be greatly facilitated by a much more drastic reduction. A single infusion of liposomal amphotericin B at a dose of 10 mg/kg of body weight was recently reported not to be inferior to and less expensive than conventional treatment with amphotericin B deoxycholate. In this study, conducted in India, 304 of 304 (100%) patients with VL in the liposomal therapy group and 106 of 108 (98%) in the conventional therapy group had apparent cure responses at day 30. Cure rates at 6 months were similar: 95.7% with liposomal therapy and 96.3% with conventional therapy.[1]

Combinations/Coadministration

To limit extension of the resistance to pentavalent antimonials and prevent the emergence of resistance to paromomycin or miltefosine, shorter courses of therapy are being investigated. Because only miltefosine may be administered orally, this approach is based at least partly on products administered parenterally. Combinations of amphotericin with oral miltefosine and intramuscular paramonomycin can achieve high cure rates with 7 to 10-day courses of therapy.[2] A single infusion of liposomal amphotericin B followed by oral miltefosine has been highly effective in India, but confirmation studies are required here and elsewhere.

Visceral Leishmaniasis in Immunodeficient Patients

Leishmania infantum–HIV Coinfection

As with other major opportunistic infections during HIV infection, treatment may be subdivided into initial course and secondary prophylaxis. With initial treatment, the efficacy of meglumine antimoniate and that of amphotericin B are almost similar. The severe adverse effects of antimony derivatives are more common in this context. Doses of liposomal amphotericin B administered to immunodeficient patients are higher (30 to 40 mg/kg in cumulative dose) than those administered to immunocompetent patients. When therapeutic immunosuppression may not be reduced or optimization of highly active antiretroviral therapy is not possible, secondary prophylaxis is often proposed. Amphotericin B lipid complex moderately reduces the frequency of recurrences. Discontinuous administration of liposomal amphotericin B is generally used, but a progressive reduction in its efficacy has been reported, though apparently not associated with decreased parasitic sensitivity in vitro. Miltefosine is another option, especially if the reduction in parasitic load is backed up by quantitative PCR with a validated threshold (low residual load probably being associated with a lower risk for resistance). Administration of pentamidine once or twice a month is another potentially interesting option because drug levels persist for weeks or months after a single administration. Pancreatic tolerance should be monitored closely.

Leishmania donovani–HIV Coinfection

Patients should benefit from effective antiretroviral treatment. The experience with *L. infantum*–HIV coinfection is in part transposable. The potential risk for the emergence of resistance to antileishmanial agents is still more significant in this context because *L. donovani* (but not *L. infantum*) can be transmitted from human to human. Important clinical research is ongoing in East Africa.

CUTANEOUS LEISHMANIASIS

CLINICAL MANIFESTATIONS

Although the signs and symptoms of CL vary considerably (Fig. 356-2)—from pure nodular lesions to developing ulceration through dry crusty lesions and squamous plaques—there are some fairly constant features. First, firm infiltration is almost constant (the exception being the initial macule of post–kala-azar dermal leishmaniasis). Second, the evolution is subacute, which is a useful criterion in practice. A lesion reaching its maximum size in less than a week is most likely not due to CL. Finally, except in patients with very numerous satellite papulopustules, the lesion or lesions are sharply defined. Colonization of the CL ulceration with bacteria may give the lesion a purulent appearance, whereas patent superinfection adds an erythematous ring distinctly overflowing the infiltrated edge of the ulceration and making a usually cold and painless lesion feel hot and painful. Several dermatologic conditions such as staphylococcal or streptococcal infection, mycobacterial ulcer, leprosy, fungal infection, cancer, sarcoidosis, and tropical ulcer mimic CL or ML lesions (Fig. 356-2). Because treatment is costly, diagnostic confirmation is necessary.

DIAGNOSIS

Parasitology

Scraping, fine-needle aspiration, or biopsy of lesions provides appropriate samples in which amastigotes can be identified (Fig. 356-3). Scraping should be performed at both the center and edges of the lesion with a curved scalpel blade. Local anesthesia considerably reduces patients' discomfort and increases sensitivity. Using an adrenaline-containing local anesthetic (contraindicated for lesions on extremities) or pinching the lesion between the thumb and finger until blanching appears helps obtain a bloodless scraping, thus optimizing microscopic examination. The 2- to 4-mm skin fragment obtained by punch biopsy provides abundant material, which facilitates the search for scarce parasites and for an alternative diagnosis by culture (e.g., mycobacteria, fungi), as well as histopathologic examination. Culture of a biopsy sample requires homogenization in saline or culture medium under sterile conditions.

The material obtained by any of these methods can be used for microscopic examination, culture, and PCR. Microscopic examination of Giemsa-stained material is the most widely available method. Culture of the parasite in specific media (such as fetal calf serum–supplemented Schneider or Novy-Nicolle-McNeal media) allows identification, characterization, and storage of the isolate. Detection of parasitic nucleic acids by molecular diagnosis (mainly PCR) increases sensitivity and allows identification of the *Leishmania* species. This is particularly useful in regions (e.g., New World) where several *Leishmania* species—with various clinical outcomes and responses to treatment—coexist. Both culture and molecular-based diagnosis require substantial laboratory infrastructure and technical expertise.

Serology

Serologic diagnosis is of limited use for CL because of low sensitivity and variable specificity. The leishmanin (or Montenegro) skin test (LST) evaluates the cell-mediated response against *Leishmania* spp. The LST requires culture and fixation of—preferentially—local species of *Leishmania* and therefore lacks standardization. The production of commercial formulations of the LST lacks sustainability. Like serologic tests, the LST does not distinguish between past and present infections.

COMPLEX MANIFESTATIONS OF CUTANEOUS LEISHMANIASIS

Mucosal Leishmaniasis

A proportion of CL infections (about 1 to 10% in Brazil and Peru) caused by *Leishmania braziliensis* or *L. guyanensis* progress to a metastatic infection of the mucosa of the oral/nasal cavity or larynx, often 1 to 5 years after healing of the initial simple cutaneous lesion. Immunopathology results in extensive destruction of local tissue. Allergic rhinitis, paracoccidioidomycosis or other deep mycosis, cancrum oris, leprosy, and sarcoidosis may mimic the lesions of ML. Positive serology (e.g., IFA, ELISA) or LST indicate possible ML. Parasites are scarce in mucosal lesions. Therefore, a search for parasites in mucosal samples—obtained by scraping or biopsy—by microscopic examination or by culture lacks sensitivity. PCR has proved to be the most sensitive approach to confirm ML.

FIGURE 356-2. Clinical features of cutaneous leishmaniasis (CL). A, Typical forms of CL. **A1,** Papular-nodular. **A2,** Squamous. **A3,** Crusty. **A4,** Ulcerated. **A5,** Superinfected lesions. **B,** Atypical forms of CL and mucosal leishmaniasis. **B1,** Multiple papules on the face (*L. infantum*, Balearic islands). **B2,** Nodular lymphangitis (*L. braziliensis*, Brazil). **B3,** Multiple lesions with numerous peripheral papules (*L. major*, Tunisia). **B4,** Initial spread to the nasal mucosa (anterior septum, *L. braziliensis*, Bolivia). **B5,** Infiltration and ulceration of the tonsils (*L. infantum*, France). **C,** Clinical manifestations that are not CL. **C1,** Multiple papules (late secondary syphilis) (Chapter 327). **C2,** Nodular lymphangitis (sporotrichosis) (Chapter 345). **C3,** Single crusty ulceration (*Mycobacterium ulcerans* infection) (Chapter 333). **C4,** Ulcerated acute *Staphylococcus aureus* infection (Chapter 296). **C5,** Ulcerated nodule keratoacanthoma (Chapter 210).

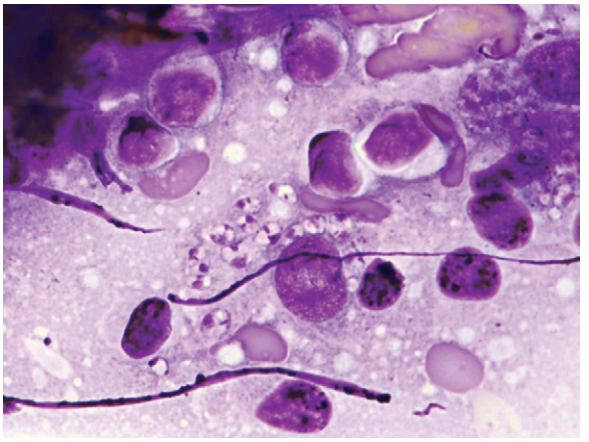

FIGURE 356-3. Amastigotes of *Leishmania major* in scrapings from a skin ulcer.

Diffuse Cutaneous Leishmaniasis

Patients with diffuse CL have an anergic response to *Leishmania* antigens, and nonulcerative nodules, loaded with parasites, disseminate from the initial site of infection to multiple sites on the patient's body. There is no self-cure and treatment is difficult. This form of the disease is found in South America and East Africa, often associated with *Leishmania amazonensis* and *Leishmania aethiopica* infection.

Recidivans Cutaneous Leishmaniasis

Recidivans CL is characterized by the development of lesions containing granulomatous tissue. The lesions often take many years to heal and may arise years after healing of a simple localized lesion. New ulcers and papules may form over the edge of the old scar. Infections are normally associated with *L. tropica* infection and are difficult to treat.

TREATMENT

Rx

The clinical consequences of CL are dermatologic; concomitant visceral impairment is exceptional. The intensity of the discomfort, related to one or several oozing or unsightly lesions, and the impact of atrophic, hypopigmented or hyperpigmented scars depend on the lesions' topography. In the New World, mucosal impairment may affect up to 10 to 15% of patients in some countries (Bolivia, Peru). The risk for metastasis (initially nasal and then affecting the entire otorhinolaryngeal zone) has strongly influenced therapeutic decisions. Systemic treatment of any New World CL has been recommended, but recent data indicate that a different strategy may perhaps be considered, at least in foci where this complication is infrequent (Central America, northern part of the Amazon basin). Inadequate surgical excision and pentavalent antimonials or systemic pentamidine administered in excessive doses or without sufficient follow-up may paradoxically be a major risk for patients with CL. Decisions should therefore be based on a careful analysis of the benefit-risk ratio of any therapeutic intervention. Analysis of the number, size, and topography of the lesions, the clinical signs of spread (cutaneous, mucous, or lymphatic), and the predictable cosmetic or functional impact helps in estimating the benefit-risk ratio.

Oral therapy with relatively nontoxic drugs (ketoconazole, fluconazole, itraconazole, miltefosine) would be the simplest option, and oral miltefosine monotherapy has been successful in Brazil.■ Local therapy with intralesional injections of pentavalent antimonials (with or without cryotherapy), photodynamic therapy, and thermotherapy are therefore attractive options to avoid potentially toxic, expensive, or impractical systemic schedules. However, implementation of these methods is hampered by logistic constraints and requires skilled health care providers. An efficient topical ointment would resolve most of these issues, but no efficient formulation is widely available. Several formulations of topical paromomycin have been tested with variable results. Recently, an ointment containing paromomycin and gentamicin has shown efficacy with acceptable local tolerance in patients with CL caused by *L. major*. Tentative algorithms for accurate therapeutic decisions in patients with Old World or New World CL are proposed in E-Figures 356-1 and 356-2, respectively.

PREVENTION

There are no modern vaccines for human disease and no prophylactic drug regimens. Leishmanization, or inoculating people with live virulent parasites to cause a local limited lesion and provide protection, has been used for CL (e.g., in Iran) but is not recommended by the World Health Organization. Sandflies are sensitive to most insecticides, and transmission has been controlled with malaria eradication campaigns and residual spraying in houses. Insecticide-impregnated bed nets and dog collars (to prevent transmission of zoonotic CL) have been investigated.

PROGNOSIS

Most untreated patients with established disease ultimately die. VL has an excellent prognosis with less than a 2% death rate in patients treated soon enough with liposomal amphotericin B. Mortality increases when bleeding (mainly from the digestive tract or lung) or secondary bacterial infection occurs, usually after prolonged untreated evolution. Post-therapeutic relapse is very frequent in HIV-coinfected patients with low initial or persistently low $CD4^+$ counts. In immunosuppressed patients, VL is rarely the direct cause of death but may give rise to complex therapeutic situations. A proportion of *L. donovani*–infected patients experience post–kala-azar dermal leishmaniasis weeks to years after the initial episode. CL caused by *L. braziliensis* may metastasize to the nose and other mucous membranes with variable frequency in different areas. CL caused by *L. tropica* often relapses (recidivans CL). A small proportion of patients infected with *L. amazonensis* and *L. aethiopica* experience diffuse CL. Even when treated, most CL lesions leave disfiguring, hypotrophic, hypopigmented, or hyperpigmented scars.

357 TOXOPLASMOSIS

JOSE G. MONTOYA

DEFINITION

The intracellular parasite *Toxoplasma gondii* is the etiologic agent of toxoplasmosis. The term *toxoplasmosis* is reserved for the disease process in which symptoms and signs are present, whereas *Toxoplasma infection* best describes the asymptomatic presence of the parasite. Toxoplasmosis may result in significant morbidity and mortality of the fetus, newborn, and immunocompromised patient. In addition, *T. gondii* can also be responsible for chorioretinitis, lymphadenopathy, myositis, myocarditis, and hepatitis in immunocompetent patients. A more aggressive form of congenital toxoplasmosis and toxoplasmosis in the adult appears to occur in certain geographic locales in South America, where pneumonia, fever of unknown origin, brain abscesses, and death have been reported in HIV-negative and apparently healthy individuals. Epidemiologic studies have established the role of novel risk factors for the acquisition of the acute infection, including the ingestion of untreated water, oysters, mussels, or clams.

The Pathogen

T. gondii is a protozoan and apicomplexan parasite with a high capacity for host cell invasion due to a motile invasive form (tachyzoite or trophozoite) characterized by an evolutionarily unique apical complex and a mechanism of actin-based motility.

T. gondii maintains a highly clonal population structure in North America and Europe that consists of three main lineages: types I, II, and III. This relatively low genetic diversity comes as a surprise given the fact that the parasite has the capacity to infect any warm-blooded animal. It has a sexual life cycle that takes place in the intestine of cats. Type I genotypes have been shown to exclusively contain those strains of *T. gondii* that are acutely virulent in laboratory mice, whereas type II and type III strains have been found to be significantly less virulent (e.g., types II and III have 50% lethal doses that are approximately 4 logs higher than those of type I). Secretory proteins discharged from apical organelles, called *rhoptries* (ROPs), have been reported as the key determinant of acute virulence in the mouse model. In North America and Europe, type II strains are most commonly associated with human toxoplasmosis, both in congenital infections and in immunocompromised patients. However, it appears that the type I strain has been reported more frequently in North America than in Europe. In South America, *Toxoplasma* strains appear to be genetically more diverse, with many different genotypes described mainly in Brazil and French Guiana. These atypical South American strains, initially called *exotic strains*, belong to several haplogroups that are endemic to South America and have been found to be associated with more severe clinical manifestations; physicians need to entertain this possibility in their ill patients who are from or were traveling in these endemic areas. Several groups of investigators are now attempting to establish a correlation between the genetics of the parasite and its wide spectrum of clinical manifestations.

In nature, the parasite exists in several forms, including the tachyzoite (Fig. 357-1A), the oocyst that contains sporozoites (Fig. 357-1B), the tissue cyst that contains bradyzoites (Fig. 357-1C), and macrogametes and microgametes. The tachyzoite is the rapidly proliferating form of the parasite responsible for the clinical manifestations of toxoplasmosis observed in the setting of the acute infection or reactivation of a latent infection. The tachyzoite measures 2 to 3 μm wide and 5 to 7 μm long, requires an intracellular habitat for its survival, and multiplies every 6 to 8 hours until rosette formation occurs and cell disruption inevitably follows. The tissue cyst is the slower metabolic form of the parasite responsible for chronic infection and for its transmission through meat consumption in humans and animals. Tissue cysts persist in tissues for the life of the host and cannot be eradicated by drugs. Tissue cysts vary in shape and size from younger ones that contain only a few bradyzoites to older tissue cysts that may contain several thousand bradyzoites and may reach more than 100 μm in size. The central nervous system (CNS), eye, and skeletal, smooth, and heart muscles appear to be the most common sites of tissue cyst formation (i.e., latent infection). Oocysts are shed by domestic and feral animals belonging to the Felidae family, and they are primarily responsible for the worldwide and large-scale spread of the parasite among different populations of other animals and humans. Cats shed oocysts after they ingest any of the infectious forms of the parasite: tachyzoites, tissue cysts, and oocysts. Oocysts are subspherical to spherical and measure 10×12 μm in diameter. As many as 10 million oocysts may be shed in the feces of an infected animal in a single day for periods varying from 7 to 20 days. Oocysts may remain viable for as long as 18 months in moist soil; this results in an environmental reservoir from which incidental hosts may be infected.

The parasite has a sexual and an asexual life cycle. The sexual life cycle in which macrogametes and microgametes copulate to form the fertilized gamete (gametogony) takes place only in the enteroepithelium of cats and other members of the Felidae family (the definitive host). It is during this life cycle that genetic exchange among different strains of *T. gondii* can occur. An asexual life cycle (schizogony) also takes place in the small intestine of these animals as well as in the tissues of other animals and humans (incidental hosts). Unsporulated oocysts are formed within the intestine of cats as a result of both cycles. Sporulation is required for the oocysts to become infectious, takes place outside the cat's intestine, and is more rapid at warm temperatures (2 to 3 days at 24° C compared with 14 to 21 days at 11° C).

EPIDEMIOLOGY

The prevalence of *T. gondii* infection varies significantly according to geographic locale and the socioeconomic status of the population. It can be as low as 7% in England and as high as 80% in the Central African Republic. Seroprevalence increases with age because of increasing length of exposure with age, and it is inversely associated with socioeconomic status because of the strong influence of hygienic and alimentary habits in the transmission of the parasite. The overall age-adjusted seroprevalence of *T. gondii* infection in the United States has been recently reported at 11%, but it may be higher in certain geographic areas or socioeconomic groups. The seroprevalence of the parasite has declined during the past 30 years in the United States and several other countries but appears to be stable or increasing in certain geographic locales, such as in the tropics (e.g., South America).

Humans and non-felid animals are incidental hosts and become infected primarily by the ingestion of infected meat containing tissue cysts or of contaminated food, water, or soil containing oocysts. They can also become infected during gestation by vertical transmission of the parasite from the mother to her offspring. In addition, humans can become infected through organ transplantation and, more rarely, in the setting of laboratory accidents. Ingestion of raw or undercooked meat contaminated with tissue cysts is probably one of the major routes of transmission in humans. Ingestion of untreated water, food, or soil contaminated with oocysts is another significant route of infection with the parasite. Untreated water has been found to be the source of large epidemics of toxoplasmosis in Canada and Brazil. The relative importance of tissue cyst (meat) versus oocyst (soil exposure, water or food other than meat) in the transmission of the parasite varies according to the hygienic and culinary habits of the different geographic locales where *T. gondii* is endemic.

A study reported the main risk factors for *T. gondii* infection in the United States are eating raw ground beef; eating rare lamb; eating locally produced cured, dried, or smoked meat; working with meat; drinking unpasteurized goat's milk; and having three or more kittens. In this study, eating raw oysters, clams, or mussels was also identified as a novel risk factor. Untreated water as a potential vehicle for the transmission of *T. gondii* has been established in several large epidemiologic studies and was found to have a trend toward increased risk for acute infection in the United States. A similar epidemiologic study in Europe also identified the consumption of undercooked or cured meat products as the major risk factor for acute infection, whereas soil contact was found only in a small proportion of the patients. In contrast, studies from South America have identified soil-related activities, in addition to meat, as a prominent risk factor for acute infection.

In up to 50% of individuals acutely infected with *T. gondii,* it is not possible to identify the presence of a known risk factor for their acute infection. Thus, attempting to establish whether a patient is at risk for toxoplasmosis solely on the basis of the epidemiologic history is a futile task. Patients may have been infected with *T. gondii* even if they have not owned or been in contact with cats, have not eaten undercooked meat or shellfish, and have not ingested untreated water.

The seroprevalence of *T. gondii* infection in immunocompromised patients reflects the seroprevalence of the particular population from which they

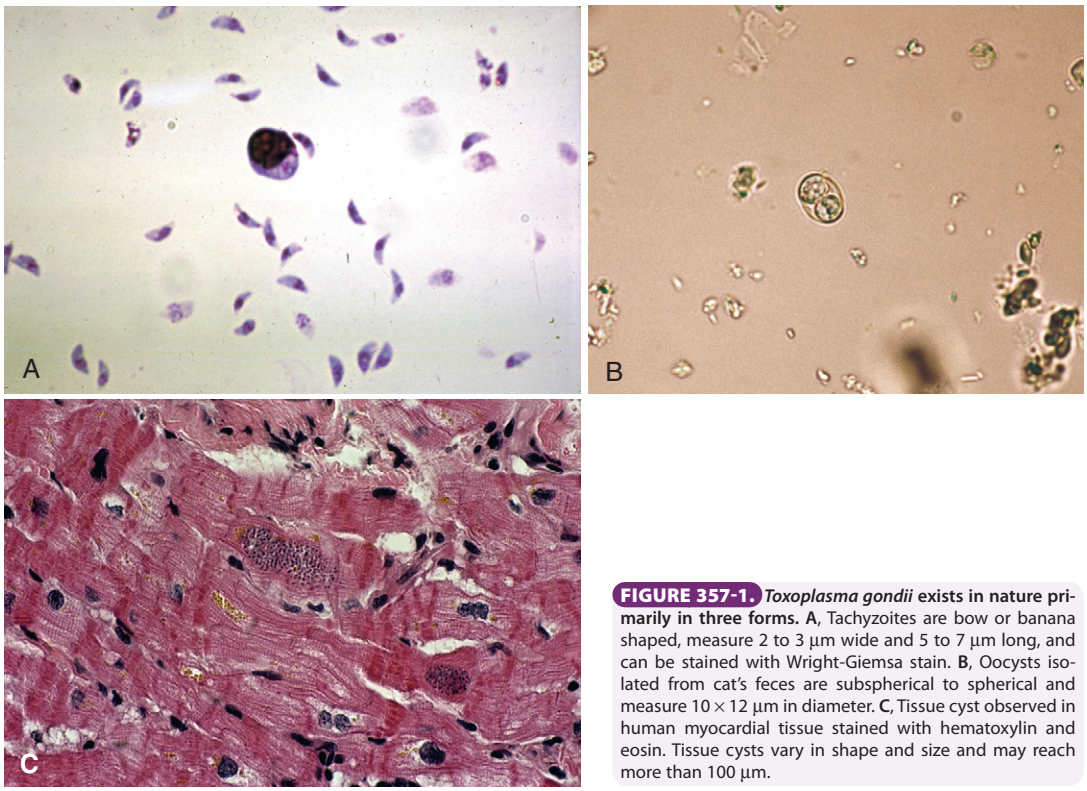

FIGURE 357-1. ***Toxoplasma gondii*** **exists in nature primarily in three forms. A**, Tachyzoites are bow or banana shaped, measure 2 to 3 µm wide and 5 to 7 µm long, and can be stained with Wright-Giemsa stain. **B**, Oocysts isolated from cat's feces are subspherical to spherical and measure 10 × 12 µm in diameter. **C**, Tissue cyst observed in human myocardial tissue stained with hematoxylin and eosin. Tissue cysts vary in shape and size and may reach more than 100 µm.

come. Latent *T. gondii* infection can reactivate in these patients, particularly in those with the acquired immunodeficiency syndrome (AIDS) and in hematopoietic stem cell transplant (HSCT), bone marrow transplant (BMT), and liver transplant patients. In these patients, it is important to establish whether they have been infected with the parasite before their transplant procedure because serologic testing after transplantation is unreliable. Approximately 30% of AIDS patients who are infected with *T. gondii* will develop toxoplasmosis by reactivation of their chronic infection if their CD4 count falls below 200 cells/µL and they are not taking anti-*Toxoplasma* primary prophylaxis. The advent of highly active antiretroviral therapy, in addition to the use of primary anti-*Toxoplasma* prophylaxis, has clearly contributed to the decline in the incidence of toxoplasmosis in AIDS patients. Among HSCT or BMT patients, those recipients who are *Toxoplasma* seropositive before transplantation, receive an allogeneic graft, and develop graft-versus-host disease (GVHD) have the highest risk of reactivation. Martino and colleagues reported that of 106 *T. gondii*–seropositive adult recipients of HSCTs, the incidence of toxoplasmosis was 6%. However, in this study, toxoplasmosis developed in 38% of those patients who had been found to be positive during routine and weekly polymerase chain reaction (PCR) testing during the first 100 days. Transmission through the bone marrow tissue or stem cells has been described but is rare.

For solid organ transplants, the highest risk for toxoplasmosis is observed when an allograft from a *Toxoplasma*-seropositive donor (D^+) is transplanted into a seronegative recipient (R^-). In D^+/R^- patients, there is a 25% risk for development of potentially life-threatening toxoplasmosis if effective anti-*Toxoplasma* prophylaxis is not instituted. It is highly advised that the *Toxoplasma* serologic status of the donor and the recipient be established before transplantation. Serologic test results are not reliable in the post-transplantation period, and they may significantly vary without any clinical relevance.

Transmission of *T. gondii* to the fetus can occur during pregnancy when a woman acquires her primary infection during gestation. The incidence of seroconversion for pregnant women in the United States has been estimated at 0.27%. The overall rate of transmission of the parasite (prevalence of congenital toxoplasmosis) in seroconverting women has been estimated between 50 and 60% before spiramycin was instituted as an attempt to decrease vertical transmission and 25 to 30% thereafter. The transmission rate increases with the gestational age at which maternal infection is acquired. In women who have been treated for toxoplasmosis during gestation, it can be as low as 4.5% during the first trimester, 31.7% during the second trimester, and as high as 63% during the third trimester. The likelihood of severe disease is inversely proportional to the gestational age at which maternal infection was acquired. Although objective data are lacking on the prevalence of congenital toxoplasmosis in the United States, it has been estimated that among the approximately 4.2 million live births per year, congenital *T. gondii* infection occurs in 500 to 5000 newborns.

Congenital transmission in women who were infected before conception has only rarely been reported in immunosuppressed patients, in those who were acutely infected shortly before conception (i.e., within 3 months of conception), and in those who have been reinfected with a more virulent strain.

PATHOBIOLOGY

Pathogenesis

After oral infection with tissue cysts (e.g., contaminated meat) or oocysts (e.g., contaminated soil or water or food), the wall of both infectious forms is disrupted by the digestive juices of the gastrointestinal tract. Bradyzoites (from cysts) and sporozoites (from oocysts) are released and converted to the tachyzoite form. Tachyzoites have the capacity to infect contiguous cells or distant tissues by hematogenous or lymphatic spread. Tachyzoites appear to actively and rapidly migrate across epithelial cells and may traffic to distant sites while they are extracellular (acute infection). Their histologic hallmark is necrosis surrounded by inflammation.

In immunocompetent individuals, the immune system controls the proliferation of the tachyzoite and induces its conversion to bradyzoites, facilitating the final formation of tissue cysts (chronic infection). Tissue cysts persist for the life of the host, and *T. gondii* can be isolated from tissues of individuals who have died without symptoms of toxoplasmosis.

It appears that the activation of well-orchestrated immune responses is required for the successful resistance against *T. gondii*. Innate, humoral, and cellular immune responses likely to be involved in preventing the uncontrolled proliferation of tachyzoites include activation of the monocyte-macrophage system, dendritic cells, natural killer cells, and αβ and γδ T cells; *T. gondii*–specific and cytotoxic $CD4^+$ and $CD8^+$ T cells; and interferon-γ, interleukin-12, tumor necrosis factor-α, interleukin-10 and other cytokines, transforming growth factor-β, costimulatory molecules (e.g., CD28, CD40 ligand), and, to a lesser degree, immunoglobulins.

In immunocompromised patients previously infected with *T. gondii*, decreased T-cell-mediated immune responses can facilitate the reactivation of their infection (i.e., conversion of bradyzoites in their tissue cysts into rapidly proliferating tachyzoites). Toxoplasmosis in this setting is 100% lethal if untreated.

TABLE 357-1 CLINICAL MANIFESTATIONS OF TOXOPLASMOSIS IN HUMANS

CLINICAL CATEGORIES	CLINICAL MANIFESTATIONS AND SYNDROMES
Primary infection	
Immunocompetent individuals and pregnant women	Most patients are asymptomatic. However, in ~10% of patients, the following symptoms or syndromes, alone or in various combinations, have been reported: fever, lymphadenopathy, headache, myalgias, arthralgias, sore throat, stiff neck, nausea, abdominal pain, anorexia, rash, confusion, earache, eye pain, general malaise, fatigue. Chorioretinitis resulting in blurred vision, eye pain, decreased visual acuity, floaters, scotoma, photophobia, or epiphora Hepatitis; myositis; myocarditis Disseminated disease, pneumonia, and even death have been observed in immunocompetent individuals infected with *T. gondii* in Latin America.
Congenital toxoplasmosis	
Fetus	Fetal death; ultrasound study can be normal or reveal hydrocephalus, brain or hepatic calcifications, splenomegaly, ascites, pericarditis.
Newborn	Newborn can be entirely normal, have a nonspecific illness, or have an abnormal physical examination including chorioretinitis, strabismus, blindness, seizures, encephalitis, abnormal cephalic perimeter (microcephaly or hydrocephalus), psychomotor or mental retardation, hepatosplenomegaly, pneumonitis, diarrhea, hypothermia, jaundice, petechiae, rash. Intracranial calcifications can be present in brain imaging studies.
Children and adults	Children can continue to suffer the chronic sequelae of the congenital disease. However, children and adults may become symptomatic for the first time during this phase of their lives, primarily in the form of reactivation of the congenitally acquired chorioretinitis.
Chronic infection	Asymptomatic. However, some investigators have proposed a role of chronic infection in individuals with traffic accidents or schizophrenia. Chorioretinitis can occur as a reactivation of congenital or postnatally acquired disease in otherwise immunocompetent individuals.
Reactivation of chronic infection in immunocompromised patients	Multiple brain abscesses, diffuse encephalitis, chorioretinitis, fever of unknown origin, pneumonia, myocarditis, hepatosplenomegaly, lymphadenopathy, rash

Certain human leukocyte antigen (HLA) types have been associated with a greater susceptibility to development of toxoplasmic encephalitis in immunocompromised patients. The major histocompatibility complex (MHC) class II gene DQ3 (HLA-DQ3) has been significantly associated with the development of toxoplasmic encephalitis in North American white AIDS patients and with the development of hydrocephalus in children with congenital toxoplasmosis. The HLA-DQB*0402 and DRB1*08 alleles were associated with a high risk for development of toxoplasmic encephalitis in South American white AIDS patients.

Pathology

Most of the data on the pathology of toxoplasmosis come from studies of congenitally infected babies and immunosuppressed patients. CNS lesions of patients with toxoplasmosis are characterized by significant necrosis and surrounding inflammation. In congenitally infected cases, necrotic areas may calcify and lead to typical radiographic findings suggestive but not diagnostic of toxoplasmosis. Hydrocephalus may result from obstruction of the aqueduct of Sylvius or foramen of Monro. Tachyzoites and tissue cysts may be visualized near necrotic foci, near or in glial nodules, in perivascular regions, and in cerebral tissue uninvolved by inflammatory changes.

Formation of multiple brain abscesses is relatively common in patients with AIDS. Three histologic zones are usually present in the brain abscesses of AIDS patients: (1) a central area that is avascular; (2) an intermediate hyperemic area with a prominent inflammatory response and perivascular cuffing by lymphocytes, plasma cells, and macrophages; and (3) an outer peripheral zone that contains *T. gondii* tissue cysts. Tissue cysts and tachyzoites may be present at the margins of the necrotic areas. In the areas around the abscesses, edema, vasculitis, hemorrhage, and cerebral infarction secondary to vascular involvement may also be present. Important associated features in toxoplasmic encephalitis are arteritis, perivascular cuffing, and astrocytosis. A "diffuse form" of toxoplasmic encephalitis has been described with histopathologic findings of widespread microglial nodules without abscess formation in the gray matter of the cerebrum, cerebellum, and brain stem.

Pulmonary involvement by *T. gondii* in the immunodeficient patient can lead to interstitial pneumonitis, necrotizing pneumonitis, consolidation, pleural effusion or empyema, or all of these. Chorioretinitis in AIDS patients is characterized by segmental panophthalmitis and areas of coagulative necrosis associated with tissue cysts and tachyzoites.

Toxoplasmic lymphadenitis in immunocompetent individuals may result in patterns of findings that are often diagnostic of the disease: a reactive follicular hyperplasia; irregular clusters of epithelioid histiocytes encroaching on and blurring the margins of the germinal centers; and focal distention of sinuses with monocytoid cells. Langerhans giant cells, granulomas, microabscesses, and foci of necrosis are not typically seen in the lymph node tissue. Rarely, tachyzoites or tissue cysts are demonstrable in tissue.

CLINICAL MANIFESTATIONS

Toxoplasmosis should be entertained in the differential diagnosis of several clinical syndromes in immunocompetent, congenitally infected, and immunocompromised patients (Table 357-1). Symptoms result from the primary infection or reactivation of the parasite due to T-cell-mediated immunodeficiency. Primary infection can be asymptomatic in a significant number of individuals, and conventional risk factors for the acute infection may not be present in a particular patient. Thus, the possibility of acute toxoplasmosis or *T. gondii* infection should not be ruled out because of the absence of epidemiologic risk factors (e.g., exposure to cats or undercooked meat) or symptoms in a given patient. For this reason, if the goal is to detect each case of primary *T. gondii* infection in a population of patients (e.g., pregnant women), only systematic and universal screening methods can achieve such an objective; testing of only symptomatic patients or those with conventional epidemiologic risk factors will miss a significant number of acute cases.

Severity of toxoplasmosis due to primary infection or reactivation in a given patient or population may be influenced by the infecting strain (e.g., type I strain), inoculum, infectious form (e.g., oocyst vs. cyst), or genetics of the host (e.g., presence of HLA-DQ3). During the past decade, it has become clear that patients infected in certain geographic locales (e.g., South America) have more aggressive clinical presentations, including a more severe primary infection and disease due to reactivation. These observations need to be entertained on seeing ill travelers returning from the endemic areas or patients who were born in these areas and in whom toxoplasmosis by reactivation has been included in their differential diagnosis.

Lymphadenopathy due to toxoplasmosis may be completely asymptomatic or be accompanied by other symptoms, such as fever (temperature as high as 104° F), headache, general malaise, and fatigue. It can be localized or generalized. A solitary, occipital, and painlessly enlarged lymph node can be the sole manifestation of toxoplasmosis in a child, pregnant woman, or adult. However, more generalized cervical, axillary, and abdominal lymphadenopathy has also been reported. Lymph nodes are usually 1 to 3 cm in size, nonsuppurative, and nontender on palpation. They usually regress within 12 weeks, but a mild relapse of the lymphadenopathy has been observed between months 3 and 6. Recurrence of toxoplasmic lymphadenopathy beyond the sixth month is extremely rare.

Ocular disease due to *T. gondii* can be asymptomatic or symptomatic and can be the result of congenital or postnatally acquired infection. In both settings (congenitally and postnatally acquired), toxoplasmic chorioretinitis can be discovered at the time of the diagnosis of the infection or as a reactivation of the subsequent latent infection months to years later. Up to 17% of patients acutely infected with the parasite in Brazil and in a Canadian outbreak of toxoplasmosis presented with concurrent symptomatic toxoplasmic chorioretinitis at the time their acute infection was diagnosed. Similar cases have been described in Europe and the United States. Symptomatic ocular disease

primarily consists of a retinochoroiditis that can result in blurred vision, eye pain, decreased visual acuity, floaters, scotoma, photophobia, or epiphora. The morphology of the retinal lesions on funduscopic examination is thought to be characteristic of toxoplasmosis. An active whitish infiltrate is usually attached to the darkly pigmented border of an older scar (Fig. 357-2). However, retinal lesions tend to be less typical in older or immunocompromised patients.

Other less common but well-documented syndromes have been associated with the acute infection, including hepatitis, myositis, myocarditis, and skin lesions. More aggressive disease including pneumonia, brain abscesses, and death has been observed in immunocompetent patients in South America.

Primary infection can be observed in solid transplant patients when an allograft from a seropositive donor is transplanted into a seronegative recipient (D^+/R^-). Disseminated and localized toxoplasmosis has been reported in this setting, including myocarditis, pneumonia, and encephalitis.

Congenital disease can be asymptomatic in the fetus, newborn, child, or adult. However, most of the infected offspring will eventually develop signs and symptoms of toxoplasmosis (see Table 357-1). The classic triad of chorioretinitis, hydrocephalus (Fig. 357-3A and B), and brain calcifications is highly suggestive of toxoplasmosis and is primarily seen in babies whose mothers have not been treated against the parasite during gestation. Eye examination by an experienced pediatric ophthalmologist may reveal active or inactive toxoplasmic chorioretinitis. New lesions have been reported in up to 30% of congenitally infected children observed up until 11 years of age.

Chronic infection is believed to be asymptomatic. However, several investigators have recently suggested the possibility that chronic infection may play a role in the predisposition of infected individuals to have a higher frequency of traffic accidents or schizophrenia.

Reactivation of the chronic infection is usually observed in patients with significant impairment of their T-cell-mediated immunity. Toxoplasmosis by reactivation can cause brain abscesses, diffuse encephalitis, chorioretinitis, fever of unknown origin, pneumonia, myocarditis, hepatosplenomegaly, lymphadenopathy, and rash. Although multiple brain abscesses (Fig. 357-3C) are commonly described in patients with toxoplasmic encephalitis, diffuse encephalitis without space-occupying lesions by magnetic resonance imaging has been reported with a very high mortality. Fever with pneumonia can be the sole manifestation of toxoplasmosis in immunocompromised patients, including HSCT and solid organ transplants. Toxoplasmic pneumonitis can present with cough, dyspnea, hypoxia, and diffuse bilateral or localized infiltrates. Fever alone has frequently been described in patients with allogeneic HSCT and liver transplant patients. Reactivation in heart tissue causing congestive heart failure, arrhythmias, and pericarditis has been described.

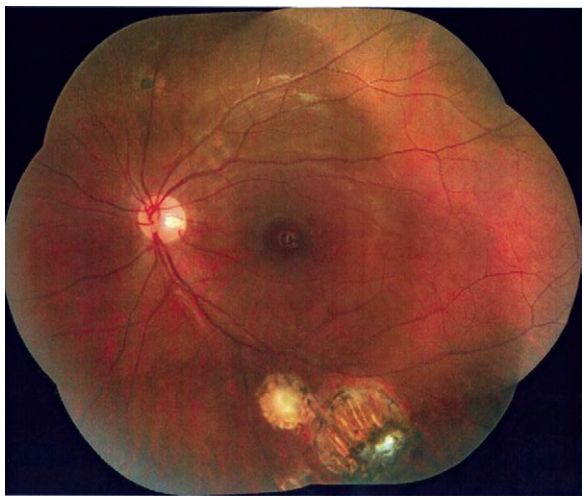

FIGURE 357-2. The morphology of the retinal lesions on funduscopic examination believed to be characteristic of toxoplasmic retinochoroiditis. An active whitish infiltrate is usually attached to the darkly pigmented border of an older scar.

DIAGNOSIS

Laboratory methods for the diagnosis of *T. gondii* infection and toxoplasmosis include serologic tests, the PCR, histologic and cytologic examination of tissue and body fluids, and attempts to isolate the parasite (Table 357-2).

The diagnosis of acute or latent *T. gondii* infection can be accomplished by serologic testing. Serologic tests can establish whether a patient is acutely or chronically infected regardless of the presence or absence of symptoms. Available serologic tools include methods to detect *T. gondii*–specific IgG-, IgM-, IgA-, IgE-, and IgG-based avidity and differential agglutination (AC/HS).

With the use of commercial kits for the detection of IgG and IgM, most hospital-based or commercial laboratories can reliably diagnose the absence of *T. gondii* infection (negative IgG/negative IgM) and the chronic infection (positive IgG/negative IgM). However, the diagnosis of acute infection is more challenging. A positive IgM test result is observed during the acute infection, but it may remain positive for months to years in certain individuals without any apparent clinical relevance. In addition, commercial IgM kits have been designed to be extremely sensitive so that an acute infection will be rarely missed; as a consequence, their specificity is somewhat sacrificed. Of patients who are found to be IgM positive at hospital-based or commercial laboratories, 60% are found to be chronically infected when their serum is tested at the national reference laboratory for the study and diagnosis of toxoplasmosis in the United States (Palo Alto Medical Foundation Toxoplasma Serology Laboratory [PAMF-TSL], Palo Alto, Calif; *www.pamf.org/serology/*; 650-853-4828; toxolab@pamf.org). At PAMF-TSL, a battery of confirmatory tests (avidity, differential agglutination, IgA, IgE) are performed in addition to the "gold standard" dye test for IgG and the "double" sandwich capture enzyme-linked immunosorbent assay (ELISA) for IgM. These tests are used in various combinations, depending on the clinical scenario of each patient and the questions of the treating physician. For an appropriate interpretation of the serologic test results obtained at PAMF-TSL, it is also crucial to have relevant clinical information available for the medical consultants (for

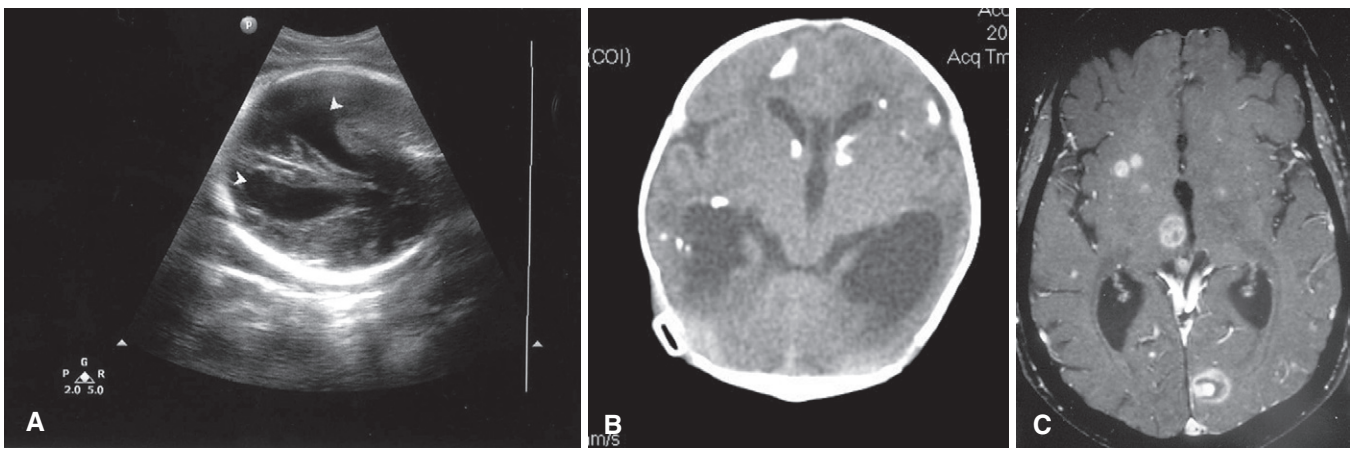

FIGURE 357-3. Radiologic manifestations of central nervous system toxoplasmosis. TABLE 357-2 LABORATORY METHODS FOR THE DIAGNOSIS OF *T. GONDII* INFECTION AND TOXOPLASMOSIS* IN HUMANS

METHOD	CLINICAL INTERPRETATION
Serologic tests	
IgG	A positive test result establishes that the patient has been infected with *T. gondii*. However, a negative test result can be seen in patients infected within 4 weeks before serum sampling or in patients unable to produce IgG (e.g., immunocompromised hosts).
IgM	A positive test result suggests but is not necessarily diagnostic of an acute infection. Sera with positive IgM test results should be sent to a reference laboratory for confirmatory testing. Positive IgM test results can be seen in chronically infected patients because of persistence of the IgM response or false-positive results observed in certain commercial kits.
Confirmatory testing for positive IgM test results	IgG avidity test; differential agglutination (AC/HS); IgA, IgE performed at a reference laboratory.† At PAMF, a high IgG avidity test result‡ or a nonacute AC/HS test result indicates that the patient has been infected for more than 4 months (avidity) or 12 months (AC/HS).
Polymerase chain reaction (PCR)	B1 and AF487550 genes are the most commonly used targets for amplification. PCR test can be performed in any body fluid, including peripheral blood, cerebrospinal fluid, bronchoalveolar lavage fluid, vitreous fluid, aqueous humor, peritoneal fluid, pleural fluid, and ascitic fluid. PCR can also be performed in any tissue. A positive test result in any body fluid establishes that the patient has either primary or reactivated toxoplasmosis. However, a positive PCR test result in tissue is more difficult to interpret because it does not differentiate toxoplasmosis from a latent infection. Although DNA extraction is more cumbersome, it can be attempted in paraffin-embedded tissue.
Direct visualization of the parasite	Identification of tachyzoites in any body fluid or tissue is diagnostic of toxoplasmosis due to primary infection or reactivation of a chronic infection. Tachyzoites can be identified by hematoxylin and eosin or cytologic studies but are better visualized with Wright-Giemsa and immunoperoxidase stains. Identification of cysts by hematoxylin and eosin or immunoperoxidase stains confirms the presence of *T. gondii* in the host but does not necessarily establish that the patient has toxoplasmosis. However, a strong inflammatory response surrounding the cysts is highly suggestive of toxoplasmosis, possibly explaining the patient's symptoms.
Attempts to isolate the parasite	A positive isolation study in any body fluid establishes the diagnosis of toxoplasmosis. Isolation of *T. gondii* in cell cultures or peritoneal cavity of mice can be attempted at reference laboratories. These studies can be important in trying to establish a correlation between the genetics of the parasite and its clinical manifestations.
Histology of the lymph node	Classic histologic triad is considered diagnostic: follicular hyperplasia, epithelioid histiocytes impinging on the margins of the germinal centers, and monocytoid cells focally distending sinus walls.

**T. gondii* infection = asymptomatic presence of the parasite. Toxoplasmosis = active symptoms and signs are present.
†For example, Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL), Palo Alto, Calif; www.pamf.org/serology; 650-853-4828; toxolab@pamf.org.
‡The window of exclusion for acute infection varies for different avidity kits (usually between 3 and 5 months).

instance, low positive IgG and positive IgM test results with a high IgG avidity test result will mean no risk of congenital toxoplasmosis for a 16-week pregnant woman, but the same results can be highly supportive of the diagnosis of toxoplasmic encephalitis for an AIDS patient with multiple brain lesions). At PAMF-TSL, three interpretations can be given to final serologic test results: (1) acute, results are consistent with a recently acquired infection; (2) chronic, consistent with an infection acquired in the distant past; and (3) equivocal, cannot exclude a recently acquired infection; an earlier or subsequent sample is required to attempt to establish whether the infection is acute or chronic. For serologic test results consistent with an acute infection, an attempt is made by the medical consultants at PAMF-TSL to establish the approximate date that the infection was acquired.

The definitive diagnosis of toxoplasmosis (due to primary infection or reactivation of a chronic infection) requires the identification of tachyzoites in tissues or body fluids or the amplification of parasite DNA in any body fluid (see Table 357-2). Tachyzoites can be visualized in histologic sections stained with hematoxylin and eosin or in cytologic preparations without any specific staining, but they are better visualized with Wright-Giemsa (see Fig. 357-1A) and immunoperoxidase stains. Real-time PCR has become a useful method for the diagnosis of toxoplasmosis, and it is the diagnostic tool of choice for toxoplasmic encephalitis in immunocompromised patients (assuming the lumbar puncture is deemed safe and feasible) and for the prenatal diagnosis of congenital toxoplasmosis. Isolation of the parasite in any body fluid is also diagnostic of toxoplasmosis and can be attempted at reference laboratories (e.g., in the United States: Palo Alto Medical Foundation Toxoplasma Serology Laboratory [PAMF-TSL], Palo Alto, Calif; *www.pamf.org/serology;* 1-650-853-4828; toxolab@pamf.org). The diagnosis of toxoplasmosis can be supported by the use of serologic tools, demonstration of cysts in tissues (see Fig. 357-1C) surrounded by an inflammatory response, and attempts to isolate the parasite (see Table 357-2); in cases of toxoplasmic lymphadenitis, histologic features can be diagnostic.

Immunocompetent Patients, Pregnant Women, and Patients with Lymphadenopathy

The first diagnostic goal in these patients is to establish whether they have ever been infected with *T. gondii*. If *T. gondii*–specific IgG and IgM test results are negative, the possibility that the patient's symptoms are due to the parasite can be ruled out. During pregnancy, these results confirm that the mother has not been exposed to *T. gondii* but that she is at risk, if exposed, to acquire the primary infection during pregnancy and therefore can potentially transmit *T. gondii* to her offspring. In attempting to determine whether the patient is infected with *T. gondii*, it is important to perform both IgG and IgM tests because during the first 4 weeks of the acute infection, the IgG can still be negative while the IgM will be positive. In these cases, seroconversion can be diagnosed by having a new positive IgG test result in a subsequent serum sample. In rare instances, infected patients may be IgG negative because of their incapacity to produce IgG.

If the patient is found to be IgG positive, the next goal is to determine whether the patient is having an acute infection or has been chronically infected (e.g., >6 months). If the IgG titer is low (e.g., a dye test at PAMF-TSL ≤512) and the IgM test result is negative, the patient has been infected for at least 6 months. With these results, a patient whose symptoms or lymphadenopathy had a date of onset within 6 months of serum sampling will be considered unlikely to have toxoplasmosis. For a pregnant woman whose serum was obtained within 6 months of gestation, they will mean that her infection was acquired before conception and that the risk for congenital toxoplasmosis is essentially zero.

If the patient is found to have a positive IgM test result confirmed to be indicative of a recently acquired infection at a reference laboratory (e.g., PAMF-TSL) and the onset of symptoms or lymphadenopathy falls within the time predicted by the serologic test results for the acquisition of *T. gondii*, the patient will be diagnosed as having acute toxoplasmosis. For a pregnant woman, if the predicted time for when the infection was acquired falls within her gestational age, she will be diagnosed with toxoplasmosis during pregnancy and at risk for transmitting the parasite to her baby.

In patients with lymphadenopathy, the histologic examination of the lymph node tissue obtained by excisional biopsy can be diagnostic or pathognomonic of toxoplasmic lymphadenitis (see earlier under Pathology).

Prenatal and Postnatal Diagnosis of Congenital Toxoplasmosis

Once the diagnosis of acute toxoplasmosis or *T. gondii* infection has been confirmed or is highly suspected in the mother, the next step is to attempt to establish whether her offspring has been infected. Consultation with reference centers for the study and diagnosis of congenital toxoplasmosis is highly recommended (in the United States: Palo Alto Medical Foundation Toxoplasma Serology Laboratory [PAMF-TSL], 650-853-4828; or U.S. [Chicago, Illinois] National Collaborative Treatment Trial Study, 773-834-4152).

Ultrasound abnormalities can be consistent with or suggestive of congenital toxoplasmosis (see Fig. 357-3A), but they are not diagnostic. The method of choice for the prenatal diagnosis of congenital toxoplasmosis is a PCR in amniotic fluid obtained at 18 weeks of gestation. Attempts to diagnose congenital toxoplasmosis from amniotic fluid obtained before 18 weeks of gestation should be avoided because the studies reported to date have included only pregnant women whose gestational age was 18 weeks or more. In addition, false-negative results have been reported in women whose amniocentesis was performed before 18 weeks of gestation. The overall sensitivity of the amniotic fluid PCR has been reported between 64 and 92% and is highly dependent of the gestational age at which the mother acquired the infection.

In the newborn, congenital toxoplasmosis can be confirmed by positive *T. gondii*–specific serologic test results or PCR. Samples for serology should be obtained in the peripheral blood of the baby. Cord blood should be avoided because of the high rate of maternal blood contamination. However, there is still a small degree of maternal blood contamination in newborn blood obtained by peripheral venipuncture, during the first 5 days of life for IgM antibodies and the first 10 days of life for IgA antibodies. A positive IgM immunosorbent agglutination assay (after 5 days of life) or IgA ELISA (after 10 days) is diagnostic of congenital disease. Congenitally infected babies can be positive for both; positive for either one, but negative for the other test; or negative for both. A positive *T. gondii*–specific IgM in cerebrospinal fluid (CSF) is diagnostic of congenital disease, but testing of the CSF by PCR rather than for IgM is strongly recommended because of the higher sensitivity of the PCR test. The diagnosis can also be made by a positive PCR in peripheral blood, CSF, or urine. The CSF of infected infants may exhibit very high levels of protein (e.g., 1000 mg/dL) and eosinophilia in addition to lymphocytosis. Brain imaging studies may reveal calcifications or hydrocephalus; computed tomography scan is superior to ultrasound examination in the detection of these CNS abnormalities (see Fig. 357-3B).

Ocular Disease

Serologic and PCR testing can be helpful in the diagnosis of toxoplasmic chorioretinitis. An IgG-negative/IgM-negative patient is unlikely to have ocular disease due to toxoplasmosis. However, patients should be tested at reference laboratories (e.g., PAMF-TSL) because their *T. gondii*–specific IgG can be present but at very low levels such that only a "gold standard" method like the dye test can detect it. In patients with eye lesions typical of toxoplasmic chorioretinitis (see Fig. 357-2), a positive IgG test result at a relatively low titer (e.g., a dye test at PAMF-TSL ≤512) and a negative IgM test result are diagnostic of ocular disease due to the parasite reactivation. If the serologic test reveals a positive IgM result and confirmatory testing at PAMF-TSL establishes the diagnosis of an acute infection in patients 1 year of age or older, the eye disease is most likely the result of eye involvement in the setting of a recent and postnatally acquired infection.

In patients with atypically appearing lesions or in whom the response to anti-*Toxoplasma* drugs is slow or absent, a *T. gondii*–specific immune load (aqueous humor) or PCR in ocular fluids (vitreous fluid is preferable to aqueous humor because of probable higher sensitivity, but it is riskier to obtain) should be considered. The immune load (Goldmann-Witmer coefficient analysis of aqueous humor) is calculated as (anti-*Toxoplasma* IgG in aqueous humor/total IgG in aqueous humor)/(anti-*Toxoplasma* IgG in serum/total IgG in serum). A value of 2 or greater has been considered by some investigators as evidence of synthesis of intraocular *T. gondii*–specific IgG in response to the presence of the replicating tachyzoite.

Immunocompromised Patients

It appears that acute infection rarely occurs in immunocompromised patients. However, life-threatening disease can occur when the patient's latent infection is reactivated by AIDS, HSCT, or other diseases characterized by severe T-cell deficiency.

Toxoplasmosis can also develop when *T. gondii* is transmitted from a seropositive donor to a seronegative recipient through an infected allograft (e.g., heart). Therefore, to establish the risk for toxoplasmosis and to have a high index of suspicion when patients develop illnesses suggestive of toxoplasmosis, all immunocompromised patients should be tested for *T. gondii*–specific IgG as soon as they have been diagnosed with the underlying disease or it has been established that they will be subsequently immunosuppressed. In addition, serologic testing may not be reliable when immunosuppression is advanced or severe. Post-transplantation serologic test results for IgG antibodies may remain positive or may rise, decrease, or even become negative. Thus, pretransplantation *Toxoplasma* serologic studies are critical for interpretation of subsequent test results and clinical evaluation. Solid organ donors should also be tested for *T. gondii*–specific IgG as their allograft has the potential to transmit the parasite to the transplanted patient (e.g., heart, heart-lung, kidney, kidney-pancreas, liver, liver-pancreas).

In AIDS patients suspected of having toxoplasmic encephalitis, the presence of multiple brain-occupying and ring-enhancing lesions (see Fig. 357-3C), a CD4 count below 200 cells/μL, and a positive *T. gondii*–specific IgG, the response to anti-*Toxoplasma*–specific treatment is considered an additional "diagnostic" indicator of toxoplasmic encephalitis. In these patients, invasive diagnostic tests (e.g., lumbar puncture, brain biopsy) are considered unnecessary unless they do not respond to treatment within a 7- to 10-day period. This diagnostic paradigm should not be applied to other populations of immunosuppressed patients (e.g., transplant patients) because their differential diagnosis often includes other pathogens, such as invasive mold infections. In those patients, examination of the CSF by PCR or brain biopsy should be attempted at the outset of the illness.

The definitive diagnosis of toxoplasmosis in immunosuppressed patients relies on PCR, direct visualization of the parasite, and attempts for isolation of the organism (see Table 357-2). PCR testing is the diagnostic method of choice for immunosuppressed patients at risk for toxoplasmosis who develop unexplained fever, pneumonia, brain lesions, or other compatible syndromes (e.g., in whole blood, bronchoalveolar lavage fluid, CSF, or other fluids as clinically indicated). PCR can be performed in any body fluid or tissue. Attempts to identify the tachyzoite or tissue cyst in tissues should be enhanced with the use of the *T. gondii*–specific immunoperoxidase stain. CSF examination by PCR or brain biopsy should be initially considered in AIDS patients who have a low likelihood of having toxoplasmic encephalitis, such as those who have a single lesion by magnetic resonance imaging examination, have tested seronegative for *T. gondii* infection, have a CD4 count of more than 200 cells/μL, or who are not responding to an appropriate anti-*Toxoplasma* regimen.

TREATMENT Rx

Principles of antiparasitic therapy are discussed in Chapter 352. Treatment of toxoplasmosis is indicated for immunocompetent patients with acute infection in the setting of myocarditis, myositis, hepatitis, pneumonia, brain lesions or skin lesions, and lymphadenopathy accompanied by severe or persisting symptoms. Treatment is indicated as well for patients with active chorioretinitis due to primary infection or reactivation of a latent infection (Table 357-3). In immunocompetent patients, treatment is prescribed for 3 to 4 weeks or until symptoms have subsided, whichever is longer. For toxoplasmic lymphadenitis, co-trimazole (48 mg/kg/day divided into two doses for 1 month) increased the cure rate to 65% compared with a 13% resolution rate with placebo.[1] Treatment is also often recommended for all pregnant women suspected of having or diagnosed with primary infection during gestation (Table 357-4) in an attempt to prevent transmission of the parasite to the fetus (spiramycin) or, if congenital infection has occurred, to start treatment of the fetus in utero (pyrimethamine, sulfadiazine, and folinic acid). During pregnancy, treatment regimens are prescribed for the duration of the gestation. There is worldwide controversy about the efficacy of spiramycin to decrease the incidence of congenital toxoplasmosis. There are no definitive studies proving or disproving its efficacy. However, until the results of such studies become available, the use of spiramycin is still recommended in the United States for pregnant women who have been definitively diagnosed to have or are highly suspected of having acute acquired infection during gestation. In addition, newborns and infants diagnosed with or suspected of having congenital toxoplasmosis should also be treated during their first year of life (see Table 357-4).

Treatment, at higher doses, is urgently indicated for all immunocompromised patients with toxoplasmosis due to reactivation of their latent infection or primary infection acquired by natural exposure to the parasite or solid organ transplantation (see Table 357-3). If untreated, toxoplasmosis in these patients has a very high morbidity and mortality.

PREVENTION

Primary Infection

Because approximately 50% of patients may inadvertently become infected with the parasite without having a recognized risk factor for acute infection, only systematic serologic testing can establish whether a patient has been exposed to *T. gondii*. Thus, each pregnant woman and immunocompromised patient should be screened for *T. gondii*–specific IgG and IgM regardless of their epidemiologic history. Seronegative pregnant women and immunocompromised individuals should be counseled on how to maximize their

TABLE 357-3 TREATMENT REGIMENS FOR PATIENTS WITH ACUTE OR PRIMARY TOXOPLASMOSIS AND IMMUNOCOMPROMISED PATIENTS WITH TOXOPLASMOSIS DUE TO REACTIVATION*

	IMMUNOCOMPETENT PATIENTS WITH ACUTE INFECTION†	IMMUNOCOMPROMISED PATIENTS
Pyrimethamine (PO) *plus*	50 mg every 12 hr for 2 days, followed by 25 to 50 mg daily	200-mg loading dose, followed by 50 mg/day (<60 kg) to 75 mg/day (>60 kg)
Folinic acid‡ (PO) *plus*	10-20 mg daily (during and 1 week after therapy with pyrimethamine)	10 to 20 mg daily (up to 50 mg/day)
Sulfadiazine (PO) *or*	75 mg/kg (first dose), followed by 50 mg/kg every 12 hr (maximum 4 g/day)	1000 mg (<60 kg) to 1500 mg (>60 kg) every 6 hr
Clindamycin (PO or IV) *or*	300 mg every 6 hr	600 mg every 6 hr (up to 1200 mg every 6 hr)
Atovaquone (PO)	1500 mg orally twice daily	1500 mg orally twice daily
Trimethoprim-sulfamethoxazole (PO or IV)	10 mg/kg/day (trimethoprim component) in two or three doses	10 mg/kg/day (trimethoprim component) in two or three doses (doses as high as 15-20 mg/kg/day have been used)
Pyrimethamine and folinic acid *plus*	Same doses as above	Same doses as above
Clarithromycin (PO) *or*	500 mg every 12 hr	500 mg every 12 hr
Dapsone (PO) *or*	100 mg/day	100 mg/day
Azithromycin (PO)	900 to 1200 mg/day	900 to 1200 mg/day

*Preferred regimens: pyrimethamine, sulfadiazine, and folinic acid or trimethoprim-sulfamethoxazole. Assistance is available for the diagnosis and management of patients with toxoplasmosis at the Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL), Palo Alto, Calif; www.pamf.org/serology; 650-853-4828; toxolab@pamf.org.
†Particularly in the setting of myocarditis, myositis, hepatitis, pneumonia, brain or skin lesions, and lymphadenopathy accompanied by severe or persisting symptoms. Also indicated for those with active ocular disease due to primary infection or reactivation.
‡Folinic acid = leucovorin; folic acid must not be used as a substitute for folinic acid.
After the successful use of a combination regimen during the acute or primary therapy phase, the same agents at half-dose are usually used for maintenance or secondary prophylaxis.

TABLE 357-4 TREATMENT REGIMENS FOR PREGNANT WOMEN WHO HAVE LIKELY ACQUIRED *T. GONDII* INFECTION DURING GESTATION AND INFANTS SUSPECTED OF HAVING OR CONFIRMED TO HAVE CONGENITAL TOXOPLASMOSIS

	DURING PREGNANCY	IN CONGENITAL DISEASE
Spiramycin (oral)	Recommended for pregnant women suspected of having or confirmed to have acquired the infection before 18 weeks of gestation. Spiramycin should be administered until delivery in those with negative amniotic fluid PCR test results and normal follow-up ultrasound studies or low suspicion of fetal infection. Spiramycin is not teratogenic, and it is available in the United States only through the Investigational New Drug (IND) process at the Food and Drug Administration (301-796-1600). Prior medical consultation is required.* Dosage: 1 g (3 million units) every 8 hr (for a total of 3 g or 9 million units per day)	Not recommended during pregnancy if the fetus has been documented to be or suspected to have been infected. In the setting of fetal infection, pyrimethamine, sulfadiazine, and folinic acid should be instituted (see below)
Pyrimethamine (oral) plus sulfadiazine (oral) plus folinic acid† (oral)	Recommended for women ≥18 weeks of gestation in whom it is suspected or confirmed that the acute infection has been acquired at or after 18 weeks of gestation or who have a positive amniotic fluid PCR test result or an abnormal ultrasound study suggestive of congenital toxoplasmosis. Pyrimethamine is teratogenic and should not be used during pregnancy before week 18 (in some centers in Europe, it is used as early as week 14). Sulfadiazine should not be used alone. Dosages: Pyrimethamine: 50 mg every 12 hr for 2 days followed by 50 mg daily Sulfadiazine: 75 mg/kg (first dose) followed by 50 mg/kg every 12 hr (maximum 4 g/day) Folinic acid† (leucovorin): 10-20 mg daily (during and for 1 week after pyrimethamine therapy)	**Infants** (treatment regimen is usually recommended for 1 year): Pyrimethamine: 1 mg/kg every 12 hr for 2 days; followed by 1 mg/kg/day for 2 or 6 months; followed by 1 mg/kg/day every Monday, Wednesday, Friday Sulfadiazine: 50 mg/kg every 12 hr Folinic acid† (leucovorin): 10 mg three times weekly Prednisone (if CSF protein ≥1 g/dL or severe chorioretinitis): 0.5 mg/kg every 12 hr (until CSF protein <1 g/dL or resolution of severe chorioretinitis) **Older children with active disease** (usually 1-2 weeks beyond resolution of clinical manifestations): Pyrimethamine: 1 mg/kg every 12 hr (maximum 50 mg) for 2 days followed by 1 mg/kg/day (maximum 25 mg) Sulfadiazine: 75 mg/kg (first dose) followed by 50 mg/kg every 12 hr Folinic acid† (leucovorin): 10-20 mg three times weekly Prednisone (severe chorioretinitis): 1 mg/kg/day, divided bid, maximum 40 mg/day, rapid taper

*Palo Alto Medical Foundation Toxoplasma Serology Laboratory (PAMF-TSL), Palo Alto, Calif; www.pamf.org/serology; 650-853-4828; toxolab@pamf.org; or U.S. (Chicago) National Collaborative Treatment Trial Study (NCCTS), 773-834-4152.
†Folic acid should not be used as a substitute for folinic acid.

E-TABLE 357-1 MEASURES FOR PRIMARY PREVENTION OF *T. GONDII* INFECTION IN SERONEGATIVE INDIVIDUALS*

CATEGORY	PREVENTION MEASURE
Meat and other food	Cook meat to "well done" or thoroughly to 67° C. Meat should not be "pink" in the center. Freeze meat to −20° C for at least 24 hours. Note that meat that is smoked, cured in brine, or dried may still be infectious. Avoid mucous membrane contact when handling raw meat. Wash hands carefully after contact with raw meat. Kitchen surfaces and utensils that have come in contact with raw meat should be washed wearing gloves. Refrain from skinning or butchering animals without gloves. Avoid drinking unpasteurized goat's milk. Avoid eating raw oysters, clams, or mussels.
Water	Avoid drinking untreated water including that from wells or reservoirs that have not been secured from potential contamination by feces from wild or domestic cats.
Cat feces and soil exposure	Avoid contact with materials potentially contaminated with cat feces, especially handling of cat litter or gardening. Wearing gloves is recommended when these activities cannot be avoided.

*Note that up to 50% of individuals can become infected with *T. gondii* even if they do not engage in behaviors associated with the acute infection.

prevention efforts to avoid infection with *T. gondii* (E-Table 357-1). In addition, seronegative pregnant women should be tested serially during gestation in an attempt to diagnose seroconversion at the earliest time possible. In some countries, such as France, seronegative pregnant women are mandated by law to be tested every month for *T. gondii*–specific IgG and IgM. Women who seroconvert are offered spiramycin (if infected before 18 weeks of gestation) or pyrimethamine, sulfadiazine, and folinic acid (if infected after 18 weeks) and PCR testing in amniotic fluid. Mothers whose amniotic fluid is found to be positive by PCR or those in whom fetal ultrasound study is highly suggestive of congenital toxoplasmosis are offered pyrimethamine, sulfadiazine, and folinic acid. Although infection often occurs in the absence of known risk factors for the acute infection, educational interventions to avoid exposure to the parasite have been shown to be effective in decreasing the incidence of seroconversion during gestation.

The majority of epidemiologic studies worldwide have recognized contaminated and undercooked meat as one of the main risk factors for the transmission of the parasite. This appears to be the case in Europe, North America, and Latin America. Tissue cysts in meat are rendered nonviable by γ-irradiation (0.4 kGy), heating throughout to 67° C, or freezing to −20° C for 24 hours and then thawing. Cured, dried, or smoked meat has been associated with the acute infection and should not be considered *Toxoplasma* free. Soil exposure and soil-related activities have been reported to play a more prominent role in transmission in certain geographic areas, such as Latin America.

In seronegative recipients of a solid organ from a seropositive donor, trimethoprim-sulfamethoxazole (TMP-SMZ) for at least 6 months or pyrimethamine for at least 6 weeks has been reported to be effective in the prevention of primary infection in the newly immunosuppressed patient.

Reactivation of Latent Infection in Immunocompromised Patients and Those with Ocular Disease

Drugs used to prevent reactivation of the latent infection in immunosuppressed hosts include TMP-SMZ (e.g., single-strength or 80 mg TMP and 400 mg SMZ, 1 tablet per day) and atovaquone (1500 mg/day). Dapsone-pyrimethamine and sulfadoxine-pyrimethamine have been also reported to be effective, but their use appears to be limited because of potential hematologic toxicity.

Prophylaxis against reactivation of latent infection has been successful in AIDS patients dually infected with *T. gondii* (*Toxoplasma* IgG seropositive) and whose $CD4^+$ T-cell counts are below 200 cells/μL. For prophylactic purposes, TMP-SMZ should probably not be used below a minimum dose of 160 mg and 800 mg orally twice a day on a thrice-weekly regimen. In AIDS patients, 100 mg of dapsone plus 50 mg of pyrimethamine orally twice weekly or atovaquone (1500 mg/day) have also been effective in preventing toxoplasmic encephalitis. Findings in these studies have been extrapolated to non-AIDS immunosuppressed patients because of the absence of data in this population of patients.

Toxoplasma-seropositive recipients of an allogeneic HSCT (Chapter 181) who develop GVHD represent a unique challenge. Reactivation of toxoplasmosis can be manifested by a nonspecific illness (e.g., fever or pneumonia) and be life-threatening. The disease is often not recognized. Atovaquone prophylaxis has been proposed as an alternative regimen in these patients given the potential bone marrow toxicity of TMP-SMZ. Some investigators have proposed a preemptive strategy in which *Toxoplasma*-seropositive patients who receive an allogeneic HSCT are monitored on a routine basis (e.g., weekly for the first 100 days) with *T. gondii* PCR. Those found positive would receive preemptive prophylaxis with TMP-SMZ or atovaquone.

Discontinuation of prophylaxis against toxoplasmic encephalitis has proved safe in AIDS patients receiving highly active antiretroviral therapy who demonstrate an increase in their $CD4^+$ T-cell counts to at least 200 cells/μL and whose viral load has been undetectable for at least 6 months.

In patients with ocular toxoplasmosis who experience frequent relapses (e.g., more than two episodes per year), TMP-SMZ for at least 1 year has been shown to be effective in the prevention of their recurrences.

PROGNOSIS

The primary infection has a wide spectrum of manifestations in humans, from asymptomatic in most individuals to pneumonia or life-threatening if it is acquired in certain areas of the world. Primary infection can also be fatal in the fetus and in immunocompromised individuals. Early diagnosis and treatment can make a significant difference in the prognosis of these patients.

It is not clear at this time whether chronic infection in immunocompetent individuals is clinically irrelevant. Several investigators have proposed that latent infection with the parasite may play a significant role in mental illness (e.g., schizophrenia) or in the propensity of the infected individual to incur motor vehicle accidents. Immunocompetent patients can reactivate chronic infection in their retina, and the prognosis is influenced by the proximity of the lesions to the macula, involvement of one or both eyes, and number of relapses. It is believed that treatment can slow the progression of these lesions and expedite their healing.

Reactivation of latent infection in immunosuppressed individuals with significant defects in their T-cell-mediated immunity, if untreated, is 100% fatal.

CRYPTOSPORIDIOSIS

ALDO A. M. LIMA AND RICHARD L. GUERRANT

DEFINITION

Cryptosporidiosis is the clinical disease caused by protozoal parasites of the genus *Cryptosporidium*. The *Cryptosporidium* species considered important as human pathogens are *Cryptosporidium hominis*, *Cryptosporidium parvum*, *Cryptosporidium meleagridis*, *Cryptosporidium felis*, *Cryptosporidium canis*, and the *Cryptosporidium* rabbit genotype. *C. parvum* and *C. hominis* are considered the major human pathogens.

The Pathogen

Cryptosporidium spp belong to the protozoal phylum Apicomplexa (sporozoans), which features apical polar rings, micronemes, and subpellicular microtubules, structures responsible for penetration into host cells; the order Eucoccidiorida (Eucoccidiida); and the suborder Eimeriorina (Eimeriina), based on merogony and independent development of male and female gametocytes within vertebrate host. The family Cryptosporidiidae has a hidden sporocyst and undergoes monoxenous completion of its cycle in one host, where it can cause predominantly intestinal, cloacal, and gastric infections.

EPIDEMIOLOGY

The life cycle begins with ingestion of *Cryptosporidium* oocysts (2 to 5 µm) by the vertebrate host, with subsequent excystation within the lumen of the small intestine to release four sporozoites (Fig. 358-1). The sporozoites attach to and enter the host's epithelial cells to form intracellular but extracytoplasmic parasitophorous vacuoles, where they develop into trophozoites and subsequently type 1 meronts (schizonts). By asexual nuclear division they multiply and release six to eight type 1 merozoites that invade neighboring host cells and develop into type 2 meronts, or trophozoites, to complete the asexual reproductive cycle. Type 2 meronts undergo two nuclear divisions and release four type 2 merozoites that can infect the host's cells and further develop into male (microgamont) or female (macrogamete) forms. Microgametes released from the microgamont can penetrate the macrogametes to form zygotes. Approximately 20% of the zygotes develop into thin-walled autoinfectious oocysts; some 80% become thick-walled oocysts, which are excreted in stool.

Cryptosporidium oocysts have at least five characteristics that make this organism a common problem and potential risk for person-to-person spread and for waterborne and food-borne disease outbreaks. First, *Cryptosporidium* oocysts are resistant to many chemical disinfectants such as chlorine. Second, the organism is highly infectious, with the median *C. parvum* infectious dose being 132 or fewer oocysts. Third, the size of the oocysts, 2 to 5 µm, allows them to pass through most conventional filters, even those capable of removing some particles smaller than 1 µm. Fourth, the monoxenous life cycle allows infectious oocysts to be excreted in large numbers in feces, which can easily spread. Fifth, the organism is associated with geographic, seasonal, and socioeconomic differences in the distribution of *Cryptosporidium* spp.

Cryptosporidiosis is seasonal and related to precipitation and temperature fluctuations worldwide. Excystation of *C. parvum* increases in water temperatures up to 46° C (natural sunlight for 12 hours). Two waterborne outbreaks brought cryptosporidiosis to public health attention. In January 1989, an increased number of cases of cryptosporidiosis were reported in Swindon and Oxfordshire, United Kingdom, with a peak reached in March. Mapping of the addresses of early cases showed associations with water supplies. In late February the water authority detected *Cryptosporidium* oocysts in samples from the water that supplied the affected areas and in the treated water. Contamination of the raw Thames River water used at three water treatment plants was found, with evidence of pollution by farm effluent. This outbreak resulted in 516 cases and thus ignited public interest and led to an official inquiry. The second outbreak occurred in early spring 1993 in Milwaukee, Wisconsin, and was the largest documented outbreak of waterborne disease ever in the United States, with an estimated 403,000 people having acute watery diarrhea and potentially 112 deaths. Findings from this outbreak suggested that *Cryptosporidium* oocysts passed through the filtration system of one of the city's water treatment plants. Again, this suggested that the water quality standards and detection methods for *Cryptosporidium* were inadequate. Swimming pool contamination, especially toddler pools, is often associated with accidental fecal contamination. Foodborne outbreaks have also been reported in association with contaminated apple cider, unpasteurized milk, chicken salad, vegetables, raw produce, and shellfish.

The prevalence of cryptosporidiosis varies by geographic region, with the highest rates seen in developing countries. Most cases of cryptosporidiosis occur in young children, thus suggesting that host's immune response plays a key role in susceptibility. Furthermore, cryptosporidiosis in individuals infected with human immunodeficiency virus (HIV) and in those with acquired immunodeficiency syndrome (AIDS) is persistent and occasionally life-threatening and may involve infections of the hepatobiliary and respiratory tracts, in addition to the entire gastrointestinal tract. Only effective antiretroviral therapy with restoration of immune function controls this devastating disease. The prevalence of cryptosporidiosis in patients with HIV/AIDS varies from 23% in those with $CD4^+$ cell counts greater than 1000/µL to 46% in those with $CD4^+$ cell counts less than 100/µL.

PATHOBIOLOGY

Oocysts of *Cryptosporidium* spp excyst in the upper part of the small bowel and release infective sporozoites that invade the mucosal epithelium and occasionally Peyer's patch M cells, often to the terminal ileum and colon. In immunocompromised patients the organisms can be found throughout the gut, biliary tract, pancreas, and respiratory tract. As noted earlier, trophozoites undergo asexual reproduction by merogony to form type 1 and then type 2 meronts. Sporozoites and merozoites are internalized via similar invasion machinery and actin reorganization. Entry into the host's cell occurs within 30 seconds and is dependent on the parasite's actinomyosin cytoskeleton to enter host-derived bimembrane parasitophorous vacuoles in a unique intracellular, but extracytoplasmic niche. Dense polymerized actin forms at the base fusion of the host-parasite bimembranes. Invasion of cells of the host leads to displacement of the microvillous border, villous atrophy, blunting and crypt cell hyperplasia, and marked infiltration by lymphocytes, plasma cells, and some neutrophils into the lamina propria, with apoptosis of infected cells and significant alteration in intestinal permeability, as measured by mannitol and lactulose markers. This noninvasive functional test shows both reduced absorptive area and disrupted barrier function, which is even more severe in patients with HIV/AIDS. Upregulation of nuclear factor κB and the pro-inflammatory cascade causes secretory and mildly inflammatory diarrhea. Pro-inflammatory cytokines, such as tumor necrosis factor-α, interleukin-1β (IL-1β), IL-8, and lactoferrin, are significantly increased in murine and human infections. IL-1β and IL-8 both upregulate cyclooxygenase-2, which results in prostaglandin synthesis in the epithelial cells and production of substance P by the inflammatory cells; these products together decrease net sodium absorption and increase net chloride secretion, which causes the secretory diarrhea often seen with this infection.

Both innate and adaptive immune responses are associated with immunity to cryptosporidiosis. Two chemokines, CXCL-10 and perhaps CXCL-8, are initially implicated in the attraction of pro-inflammatory cells. Activation of the immune system involves early stimulation by IL-15, which may be important for initial clearance of the parasite. $CD4^+$ T cells and interferon-γ play important roles in the eventual immune defense against this infection, probably more so than B cells or $CD8^+$ cells.

CLINICAL MANIFESTATIONS

Cryptosporidiosis is a cosmopolitan, self-limited infection in immunocompetent hosts that affects all age groups and both sexes. In developing

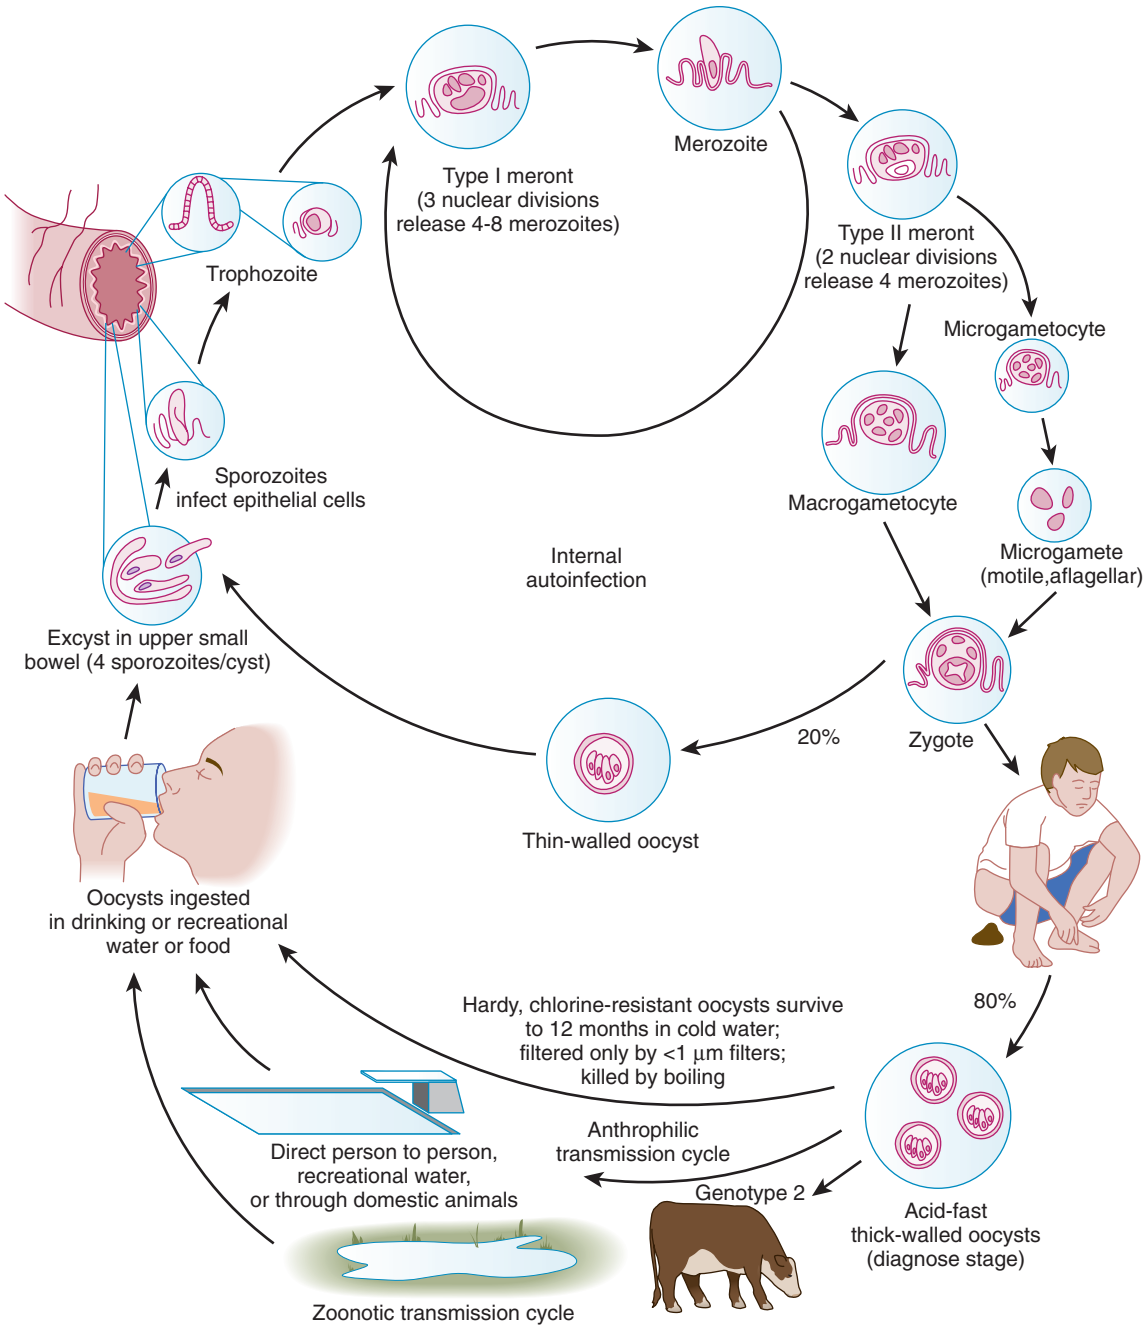

FIGURE 358-1. Life cycle of *Cryptosporidium* spp. (Redrawn with permission from Kosek M, Alcantara C, Lima AAM, et al. Cryptosporidiosis: an update. *Lancet Infect Dis.* 2001;1:262-269.)

countries, the disease occurs most frequently in children younger than 5 years because of high rates of fecal-oral exposure and the development of partial immunity in older children and adults. In developed countries the disease occurs at all ages and most cases are associated with small waterborne outbreaks, frequently with contamination of recreational water. Travelers from developed countries are more often adults. The incubation period is approximately 1 week, with a range of 1 to 30 days. The diarrhea can have a sudden onset, frequently with voluminous watery stools, abdominal pain, nausea or vomiting, bloating, malaise, fatigue and weight loss, occasional pyrexia, and a long-term impact on physical activity, school performance, and development of cognitive function, especially in young children at risk in developing countries. Rarely, respiratory infection and cough have been reported. In normal hosts the disease usually lasts 2 to 3 weeks but sometimes for more than a month. Oocyst shedding typically lasts 1 to 2 weeks but can occur for up to 2 months. Patients with T-cell immune deficiency, such as those with hematologic malignancies (particularly children), primary T-cell deficiencies (severe combined immunodeficiency [SCID] and CD40 ligand deficiency), and HIV/AIDS, are at high risk for the development of more severe disease and have an increased risk for death.

Immunocompetent Host

Data on the natural history of cryptosporidiosis in immunocompetent hosts have been obtained mostly from developed countries, and such data are derived from waterborne outbreaks, patients seeking medical assistance, travelers, animal workers, children in daycare, and their contacts. Most patients in outbreaks and travelers are adults and usually have diarrhea with a median duration of 14 days and a range of 1 to 100 days. The duration and severity of diarrhea appear to be similar for *C. parvum* and *C. hominis*. Recurrence of diarrhea is common and occurs in 30 to 41% of patients. Reports from the United Kingdom describe abdominal pain (96%), vomiting (65%), fever (59%), and bloody diarrhea (11%). The clinical manifestations in 285 people surveyed with a confirmed laboratory diagnosis of *Cryptosporidium* infection in the massive outbreak in Milwaukee showed a median duration of 9 days (range, 1 to 55 days), with watery diarrhea in 93%, abdominal cramps in 84%, fever in 57%, and vomiting in 48%.

Childhood Cryptosporidiosis in Developing Countries

In developing countries, cryptosporidiosis is associated with persistent diarrhea, increased overall burden of diarrhea, risk for malnutrition, and infant

mortality. A nested case-control study from a cohort of children in Brazil showed that children younger than 1 year with cryptosporidiosis had subsequent increased diarrheal burdens and growth shortfalls. These findings have been extended in a shantytown in Peru, where cryptosporidiosis is associated with growth faltering and stunting. This was even true for children with asymptomatic infections, which are even more common in endemic areas. The long-term impact of childhood diarrhea and cryptosporidiosis was also evaluated in a cohort study in Brazil in which it was shown that children with more diarrhea morbidity or cryptosporidiosis early in life (0 to 2 years) had reduced fitness and impaired cognitive function at 6 to 9 years of age. Several studies have now shown that oocysts are shed longer and the number of oocysts is higher with *C. hominis* than with *C. parvum* infection. In Brazil, a birth cohort study demonstrated that children with *C. hominis* infection had higher fecal lactoferrin and delayed growth in comparison to those with *C. parvum* infections. Diarrhea, nausea, vomiting, and general malaise were more frequently associated with *C. hominis* infection in a longitudinal study of children in Peru. Subtype family analysis of *C. hominis* (Ia, Ib, Id, and Ie) also showed that Ib was more commonly associated with nausea, vomiting, and general malaise.

Immunocompromised Hosts

Low $CD4^+$ lymphocyte counts in HIV-infected patients are associated with severe cryptosporidial diarrhea. For example, patients with $CD4^+$ counts higher than $180/mm^3$ usually have transient or self-limited disease, whereas those with $CD4^+$ counts lower than $50/mm^3$ often have severe disease with more than 2 L of stool per day. The introduction of highly active antiretroviral therapy (HAART) heralded reduced rates of cryptosporidiosis in patients with HIV/AIDS. HAART may also directly inhibit sporozoite development and invasion in the host's cells. Patients with other immune disorders such as T-cell immune deficiency (SCID and CD40 ligand deficiency) or hematologic malignancies, particularly children, are at higher risk for more severe, prolonged, or extensive disease, with infection occasionally extending to the gallbladder, pancreatic duct, and even the bronchial tree. Several complications in these patients have been described, including pancreatitis, cholecystitis, sclerosing cholangitis, papillitis, and terminal bile duct stenosis with subsequent biliary cirrhosis.

DIAGNOSIS

The clinical manifestations and physical examination findings in patients with cryptosporidiosis are not unique, and the differential diagnosis should include other causes of infectious gastroenteritis, such as *Giardia*, *Cyclospora*, *Isospora*, microsporidia, *E. coli* pathotypes (enteropathogenic [EPEC], enteroaggregative [EAEC], diffusely adherent [DAEC], enterohemorrhagic [EHEC], enteroinvasive [EIEC], and enterotoxigenic [ETEC]), *Campylobacter*, *Salmonella*, *Shigella*, rotavirus, norovirus, and others. Definitive diagnosis of *Cryptosporidium* enteric infection is made by stool examination. Up to three fecal samples with fixation and concentration before permanent staining may increase detection rates. Oocysts are stained with the acid-fast stain, modified Ziehl-Nielsen stain, fluorescence staining with auramine-phenol, or immunofluorescent stains. Acid-fast staining requires around 500,000 oocysts per gram for detection in formed stools, whereas immunofluorescence is at least 10 times more sensitive, and commercially available enzyme-linked immunoassays have a sensitivity and specificity approaching 100% for *Cryptosporidium*. Polymerase chain reaction testing can detect as few as 50 to 500 oocysts per milliliter of liquid stool and can be used to differentiate *Cryptosporidium* species and genotypes.

TREATMENT

Rx

Nitazoxanide has emerged as the only promising candidate for treating cryptosporidiosis, is licensed in the United States for treating cryptosporidiosis in nonimmunodeficient children and adults, and has reportedly reduced the duration of diarrhea and oocyst shedding in several double-blind, placebo-controlled clinical trials. A clinical trial in Egypt in adults (500 mg twice daily for 3 days) and children (200 mg for 4- to 11-year-olds and 100 mg for 1- to 3-year-olds, twice daily for 3 days) with cryptosporidiosis showed that 80% exhibited resolution of diarrhea versus 41% of the placebo group.[1] A second clinical trial of a 3-day course of treatment showed resolution of symptoms at 4 days in 96% of the patients receiving nitazoxanide tablets (500 mg twice daily for 3 days) versus only 41% of those receiving placebo tablets.[2]

Prevention and treatment of cryptosporidiosis in immunocompromised patients have been reviewed recently, and there was no evidence of a reduction in the duration or frequency of diarrhea with nitazoxanide. However, nitazoxanide did result in significantly greater oocyst clearance than did placebo in all children. In patients with HIV/AIDS, HAART has emerged as the most important therapy to prevent and reduce the severity and frequency of cryptosporidiosis. Oral rehydration therapy or intravenous fluid replacement for more severe disease is key to preventing dehydration and risk for immediate death.

PREVENTION

Prevention of person-to-person spread should be achieved with personal hygiene guidelines such as frequent handwashing after using or cleaning the toilet, changing diapers, and caring for a person with diarrhea. It is recommended that people with cryptosporidiosis be excluded from the workplace setting until 48 hours after the last diarrheal episode. Handwashing facilities should be available and used at farms to facilitate personal hygiene. Because most outbreaks of cryptosporidiosis are linked to oocysts in source water, routine survey of treated water for this parasite is key to preventing major spread of this disease. Optimization of multibarrier approaches, including chemical treatment and water filtration and treatment systems, is highly recommended. Ultraviolet irradiation and ozone are effective in inactivating *Cryptosporidium* and *Giardia* cysts in water and may prove useful in controlling the transmission of waterborne protozoa.

GIARDIASIS

THEODORE E. NASH AND DAVID R. HILL

DEFINITION

Giardia lamblia (Giardia duodenalis, Giardia intestinalis) is a ubiquitous protozoan parasite of humans and other mammals that resides in the small intestine. It is the most common parasitic infection of the gastrointestinal tract in the United States as well as worldwide and is responsible for outbreaks of diarrhea and sporadic endemic disease.

The Pathogen

Giardia has a simple life cycle. The trophozoite, which is 9 to 21 μm long, 5 to 15 μm wide, and 2 to 4 μm thick (Fig. 359-1), resides in the small intestine and is responsible for manifestations of disease. It has four pairs of flagella, two equal functioning nuclei, and a ventral sucking disc by which it may adhere to intestinal epithelial cells. The dorsal surface is pear shaped and bilaterally symmetrical, with the two highly characteristic nuclei best

FIGURE 359-1. Giardia lamblia. This scanning electron micrograph reveals some of the external ultrastructural details displayed by a flagellated *G. lamblia* protozoan parasite.

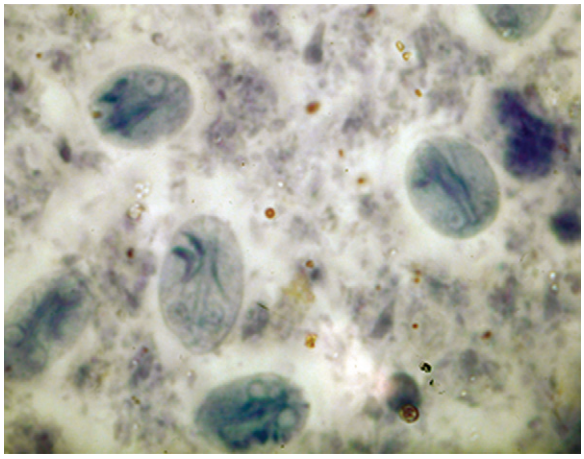

FIGURE 359-2. Iron hematoxylin stain of *Giardia lamblia* cysts from stool.

visualized after staining. In the lower small intestine, the trophozoite develops into an environmentally resistant cyst. Detection of soluble cyst wall proteins in the feces forms the basis of most stool antigen assays.

Excreted cysts are mature and infectious. They are oval and about 8 to 12 μm in length and 7 to 10 μm in width (Fig. 359-2). After ingestion and exposure to acid and proteases in the stomach and intestines, they excyst in the small intestine, yielding two trophozoites from each cyst, which quickly divide again. Trophozoites double in number every 6 hours for the fastest growing isolates.

A number of morphologically identical but genetically distinct *Giardia* infect humans and animals. There is no agreed on nomenclature. Initially separated into groups, these are now referred to as assemblages or genotypes. Humans and some animals are infected with either assemblage A or B. These two assemblages are genetically and biologically diverse and may be two separate species.

Giardia is well adapted to its existence as a parasite. It has two equal functioning nuclei and lacks mitochondria and peroxisomes. It has a simplified metabolism and is dependent on the host for nutrients such as purines, pyrimidines, cysteine, and cholesterol. The WB isolate, assemblage A, has a compact genome (11.7 Mb) with unusually short promoters. The parasite's rigid cytoskeleton is composed of unique families of structural proteins and carbohydrates.

Giardia is the only bowel-dwelling parasite that undergoes antigenic variation. Only one of a family of about 250 variant-specific proteins (VSPs) is expressed on the surface of the trophozoite at a time. Both immune and biologic selection of trophozoites that express specific VSPs occurs in humans and animals with giardiasis. Expressed VSPs must be compatible with the host's intestinal environment and are probably not recognized by the host's immune system because antibodies to VSPs are inhibitory or cytotoxic. The mechanisms involved in antigenic variation are incompletely understood, but they do not involve gene movement and appear to be controlled post-transcriptionally. Whereas all VSPs are transcribed, all but one of the transcripts are eliminated by RNA interference–based mechanisms, resulting in expression of a single VSP surface protein. Exactly how selection and switching occur is unclear.

EPIDEMIOLOGY

Giardia is among the most common parasitic infections of humans; it is highly infectious, and cysts are frequently excreted in large numbers (as high as 10^7 cysts per gram of feces), especially in young children. Cysts can survive for months in cold water, are relatively resistant to chlorination, but are intolerant of desiccation and heat in comparison to *Cryptosporidia* and helminth ova. Between 10 and 100 cysts is sufficient to establish infection. Consequently, ingestion of water or food that contains small levels of contamination can result in infection. Approximately 20,000 infections are reported annually in the United States, but because of underreporting, actual infections are estimated at between 100,000 and 2.5 million cases per year.

Infections are most common in young children and are more frequent in summer and fall months. Giardiasis is acquired after ingestion of contaminated water or food or through person-to-person contact. In past decades, large outbreaks in high-income countries such as the United States occurred after ingestion of contaminated drinking water obtained from surface sources such as reservoirs, lakes, and mountain streams. However, with improved water treatment measures, ingestion of contaminated recreational water from pools or lakes is now a more common source of outbreaks and sporadic infection. Backpackers who ingest untreated surface water remain at risk of infection.

Although outbreaks from contaminated food or infected food handlers are well described, they are not often documented. Worldwide, person-to-person transmission may be the most frequent mode of infection and is the primary way children are infected in daycare centers, where historically prevalence has been as high as 50%. Person-to-person spread occurs among family members with infected children and following sexual practices that lead to fecal-oral contact. In low-income, highly endemic regions, almost all children are infected by 2 to 3 years of age. Although partial immunity can develop in previously exposed adults, reinfection of children after treatment is common in highly endemic regions. Longer-term travel, particularly to south Asia, increases the risk of giardiasis. For the returned traveler with persistent diarrhea, giardiasis should be ruled out.

The understanding of immunity in humans is based mostly on animal models that have limited applicability to human infection and disease. In addition, some of the findings are conflicting. In the classic human experimental infections reported by Rendtorff and colleagues in the 1950s, self-cure occurred in about 84% of the persons. In a more recent experimental human challenge study, in which the infecting parasite was well characterized and the inoculum known, rechallenge with the same isolate after treatment resulted in brief, asymptomatic infections in two persons, suggesting development of partial immunity. Humans with hypogammaglobulinemia are susceptible to *Giardia* and have more severe disease that is resistant to treatment. Studies in animals support a major role of intestinal antibodies (particularly IgA) in protective immunity and an essential role of T-cell immunity in the control of *G. lamblia* infection.

Giardia infections are neither more severe nor more common in most other immunosuppressed states and in persons with selective IgA deficiency. Even though most human immunodeficiency virus–infected patients respond to usual treatment, a subset develop recurrent or repeated infections that are difficult to treat.

PATHOBIOLOGY

Giardia infections involve complex interactions between host and parasite. The two assemblages (A and B) that infect humans are composed of genetically distinguishable isolates, which may vary in infectivity, antigenicity, and virulence. They express different sets of VSPs. In addition, human hosts vary in susceptibility to infection and disease and in the response or tolerance to infection. Pathogenic mechanisms need to explain the varied clinical manifestations, as well as the contrasting situation in which there are high rates of infection and disease seen in water-borne outbreaks of giardiasis, compared with the large number of asymptomatic infections in children in low-income

regions. In addition, infection with *Giardia* can lead to malabsorption, weight loss, and nutritional deficiencies in some settings and little effect on nutritional parameters in other settings.

Giardia is strictly an intraluminal parasite that adheres to the epithelium by way of an adhesive or sucking disc. Invasion of the epithelium either does not occur or is rare. The number of trophozoites in the intestine can be so large that adherent organisms cover much of the epithelial surface. This could disrupt the epithelial brush border and contribute to disaccharidase deficiency seen in some patients. A number of studies demonstrate direct epithelial cell barrier dysfunction in vitro and in vivo in humans. Exactly how this occurs is not known. There is no evidence of production of a classic enterotoxin, although it is possible that secreted or surface proteins may be injurious to cells. Of patients with persistent giardiasis after treatment, 47% exhibited inflammation on small bowel biopsy specimens, supporting the view that chronic inflammatory responses contribute to disease at least in this subset.

CLINICAL MANIFESTATIONS

The clinical manifestations, course, and duration of *Giardia* infections are variable. Infections may be self-limited or persistent, asymptomatic or symptomatic. In general, patients are not as sick as those with bacterial diarrheas. Acute disease manifestations occur commonly in travelers and in outbreaks and are characterized by diarrhea, nausea, vomiting, anorexia, dehydration, flatulence, eructation, foul-smelling stools, distention, abdominal cramping, and weight loss. Malabsorption is more commonly seen in chronic infection. Fever is uncommon. Blood, mucus, and polymorphonuclear cells in the stool, which are not usual features of small bowel infections, should suggest an alternative or additional diagnosis. Dehydration, although uncommon, may be severe and require hospitalization; hospitalization for giardiasis has occurred in the United States with a frequency similar to that for shigellosis. On occasion, nausea and vomiting will predominate and suggest other causes.

In experimental infections using inoculated cysts, presence of cysts in the stool occurred 6 to 15 days (mean, 9 days) after inoculation. In more recent experimental infections, *Giardia* antigen was detected 1 day before cyst excretion. In one well-documented food-borne outbreak, 74% became ill, with an incubation period of 2 to 19 days and peak symptoms at 5 to 6 days. Symptoms continued for a median of 18 days.

Acute symptoms can resolve, wax and wane, or settle into a chronic phase, which can be prolonged and last weeks to months. Long-lasting symptoms should suggest a search for the parasite. Lactose deficiency is common and can persist for some weeks after treatment, and it needs to be distinguished in symptomatic patients from relapse or reinfection. In extreme cases, malabsorption and weight loss are severe and mimic sprue. Infants and children are particularly susceptible to infection and disease, which can result in growth failure that is reversed on successful treatment.

A typical scenario is a mildly to moderately ill person who complains of an increased number of urgent loose stools, with flatus, cramping, anorexia, and weight loss. There may be periods when the person feels better only to relapse and become noticeably worse. After days to several weeks, the individual will seek medical help. Similar to other causes of infectious diarrheas, symptoms can continue after successful treatment and evolve into irritable bowel syndrome. Uncommonly, *Giardia* is found in biliary and pancreatic ducts and can cause cholecystitis and pancreatitis. Arthritis, uveitis, and urticaria are rarely attributed to *Giardia* infections, but it is unclear if the infection is causative.

Disease and symptoms caused by *Giardia* in children in low-income regions are variably present despite almost universal infection by the age of 3 years and frequent reinfection with prevalence rates that are commonly above 20%. Although there are convincing studies showing detrimental growth and nutritional effects in some populations, other studies show little or no effects. The reasons for these disparate results may be due to differences in the populations, such as prior exposures, maternal factors, and diet, or variability in the organism, including the genetics of the isolate (e.g., assemblage type) and properties of the expressed VSP. In contrast, *Giardia*-naïve visitors frequently develop symptomatic giardiasis while visiting or working in highly endemic regions, in contrast to a mostly asymptomatic population, suggesting that the endemic population has developed an accommodation to the disease.

DIAGNOSIS

The diagnosis of giardiasis is based on detection of cysts, trophozoites, or, more recently, parasite-specific antigens in fecal samples. Polymerase chain reaction analysis for *Giardia* detection in stool is experimental but has been useful to determine assemblage. Because excretion of cysts may be variable or in low concentrations, a single examination for ova and parasites is only 50 to 80% sensitive, and two or three examinations may be necessary. Antigen detection by direct immunofluorescence microscopy increases the sensitivity of a single examination to more than 90%. Stool antigen tests are generally sensitive (>90%), specific (close to 100%), and relatively inexpensive and do not require a trained microscopist. Examination of small intestine biopsy specimens or intestinal contents for trophozoites was the previous "gold standard" for diagnosis but is now uncommonly needed to establish or to confirm the diagnosis. In low-intensity infections, all testing methods can be falsely negative and require repeated testing.

The laboratory findings are nonspecific. Vital signs are generally normal or the patient may have a low-grade fever. The white blood cell count and liver function test results are usually normal. Electrolyte disturbances can be present if diarrhea and vomiting are severe. Lactose deficiency can occur along with other signs or symptoms of small bowel dysfunction. White blood cells, lactoferrin, blood, and mucus are not found in the stool. Immunoglobulin levels are usually normal but abnormally low or absent in susceptible hypogammaglobulinemic individuals.

TREATMENT Rx

Details of antiparasitic therapy in general are provided in Chapter 352. Tinidazole (Tindamax), a Food and Drug Administration (FDA)–approved nitroimidazole drug similar to metronidazole (Flagyl), is the treatment of choice; other nitroimidazoles (e.g., ornidazole and secnidazole) not approved in the United States are also effective. Tinidazole is given as a single dose, and compared with metronidazole, it has fewer side effects and greater efficacy. In adults, the dose is 2 g orally; in children, the dose is 50 mg/kg as a single dose with a maximum of 2 g. Metronidazole has been used to treat giardiasis for decades but has never been approved by the FDA for this indication; it requires multiple dosing at 250 mg orally three times a day for 5 to 7 days for adults and 15 mg/kg/day in three divided doses for 5 to 7 days for children. Gastrointestinal side effects of metronidazole are relatively common, and alcohol should not be taken concomitantly because of the possibility of a disulfiram reaction with both drugs. Albendazole (400 mg/day for 5 days) is as effective as metronidazole and has fewer side effects. Nitazoxanide is a drug with broad activity against protozoa, helminths, and bacteria and is FDA approved for the treatment of giardiasis. It is given at a dose of 100 mg orally every 12 hours for 3 days for children aged 12 to 47 months, 200 mg orally every 12 hours for 3 days for children 4 to 11 years of age, and 500 mg orally every 12 hours for 3 days for persons older than 12 years. Because it is available in a liquid suspension as well as in a 500-mg tablet, it is advantageous for the treatment of younger children. It should be given with food. Most of the side effects are gastrointestinal symptoms and headache.

Paromomycin, a nonabsorbable aminoglycoside, has activity against *Giardia* and has been used in pregnant women to avoid the theoretical fetal adverse events of nitroimidazoles, particularly during the first trimester. It is given to adults at 500 mg three times a day for 5 to 10 days and to children at 25 to 35 mg/kg/day orally in three divided doses for 5 to 10 days. Albendazole is not approved by the FDA but has activity against *Giardia*. It is usually given at 15 mg/kg/day with a maximum dose of 400 mg for 5 to 7 days. Quinacrine and furazolidone (FDA approved but not usually available) are also active against *Giardia* but should be reserved for use in particular situations.

Patients usually experience relief of symptoms on treatment. Failure of treatment is frequently heralded by a return of symptoms days to weeks after cessation of therapy and requires either re-treatment with an alternative class of drug or an increased dosing of the initial therapy. Clinically resistant cases usually respond to combination treatment; quinacrine and metronidazole have been most effective, with metronidazole plus albendazole also showing efficacy.

PREVENTION

Infection is prevented by scrupulous personal hygiene, proper disposal of sewage, removal of cysts from water supplies, or killing of cysts in potentially contaminated water or food. Cysts are relatively labile and are susceptible to heating and filtration with small water volume filters of 0.2 to 1 μm. Heating (bringing water to a boil) is preferred because other pathogens found in feces are also inactivated. Cysts are susceptible to bleach (chlorine) and iodine, but killing is dependent on turbidity, pH, and temperature of the water as well as on the concentration and physical state of the halogen. Four drops of 5.25% bleach to 1 liter for 1 hour at room temperature is sufficient for killing. At lower temperatures, inactivation may not be complete.

360

AMEBIASIS

WILLIAM A. PETRI, Jr. AND RASHIDUL HAQUE

DEFINITION

Amebiasis is due to infection with the enteric protozoan parasite *Entamoeba histolytica*. Amebiasis can cause asymptomatic colonization, diarrhea, dysentery, and colitis, as well as spread extraintestinally to cause liver and rarely brain abscess (Fig. 360-1).

The Pathogen

E. histolytica has a low infectious dose (<100 organisms), is resistant to chlorine, and is environmentally stable. These properties make it a threat to food and water supplies, as the recent municipal water outbreak of amebic liver abscess in Tbilisi, Georgia, demonstrated. Its tissue-destructive properties are the reason for the parasite being named *histolytica*.

EPIDEMIOLOGY

Most *E. histolytica* infections occur in the developing world, including the Indian subcontinent, Southeast Asia, sub-Saharan Africa, and Central and South America, as a result of fecal-oral transmission. A national serologic survey in Mexico demonstrated antibody to *E. histolytica* in 8.4% of the population. In an urban slum of Fortaleza, Brazil, 25% of the population tested carried antibody to *E. histolytica*, and the prevalence in children 6 to 14 years of age was 40%. In Dhaka, Bangladesh, where diarrheal diseases are the leading cause of childhood death, the annual incidence of *E. histolytica* infection in a cohort of preschool children was 40%. The annual incidence of amebic liver abscess was 21 cases per 100,000 inhabitants in Hue City, Vietnam. The best current estimate by the World Health Organization is that *E. histolytica* infection results in 34 to 50 million symptomatic cases each year worldwide and as many as 100,000 deaths.

In the United States, amebiasis is the third most common parasitic infection after giardiasis and cryptosporidiosis (1.2 cases/100,000 U.S. population). Most cases in industrialized countries occur in travelers to and immigrants from endemic regions, as well as in institutionalized individuals. In returning travelers, diarrhea is the predominant reason for a patient to visit a physician, and amebiasis is the second most common cause of diarrhea in returning travelers. Previously reported high rates of *E. histolytica* infection in homosexual men in the United States actually reflect a high prevalence of *Entamoeba dispar* infection in this population. In contrast, in Asia, amebiasis is more frequently an initial symptom of human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome because of the common risk for acquisition of both HIV infection and amebiasis via the sexual practices of men who have sex with men. The typical patient with an amebic liver abscess in the United States is a 20- to 40-year-old Hispanic male immigrant. Several groups are at increased risk for severe amebiasis, including the very young or old, malnourished persons, pregnant women, and patients treated with corticosteroids.

PATHOBIOLOGY

Killing of host cells is required for invasion of the intestine by the parasite. The process of host cell destruction has been experimentally separated into sequential steps of adherence, contact-dependent cytotoxicity, followed finally by phagocytosis of the host cell corpse. The initial contact of parasite to host is mediated by the parasite's galactose and N-acetyl-D-galactosamine (Gal/GalNAc)-specific lectin, which binds to carbohydrate determinants on the host's intestinal epithelium. Human cells die by apoptosis induced by *E. histolytica*, a process that requires attachment of the Gal/GalNAc lectin to a host cell's receptor, as well as the parasite's acid intracellular vesicles, which may serve as delivery vehicles for an amebic pore-forming protein. *E. histolytica* initiates apoptosis in host cells by directly activating the host cell's distal apoptotic machinery: caspase 3 is activated within minutes of *E. histolytica* adherence, a caspase 3 inhibitor blocks *E. histolytica* killing, and caspase 3–deficient or bcl-2–overexpressing mice are resistant to amebic infection. Recognition and ingestion of the apoptotic host's corpse are required for colonic infection by the parasite, and multiple ligands and receptors are involved, including the Gal/GalNAc lectin, a phosphatidylserine receptor, serine-rich *E. histolytica* protein, and collectins. After ingestion of the corpse of the host cell, additional parasitic factors participate in invasion into the intestinal mucosa. For example, *E. histolytica* encodes at least 44 cysteine proteinase genes that have been implicated in degradation of colonic mucin glycoproteins; digestion of extracellular matrix, hemoglobin, and villin; and inactivation of interleukin-18 (IL-18).

The innate immune response to amebic infection includes activation of the alternative complement pathway, with C3a and C5a recruiting neutrophils to the site of infection but with amebae resisting killing by the membrane attack complex via the Gal/GalNAc lectin. In the murine model of intestinal amebiasis, innate resistance is conferred by nonhematopoietic cells, thus suggesting importance of the epithelial production of cytokines such as tumor necrosis factor-α (TNF-α), IL-1α, IL-6, IL-8, growth related oncogene alpha (GROα), and granulocyte-macrophage colony-stimulating factor. Neutrophils are the earliest innate cellular immune response (within 1 to 2 days) for both intestinal and hepatic amebiasis. Depletion of neutrophils with anti–Gr-1 neutralizing antibody in a murine model results in exacerbated amebic hepatic and intestinal disease. Macrophages and T lymphocytes are also recruited by day 3 of an infection. Macrophages acquire amebicidal activity after in vitro stimulation with interferon-γ (IFN-γ), TNF-α, or colony-stimulating factor-1. Natural killer cells may be important in part as a source of IFN-γ, as well as infiltrating mast cells for their ability to contribute to the innate immune response via the production of IL-6 and TNF-α.

The acquired immune response reflects the opposing roles of IL-4 and IFN-γ in persistence and clearance of amebic infection, respectively. Inbred mice of the CBA strain are susceptible to intestinal amebiasis and develop a rapid T_H2 phenotypic immune response, and this response is deleterious in so far as inhibition of IL-4 can convert the response to a healing IFN-γ response. Effective acquired immunity in humans is associated with both a systemic IFN-γ and a mucosal IgA response directed at the Gal/GalNAc lectin. Children with mucosal IgA against the Gal/GalNAc lectin were found to have 86% fewer new *E. histolytica* infections in the following year. Similarly, the risk for amebiasis was 50% lower in children who were in the 50th percentile and above for the production of IFN-γ by peripheral blood mononuclear cells stimulated with soluble amebic antigen. In contrast, there is an association between higher TNF-α production and *E. histolytica* diarrhea, thus indicating that there is a fine line between a pro-inflammatory cellular immune response that is protective and one that is disease enhancing.

CLINICAL MANIFESTATIONS

Asymptomatic Intraluminal Amebiasis

The asymptomatic cyst-passing carrier state is the most common type of amebic infection. All *Entamoeba moshkovskii* and *E. dispar* infections and as many as 80% of *E. histolytica* infections are asymptomatic. Asymptomatically infected individuals represent a risk to the community because they are a source of new infections and a risk to themselves because 1 in 10 to 20 colonized individuals progress to symptomatic infection. The host has a bearing

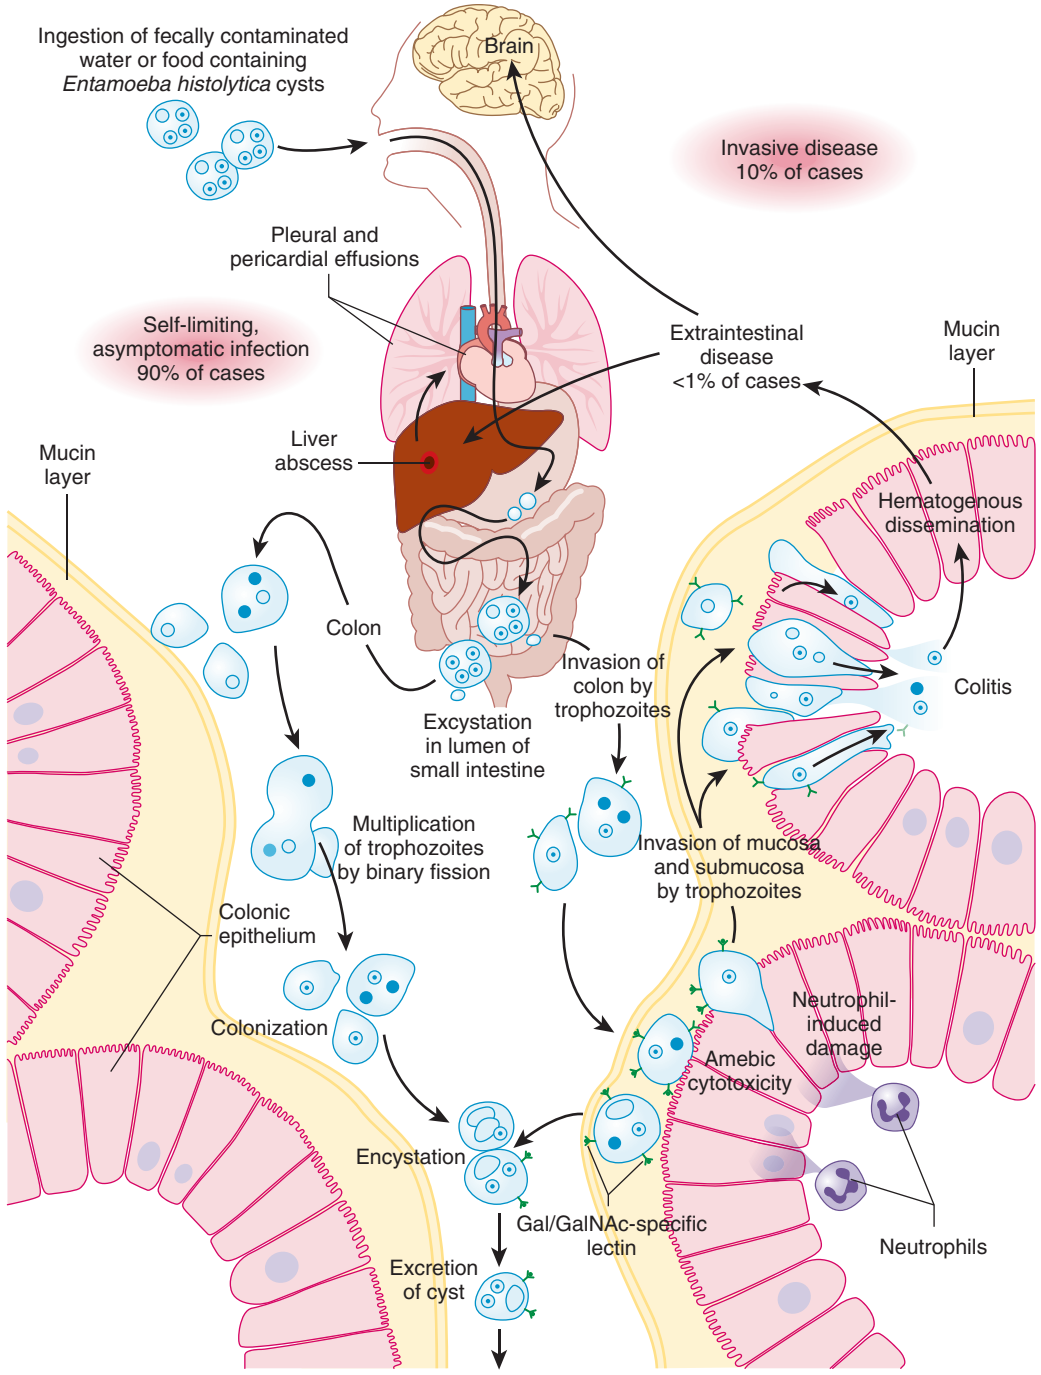

FIGURE 360-1. Life cycle of *Entamoeba histolytica*. Infection is normally initiated by the ingestion of fecally contaminated water or food containing *E. histolytica* cysts. The infective cyst form of the parasite survives passage through the stomach and small intestine. Excystation occurs in the bowel lumen, where motile and potentially invasive trophozoites are formed. In most infections, the trophozoites aggregate in the intestinal mucin layer and form new cysts, which results in a self-limited and asymptomatic infection. In some cases, however, adherence to and lysis of the colonic epithelium, mediated by the galactose and N-acetyl-D-galactosamine (Gal/GalNAc)-specific lectin, initiates invasion of the colon by trophozoites. Neutrophils responding to the invasion contribute to cellular protection at the site of invasion. Once the intestinal epithelium is invaded, extraintestinal spread to the peritoneum, liver, and other sites may follow. Factors controlling invasion, as opposed to encystation, probably include parasitic "quorum sensing" signaled by the Gal/GalNAc-specific lectin, interactions of amebae with the bacterial flora of the intestine, and innate and acquired immune responses of the host. (Redrawn with permission from Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med.* 2003;348:1565-1573).

on whether infection is asymptomatic in that children heterozygous for the HLA class II DQB1*0601/DRB1*1501 haplotype have been found to be protected from symptomatic infection with amebiasis. In addition, certain genotypes of *E. histolytica* appear to be associated with the propensity for colonization as opposed to invasion.

Amebic Diarrhea

Amebic diarrhea without dysentery is the most common amebic disease. It is defined as diarrhea in an *E. histolytica*–infected individual (there is no requirement for the presence of mucus or visible or microscopic blood in stool for the diagnosis of amebic diarrhea). In one community-based study of a cohort of preschool children in Bangladesh, the annual incidence of amebic infection, diarrhea, and dysentery was 45%, 9%, and 3%, respectively. The mean duration of amebic diarrhea was 3 days in one study. It causes approximately 2% of cases of diarrhea severe enough to warrant hospital evaluation in developing countries such as Bangladesh.

Amebic Dysentery or Colitis

Diarrhea with mucus or visible or microscopic blood in a patient with *E. histolytica* infection is the definition of amebic dysentery or colitis. Approximately 15 to 33% of patients with *E. histolytica* diarrhea also have amebic dysentery. The onset of symptoms is typically gradual over a period of 3 or 4 weeks after infection, with abdominal tenderness and increasingly severe diarrhea being the primary complaints. Patients with bacterial causes of

dysentery usually have only 1 to 2 days of symptoms. Surprisingly, fever is present in only a minority of patients with amebic colitis. In young children, intussusception, perforation, peritonitis, or necrotizing colitis may develop rapidly (Fig. 360-2). Unusual manifestations of amebic colitis include toxic megacolon (0.5% of cases, usually requiring surgical intervention) and ameboma (granulation tissue in the colonic lumen mimicking colon cancer in appearance).

Amebic Liver Abscess

Amebic liver abscess is 10 times as common in men as in women and is unusual in children. The typical patient with an amebic liver abscess in the United States is an immigrant from an endemic area, a man aged 20 to 40 years with fever, right upper quadrant pain, leukocytosis, abnormal serum transaminase and alkaline phosphatase levels, and a defect seen on hepatic imaging studies. Most patients have 2 to 4 weeks of prior fever, cough, and abdominal pain in the right upper quadrant or epigastrium. Involvement of the diaphragmatic surface of the liver may lead to right-sided pleural pain or referred shoulder pain and an elevated right hemidiaphragm seen on chest radiography (Fig. 360-3). Hepatomegaly with point tenderness over the liver, below the ribs, or in the intercostal spaces is a typical finding.

If a space-filling defect in the liver is observed, the differential diagnosis includes (1) amebiasis (most common in mean with a history of travel or residence in a developing country), (2) pyogenic or bacterial abscess (particularly suspected in women, patients with cholecystitis, the elderly, individuals with diabetes, and patients with jaundice), (3) echinococcal abscess (which would be an incidental finding because echinococcal abscess should not cause pain or fever), and (4) cancer. Most patients with amebic liver abscess will have detectable circulating antigen in serum, as well as serum antiamebic antibodies.

In children, abdominal pain is reported infrequently with amebic liver abscess. More commonly, high fever, abdominal distention, irritability, and tachypnea are noted. Some of these children are admitted to the hospital with fever of unknown origin. Hepatomegaly occurs frequently, but elicitation of hepatic tenderness is not well documented. In one report, four of five children younger than 5 years died of amebic liver abscess because the diagnosis was not suspected.

Unusual extraintestinal manifestations of amebiasis include direct extension of the liver abscess to the pleura or pericardium and brain abscess. Death usually results from rupture of the liver abscess into the peritoneum, thorax, or pericardium, but it may also be caused by extensive hepatic damage and liver failure.

Other Extraintestinal Infections

Thoracic amebiasis is the most common type of extra-abdominal amebiasis after liver abscess and occurs in about 10% of patients with amebic liver abscess. It develops via direct extension from the liver. Pericardial amebiasis is the next most common form of extraintestinal involvement and may result from rupture of a liver abscess in the left lobe of the liver into the pericardium or from extension of the right-sided pleural amebiasis. Cerebral amebic abscesses have been found in about 0.5 to 5% of patients with amebic liver abscess. In one series of 18 patients with proven cerebral amebiasis, findings on the initial neurologic examination were normal in 13. Other foci of infection are rare, but amebic rectovesical fistula formation and involvement of the pharynx, heart, aorta, and scapula have been reported. Cutaneous infection may arise from trophozoites emerging from the rectum.

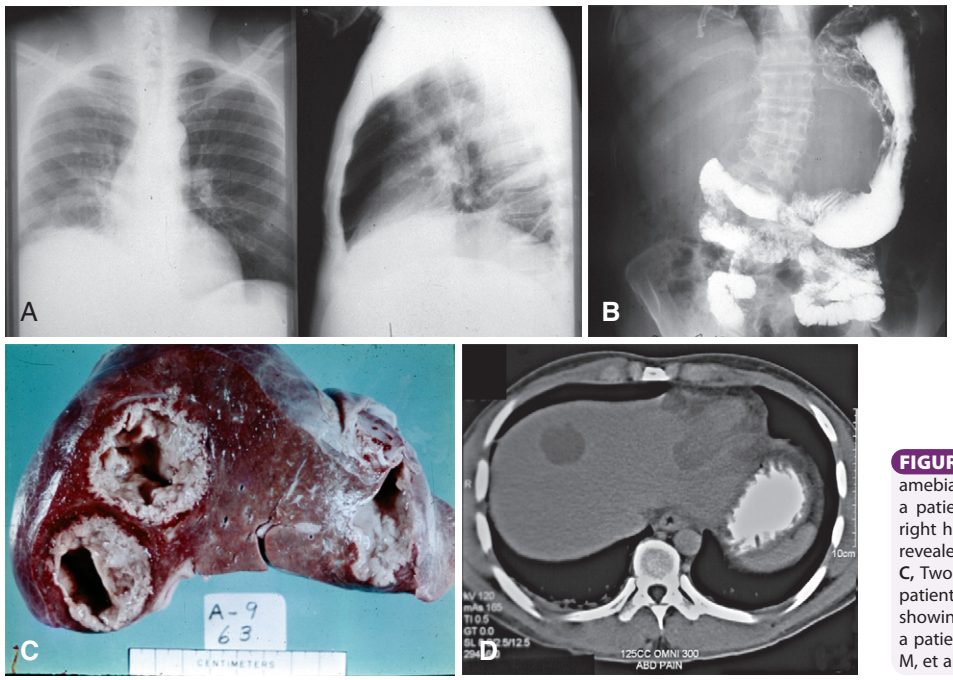

FIGURE 360-3. Radiographic and pathologic features of extraintestinal amebiasis. **A,** Left posteroanterior and right lateral chest radiographs in a patient with amebic liver abscess. The findings include an elevated right hemidiaphragm and evidence of atelectasis. **B,** Luminal narrowing revealed by barium enema examination in a patient with an ameboma. **C,** Two abscesses in the right lobe and one abscess in the left lobe of a patient with amebic liver abscess. **D,** Abdominal computed tomography showing one abscess in the right lobe and one abscess in the left lobe in a patient with amebic liver abscess. TABLE 360-1 SENSITIVITY OF TESTS FOR DIAGNOSIS OF AMEBIASIS

TEST	COLITIS	LIVER ABSCESS
Microscopy: stool	25-60%	10-40%
Stool antigen detection	80%	≈40%
Serum antigen detection	65%	>95%
Microscopy: abscess fluid	N/A	≤20%
Real-time PCR	>95%	>95%
Serologic testing (indirect hemagglutination)		
Acute	70%	70-80%
Convalescent	>90%	>90%

N/A = not available; PCR = polymerase chain reaction.
Adapted from Haque R, Huston CD, Hughes M, et al. Current concepts: amebiasis. *N Engl J Med.* 2003;348:1565-1573.

DIAGNOSIS

Diagnosis of amebiasis is best accomplished by the combination of serology and identification of the parasite in feces or at extraintestinal sites of invasion (such as pus from a liver abscess). Examination of stool for ova and parasites should *not* be used to diagnose amebiasis (Table 360-1). The most sensitive diagnostic approach is the combined use of *E. histolytica*–specific antigen detection or polymerase chain reaction plus serology.

TREATMENT (also see Chapter 352)

Rx

Therapy for invasive infection differs from that for noninvasive infection, which may be treated with paromomycin (Table 360-2). Invasive infections require treatment with nitroimidazoles, particularly metronidazole, tinidazole, secnidazole, or ornidazole. For amebic colitis, tinidazole reduces treatment failure rates and adverse effects compared with metronidazole.[1] In the rare case of fulminant amebic colitis, it is prudent to add broad-spectrum antibiotics to treat intestinal bacteria that may spill into the peritoneum. Parasites persist in up to half of the patients who are treated with a nitroimidazole, so treatment should be followed with paromomycin or the second-line agent diloxanide furoate to cure luminal infection. Drainage of a liver abscess should be considered in patients who do not show a clinical response to drug therapy within 5 to 7 days or those with a high risk for rupture of the abscess, as defined by a cavity with a diameter of greater than 5 cm or by the presence of lesions in the left lobe. Percutaneous needle aspiration or catheter drainage is the procedure of choice for drainage of a liver abscess. Surgical intervention is occasionally required for drainage of a liver abscess, acute abdomen, gastrointestinal bleeding, or toxic megacolon.

TABLE 360-2 DRUG THERAPY FOR TREATMENT OF AMEBIASIS

DRUG	ADULT DOSAGE	SIDE EFFECTS
AMEBIC LIVER ABSCESS		
Metronidazole	750 mg PO tid × 10 days	Primarily GI side effects: anorexia, nausea, vomiting, diarrhea, abdominal discomfort, or unpleasant metallic taste Disulfiram-like intolerance reaction to alcoholic beverages Neurotoxicity, including seizures, peripheral neuropathy, dizziness, confusion, irritability
or		
Tinidazole	2 g PO once daily × 5 days	Primarily GI side effects and disulfiram-like intolerance reaction to alcoholic beverages as for metronidazole
Followed by a luminal agent		
Paromomycin	30 mg/kg/day PO in 3 divided doses per day × 5-10 days	Primarily GI side effects: diarrhea, GI upset
or		
Diloxanide furoate	500 mg PO tid × 10 days	Primarily GI side effects: flatulence, nausea, vomiting Pruritus, urticaria
AMEBIC COLITIS		
Metronidazole	750 mg PO tid × 5-10 days	Same as for amebic liver abscess
Plus a luminal agent (same as for amebic liver abscess)		
ASYMPTOMATIC INTESTINAL COLONIZATION		
Treatment with a luminal agent as for amebic liver abscess		

GI = gastrointestinal.

TABLE 360-3 FREE LIVING AMEBAE

ORGANISM	DISEASE	EPIDEMIOLOGY	DIAGNOSIS	CLINICAL COURSE	THERAPY
Naegleria fowleri	Primary amebic encephalitis	Warm freshwater exposure	CSF wet mount for ameba, PCR	Death within 1-2 weeks of onset	Amphotericin B
Acanthamoeba spp	Keratitis	Corneal trauma, usually from contact lens	Corneal scraping for amebae and cysts	Subacute	Polyhexamethylene biguanide, chlorhexidine, propamidine, hexamidine
Acanthamoeba spp	Granulomatous amebic encephalitis	Immunodeficient (organ transplants, HIV/AIDS)	Biopsy of brain or skin abscess—IFA or PCR	Subacute	Combination therapy with pentamidine, fluconazole, or itraconazole. Flucytosine, sulfadiazine
Balamuthia mandrillaris	Granulomatous amebic encephalitis	Immunodeficient but also immunocompetent	Biopsy of brain	Subacute	Combination therapy with flucytosine, pentamidine, fluconazole, and sulfadiazine plus either azithromycin or clarithromycin
Sappinia	Amebic encephalitis	Single patient was not immunodeficient			Azithromycin, pentamidine, itraconazole, flucytosine

AIDS = acquired immunodeficiency syndrome; HIV = human immunodeficiency virus; IFA = indirect fluorescent antibody; PCR = polymerase chain reaction.
Adapted from Visvesvara GS, Moura H, Schuster FL. Pathogenic and opportunistic free-living amoebae: *Acanthamoeba* spp, *Balamuthia mandrillaris*, *Naegleria fowleri*, and *Sappinia diploidea*. *FEMS Immunol Med Microbiol*. 2007;50:1-26.

PREVENTION

The feasibility of prevention by vaccination with the parasite's Gal/GalNAc lectin is supported by substantial data from human, animal model, and in vitro studies. This vaccine is in the late stages of preclinical development for the prevention of amebiasis in infants and children in the developing world. Provision of sanitation and clean water and safe sexual practices to prevent fecal-oral transmission are of great importance but not universally effective because of the low infectious dose and chlorine resistance of the cyst.

PROGNOSIS

Therapy for amebiasis is highly effective and drug resistance is not reported.

FREE-LIVING AMEBAE

Rare infections of the central nervous system can be seen with infection by free-living amebae of the genera *Naegleria*, *Balamuthia*, *Acanthamoeba*, and *Sappinia*. *Naegleria fowleri* is the agent of primary amebic meningoencephalitis, which occurs in previously healthy children and young adults who have swum in fresh water 2 to 5 days before the onset of meningoencephalitis. Cerebrospinal fluid (CSF) has a polymorphonuclear predominance, and motile amebae can be seen in a wet mount of CSF. The disease is relentlessly progressive to death in most patients. In one case of successful treatment, a combination of intrathecal and intravenous amphotericin B and miconazole and oral rifampin was used. *Acanthamoeba* can cause keratitis in individuals with corneal injuries (usually from contact lens use), as well as granulomatous amebic encephalitis in the immunocompromised. Granulomatous amebic encephalitis can also be caused by *Balamuthia* and *Sappinia*; it is usually associated with focal neurologic findings and has a subacute course (Table 360-3).

361 BABESIOSIS AND OTHER PROTOZOAN DISEASES

SAM R. TELFORD III AND PETER J. KRAUSE

BABESIOSIS

Babesiosis is a tick-borne malaria-like disease caused by sporozoan parasites of the genus *Babesia*.

EPIDEMIOLOGY

Babesiosis increasingly burdens residents of the northeastern and upper midwestern regions of the United States. The number of cases reported to state health departments in the northeastern part of the United States has progressively increased over the past 2 decades as a result of increased physician awareness and the availability of diagnostic laboratory testing, as well as expansion of dense vector infestations. *Babesia* spp are the second most common hemoparasite of mammals, after trypanosomes, and animals may be infected wherever there is a stable tick-host association. Accordingly, zoonotic babesiosis is theoretically possible wherever ticks commonly attach to humans; however, zoonotic babesiosis has been reported only from North America, Eurasia, and Africa.

Three epidemiologic patterns are apparent. The first involves the rodent-maintained *Babesia microti*, which is a species complex distributed across the Holarctic. More than 1000 cases of *B. microti* babesiosis have been reported from the northeastern part of the United States and upper Midwestern states, where Lyme disease is endemic. The vector is the same as that for Lyme disease (Chapter 329), the deer tick (*Ixodes dammini*, also known as the northern population of *Ixodes scapularis*), and indeed, concurrent infection may be common. Immune-intact as well as immunocompromised individuals are at risk. In addition, cases of *B. microti* babesiosis have been reported from Germany, Japan, and Taiwan; the vector has not been definitively identified. The second pattern is represented by fewer than 40 cases of babesiosis caused by *Babesia divergens* or closely related species (e.g., "*Babesia venatorum*" or EU1) that have been reported from Europe; all have occurred in splenectomized patients residing in sites where European castor bean ticks (*Ixodes ricinus*) and deer are common. The third pattern of babesiosis involves sporadic cases caused by diverse *Babesia* spp, including *Babesia duncani* (WA-1) and "CA-type" parasites of the western portion of the United States, a *Babesia divergens*–like species (MO-1) maintained by cottontail rabbits and their ticks across the United States, *Babesia motasi*–like infection (KO-1) in Korea, and unidentified *Babesia* spp from South Africa and India.

Almost all *Babesia* spp are transmitted by ixodid ticks. Although the known zoonotic tick vectors (*I. dammini*, *I. ricinus*) have marked seasonal periods of activity (May to August) and the majority of reported cases are acquired during these times, babesiosis may be diagnosed at any time of the year. Cases of perinatal transmission have at times been reported outside the typical months of risk. In addition, there have been 70 confirmed reports of transfusion-acquired babesiosis, but the actual number of cases is thought to be much greater. Babesiosis is currently the most commonly reported transfusion-transmitted infection in the United States and may occur year-round. The number of such cases is increasing, including those ending in death. Screening of blood donations for *Babesia* spp is not done other than by targeted questions about a history of previous *Babesia* infection.

PATHOBIOLOGY

The pathophysiology of *Babesia* infection is directly related to the development of parasitemia. In hamsters infected by inoculation of a human-derived *B. microti* strain, intravascular and extravascular hemolysis develops as the parasitemia rises and results in profound anemia; the hematocrit may fall to 20%. During this acute phase of disease, there is extramedullary hematopoiesis and hyperplasia of the splenic red pulp. Livers of infected hamsters contain hypertrophied Kupffer cells, many with ingested parasitized erythrocytes but few hemoglobin breakdown products. The proximal convoluted tubules of the kidneys contain abundant hemosiderin, an observation consistent with the occurrence of marked intravascular hemolysis.

Excessive production of pro-inflammatory cytokines seems to explain the most common symptoms best, which include fever, sweats, chills, headache, myalgia, and nausea. Early work demonstrated destruction of intraerythrocytic *B. microti* and *Babesia rodhaini* in mice pretreated with bacille Calmette-Guérin or *Corynebacterium parvum*, thus suggesting that a soluble mediator released from macrophages was responsible for death of the pathogen. Tumor necrosis factor (TNF) was soon identified as a probable candidate. Administration of recombinant TNF to human volunteers induces most of the symptoms of babesiosis and malaria. Such symptoms are not seen when the erythrocyte lysis is due to noninfectious causes, which suggests that the release of merozoites serves as a trigger for the pro-inflammatory cascade. Elevated serum concentrations of TNF, as well as interferon-γ (IFN-γ), interleukin-2 (IL-2), IL-6, E-selectin, vascular cell adhesion molecule-1, and intracellular cell adhesion molecule-1, are detected during the acute phase of human *B. microti* infection and return to baseline 1 month after resolution of infection.

Severe illness caused by infection with *Babesia* almost always occurs in people who are immunosuppressed and includes a complex array of metabolic abnormalities and organ dysfunction. This suggests that the strong pro-inflammatory component of the pathobiology of babesiosis may be synergized by failure to control reproduction of the parasite. Individuals with parasitemia detectable only by polymerase chain reaction (PCR) may, however, have severe signs and symptoms. Pulmonary disease is the most common complication in people experiencing severe *Babesia* infection, with up to 20% of patients suffering from noncardiogenic pulmonary edema. Pro-inflammatory cytokines appear to mediate the pulmonary complications of *Babesia* infection at least partly. C3H/HeN mice infected with *B. duncani* suffer a fulminant illness that includes increased leukocyte margination in the lung vasculature, pulmonary edema, and death. TNF and IFN-γ mRNA is upregulated in the lungs of *B. duncani* ("WA-1")–infected mice, whereas TNF-knockout mice are less likely to die of fulminating *B. duncani* infection than are those with an intact TNF response. It is also likely that lung and other end-organ pathology is mediated, at least in part, by vascular stasis, which has been described in the lungs of hamsters and mice infected with *B. duncani*.

CLINICAL MANIFESTATIONS

About a quarter of *B. microti* infections in adults and half of those in children are subclinical. This estimate is derived from an epidemiologic study that determined the frequency of people who seroconverted over the course of the summer transmission season but reported no illness, coupled with a careful accounting of symptomatic cases. Most people experience a mild to moderate illness lasting about a week. There is a gradual onset of malaise, anorexia, fatigue, fever (temperature as high as 40° C), drenching sweats, and myalgia. Nausea, headache, shaking chills, emotional lability, depression, hemoglobinuria, and hyperesthesia have also been reported. Findings on physical examination consist of fever, pallor, splenomegaly, and hepatomegaly. Laboratory abnormalities include anemia, thrombocytopenia, and leukopenia. Parasitemia generally ranges from barely detectable on blood smear to 5% in previously healthy people but may reach 85% in asplenic and other immunocompromised patients. Lactate dehydrogenase, bilirubin, and transaminase levels may be elevated in more severe cases. Persistent relapsing illness may occur in highly immunocompromised people who fail to clear the infection for months or more than 1 year despite multiple courses of antibiotics. The case-fatality rate for *B. microti* babesiosis has been estimated to be 3 to 5% but may be as high as 20% in immunocompromised hosts. Severe babesiosis usually occurs only in people with asplenia, malignancy, coinfection with human immunodeficiency virus (HIV), immunosuppressive treatment, or age older than 50 years.

Cases of babesiosis caused by species other than *B. microti* tend to be severe, at least in part because they are reported primarily in immunocompromised patients. Virtually all European patients experiencing *B. divergens* infection have been splenectomized and about a third of the patients died. In these patients there was an acute onset of illness with hemoglobinuria, a persistent nonperiodic high fever (temperature of 40 to 41° C), shaking chills, intense sweats, headaches, and myalgia, as well as lumbar and abdominal pain. Vomiting and diarrhea have been reported. Pulmonary, renal, or liver failure may develop rapidly. In fatal cases, patients become comatose with multiorgan failure. *B. duncani*– and *B. divergens*–like infections have also often been reported in immunocompromised hosts with a similarly severe course of illness.

DIAGNOSIS

The diagnosis of babesiosis is based on epidemiologic and clinical findings and confirmed by laboratory testing. Given clinical findings consistent with babesiosis, the diagnosis may be confirmed by examination of a Giemsa-stained thin blood smear for the presence of parasites within erythrocytes. In an immunocompromised patient, parasitemias are likely to exceed one infected cell per oil immersion field and thus are detected quickly. For *B. microti* babesiosis (Fig. 361-1), examination of a slide for 10 minutes or as many fields as needed to tally 200 leukocytes (that are not infected but serve as a marker for effort) and repeated smears performed twice a day may be required. Standard Romanowsky stains (Giemsa, Wright) using malaria protocols are optimal. Artifactual inclusions are limited mainly to stained precipitates (which can be determined by their presence in the plasma spaces between cells), Howell-Jolly or Heinz bodies (Chapter 160), or platelets superimposed on erythrocytes (which always have a light-colored halo when visualized this way). *Babesia* spp have clearly defined chromatin with a lighter-colored cytoplasm (Fig. 361-2A). They may be mistaken for early malarial trophozoites. Neither malarial nor babesial rings have hemozoin (malarial pigment), so this is not a good feature to distinguish between the two. Paired piriform parasites, arranged in a "v," are very suggestive of *B. divergens* or *B. divergens*–like infection (Fig. 361-2B). "Rings" of all sizes may be seen in all species. Multiple parasites may frequently be seen in single erythrocytes, as well as clumps of extracellular parasites. Tetrad forms (Fig. 361-2C) and "Maltese cross" forms (Fig. 361-2D) are diagnostic but are rarely seen in *B. microti* babesiosis; they seem to be more common with *B. duncani* or CA-type infections.

PCR assays are an important adjunct to blood smears in laboratories with expertise in molecular biology. PCR is usually more sensitive than blood smears in cases in which parasitemias are very sparse. Real-time PCR assays performed in house would provide confirmation nearly as quickly as microscopy with the added advantage of increased sensitivity. As with many molecular diagnostic assays, use of PCR for *Babesia* (either conventional or real time quantitative) is limited by false-positives, validation of experimental assays, and insurance reimbursement. PCR sequencing, performed by collaborating research laboratories, is extremely valuable in retrospectively identifying the species of *Babesia* when the identity is not clear.

Serologic testing is useful for confirming *B. microti* infection. The indirect immunofluorescence test using antigen from infected hamster red cells is sensitive and specific and is currently the serologic method of choice. Analysis of paired acute and convalescent serum samples is most useful for confirmation of *B. microti* infection. The presence of parasite-specific IgM may indicate that the patient has an acute infection even in the absence of readily demonstrable parasitemia. Serology is not generally useful for *B. divergens* babesiosis given its fulminant natural history. Because parasitemia occurs before an antibody response, treatment needs to be initiated immediately based on clinical suspicion and initial laboratory results.

The known vectors for human babesiosis are ticks that also transmit the agents of Lyme disease, human granulocytic anaplasmosis, and tick-borne encephalitis virus. Thus, coinfections should be considered in all patients with babesiosis. Acute illness in patients coinfected with Lyme disease and babesiosis is more severe and more persistent than in patients experiencing Lyme disease alone.

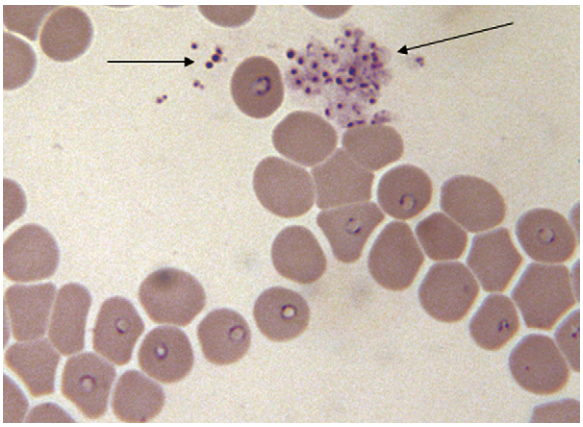

FIGURE 361-1. *Babesia microti* in a human living on Nantucket Island. A predominance of ring forms with a cluster of extraerythrocytic parasites *(arrows)* free in plasma is seen.

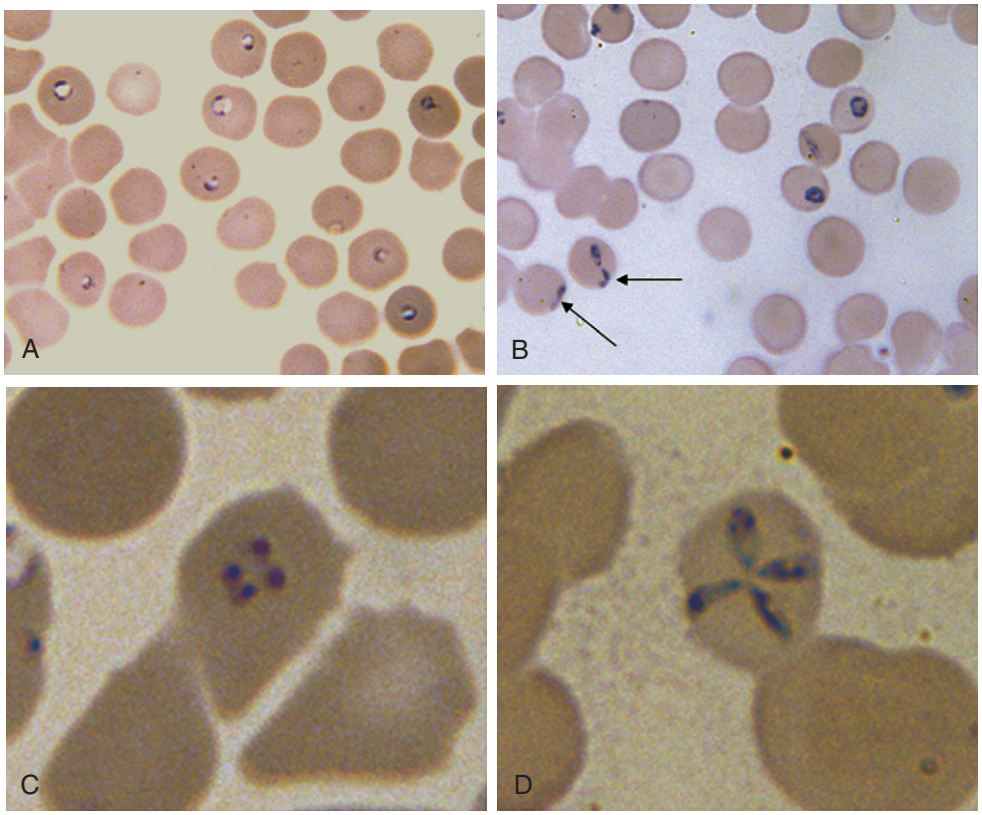

FIGURE 361-2. Diagnosis of *Babesia* infection. A, Typical thin-film field demonstrating ring forms of *Babesia microti* with a vacuole or "whitish" cytoplasm demarcated by a dark-staining, defined chromatin. **B,** *Divergens*-like ("MO-1") with robust rings. The accole form and paired piriform parasites are marked by *arrows*. **C,** Tetrad forms of *B. microti*. **D,** "MO-1," classic Maltese cross. (Microscope slide from a human case of "MO-1" kindly provided by Dr. J. F. Beattie, Department of Pathology, The Medical Center, Bowling Green, KY.)

TREATMENT

Rx

Therapy for mild to moderate *B. microti* infection should consist of the combination of atovaquone (750 mg orally twice daily for 7 to 10 days) and azithromycin (500- to 1000-mg initial dose followed by 250 mg orally daily for 7 to 10 days; for immunocompromised hosts, the dosage is 600 to 1000 mg orally daily for 7 to 10 days). A prospective randomized trial[1] demonstrated that patients treated with atovaquone and azithromycin cleared parasitemia as effectively as did those receiving clindamycin and quinine and with fewer side effects. For severe babesiosis, a 7- to 10-day course of the combination of quinine (650 mg orally every 8 hours) and clindamycin (either 300 to 600 mg every 6 hours intravenously or 600 mg orally every 8 hours) should be used. The pediatric regimen is quinine, 8 mg/kg given every 8 hours orally (maximum of 650 mg per dose), and clindamycin, 7 to 10 mg/kg given every 6 to 8 hours (maximum of 600 mg per dose).

Treatment may occasionally fail in high-risk patients or in those who must discontinue quinine because of side effects, such as severe tinnitus and gastrointestinal distress. Multiple courses of treatment over a prolonged duration may be required to clear parasitemia in immunocompromised patients; combination therapy should be used sequentially beginning with clindamycin and quinine and then atovaquone and azithromycin, until an effective combination is identified. If these fail, treatment should include two or more of the following antimicrobials: artemisinin, atovaquone, azithromycin, clindamycin, doxycycline, Malarone, pentamidine, quinine, and trimethoprim-sulfamethoxazole. Once an effective combination is identified, it should be continued for at least 6 weeks and 2 weeks beyond the time when *Babesia* can no longer be visualized on blood smear.

Exchange transfusion should be considered in severely ill patients with parasitemias in excess of 10%, evidence of severe hemolysis, or organ failure. In particularly severe babesiosis cases, partial or complete blood exchange transfusion (2 to 3 blood volumes) should be undertaken, in addition to treatment with clindamycin and quinine.

PREVENTION

Prevention depends on reducing the risk for tick bites. Immunocompromised individuals should be especially careful to use personal protection and may even consider avoiding highly endemic sites such as coastal New England and Long Island during May through July, when risk is the greatest. Use of repellants such as DEET or application of permethrin to clothing will greatly reduce tick attachment. Such products should be applied to shoes, socks, and trouser cuffs. Wearing light-colored long pants and tucking the cuffs into socks will also help prevent ticks from gaining access to attachment sites. Daily examination for attached ticks should be performed; the best way to do this is to feel for new bumps on a soapy body in the shower. Any attached ticks should be promptly removed by simple traction, which is best accomplished with the use of tweezers. As with the agent of Lyme disease, ticks must be attached for at least 36 to 48 hours before a sufficient inoculum of *Babesia* sporozoites is delivered.

Human *Babesia* vaccines are unlikely to be developed. Community-level prevention should focus on educating the public about the risks of tick-borne infection, reducing habitat for ticks (brush removal and landscaping around yards), or reducing reproductive hosts for the tick. Deer reduction will reduce the abundance of the deer tick vector for *B. microti* babesiosis.

PROGNOSIS

Long-term sequelae have not been reported in patients who have been treated adequately. In most patients who complete a full regimen, parasite DNA seems to become undetectable by PCR within 3 months. Infection does not imply protective immunity based on laboratory rodent models, but reinfection has not been demonstrated in humans.

MISCELLANEOUS PROTOZOA

Diarrhea and other lower gastrointestinal signs and symptoms may be caused by diverse protozoa. The gastrointestinal and urogenital tracts may contain representatives of the four major groupings of protozoa (amebae, sporozoa, flagellates, and ciliates). Specific clinical diagnosis is not possible; expert clinical parasitology support is required to determine whether an agent that has been detected in a stool sample is a pathogenic species. Identification is necessary because treatment options differ depending on the agent. With the exception of *Trichomonas vaginalis* infection (sexually transmitted), all of the enteric protozoa are acquired by the ingestion of food or materials contaminated by human feces. Given this shared mode of transmission ("fecal-oral"), demonstrating the presence of any of these protozoa within a stool sample from a patient is justification for an intensified search for those that are recognized as clinically significant pathogens (*Entamoeba histolytica, Giardia lamblia/intestinalis, Cyclospora cayetanensis, Cystoisospora belli,* and *Cryptosporidium parvum/hominis*). Other protozoa, many of which morphologically resemble true pathogens, are commonly detected within the stools of patients with lower gastrointestinal disturbances, but support for their role as etiologic agents is weak.

Cryptosporidiosis (Chapter 358), giardiasis (Chapter 359), and amebiasis (Chapter 360), are discussed in separate chapters. Trichomoniasis and coccidian enteritis are discussed in the following section because they are relatively common infections.

Trichomoniasis

EPIDEMIOLOGY

T. vaginalis is among the most prevalent of all pathogenic protozoa and perhaps the most common sexually transmitted infection globally with the exception of viral and chlamydial agents. As many as 30% of female college students and 40% of pregnant Nigerian women were found to be infected. The highest incidence of infection occurs in women with multiple sexual partners and those with other sexually transmitted diseases (Chapter 293). *T. vaginalis* can also be passed from infected mothers to their newborn daughters, but it is seldom symptomatic in girls before menarche. The parasite is able to survive for some time in moist environments, and nonvenereal transmission, though uncommon, can occur. Trichomoniasis, like other sexually transmitted diseases, may increase the likelihood of transmission of HIV.

PATHOBIOLOGY

T. vaginalis, known colloquially as a *flagellate*, is classified in the phylum Metamonada and class Parabasalia, along with another human pathogen, *Dientamoeba fragilis* (previously thought to be an ameba). The parabasalids are a phylogenetic sister group to the class Eopharingia, which includes *Giardia* spp. The parabasalids lack mitochondria and are anaerobic; they all have a unique cellular organelle, the hydrogenosome, which is a relic of the mitochondrion and serves as the site of anaerobic pyruvate metabolism. A hemolysin is produced that may cause epithelial damage. The 10- to 15-μm-long trophozoites multiply by longitudinal binary fission on the epithelial surface of the vagina or urethra, as well as in vaginal or urethral secretions, and are thereby transmitted by sexual intercourse. No cyst form is known, and the trophozoites are easily killed by drying.

CLINICAL MANIFESTATIONS

Trichomoniasis is one of three common causes of vaginitis or vaginosis (along with bacterial vaginosis and vulvovaginal candidiasis). It is characterized by a thin gray to yellowish green frothy discharge, vulvovaginal erythema, ectocervical erythema or "strawberry cervix" observable mainly by colposcopy, pH higher than 4.5, increased presence of polymorphonuclear leukocytes, and a positive whiff test, in which a foul fishy odor is intensified with the addition of potassium hydroxide. The incubation period for trichomoniasis is 5 to 28 days. In addition to a frothy discharge, vaginitis can be accompanied by vulvovaginal irritation, dyspareunia, abdominal pain, and dysuria. Symptoms may worsen during menstruation. Population-based studies indicate that as many as half of *T. vaginalis* infections in women and the majority in men are asymptomatic. *T. vaginalis* can frequently be isolated from the male partners of infected women and can produce symptomatic urethritis. Urethral discharge is generally scant in these cases. Rarely, *T. vaginalis* is associated with epididymitis, superficial penile ulcerations that are usually located under the prepuce, or prostatitis.

DIAGNOSIS

In women, vaginal and urethral secretions should be examined. *T. vaginalis* is seen in wet mounts of vaginal secretions in approximately 60% of infected women, thus confirming the diagnosis. Live *T. vaginalis* has a twitching or tumbling motion in wet mounts, and polymorphonuclear leukocytes are usually present. Direct immunofluorescent antibody staining is more sensitive than wet mounts, but technically more difficult. Culture is an even more sensitive method of diagnosis and commercial kits for culture are available, but the results are not available for 3 to 7 days. *T. vaginalis* is occasionally identified in Papanicolaou-stained smears; Giemsa stain may also be used (Fig. 361-3). PCR-based assays of vaginal specimens have been sensitive and specific in preliminary studies. For men, a wet mount of material from a

platinum loop scraping of the anterior urethra reveals the organism in approximately half of infected individuals. Prostatic massage before collecting urine for *Trichomonas* culture is a more sensitive diagnostic approach. *T. vaginalis* is not found in the gastrointestinal tract, and the presence of trichomonads in wet fecal mounts or stained fixed fecal smears (iron hematoxylin or trichrome) most likely represents the commensal *Pentatrichomonas* (formerly *Trichomonas*) *hominis*. Serologic studies lack sensitivity and specificity.

TREATMENT (ALSO SEE CHAPTER 352) Rx

Tinidazole, a single 2-g oral dose or 500 mg daily for 7 days in adults, or metronidazole, as either a single 2-g oral dose or 500 mg twice daily for 7 days, is the treatment of choice. Tinidazole is the better tolerated of the two. Single-dose therapy (metronidazole or tinidazole) ensures patient compliance but can produce nausea and a metallic taste, particularly with metronidazole. Both tinidazole and metronidazole have a disulfiram-like effect, and patients who consume alcohol within 24 hours of taking metronidazole or 72 hours of tinidazole may experience severe nausea, vomiting, and flushing. Use of tinidazole and metronidazole is relatively contraindicated during pregnancy given the lack of well-controlled studies involving pregnant subjects. Treatment failures with metronidazole are uncommon but well documented. Some result from reinfection and others from poor compliance, but some are caused by metronidazole-resistant parasites. A repeated course of metronidazole (500 mg twice a day orally for 7 days or 2 g orally for 5 days) may be tried. Alternatively, tinidazole, 2 g orally for 5 days, has been effective in treating a subset of persons with metronidazole-resistant isolates. If patients remain refractory to appropriate treatment, sensitivity to metronidazole can be tested by the Centers for Disease Control and Prevention (available at *www.dpd.cdc.gov/dpdx/HTML/DiagnosticProcedures.htm*).

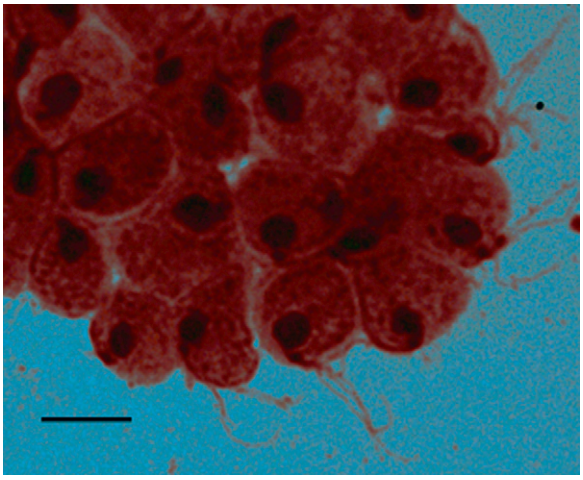

FIGURE 361-3. ***Trichomonas vaginalis*.** A Giemsa-stained smear of cultivated trophozoites is seen on bright-field microscopy (×630). The scale bar is 15 µm.

PREVENTION

Condoms (male or female) reduce the risk of acquiring trichomoniasis. Sexual partners should be treated concurrently to prevent reinfection because nearly 20% of male partners also become infected.

PROGNOSIS

Rare complications include pelvic inflammatory disease. Infection during gestation may lead to fetal growth retardation. There is no natural or acquired immunity, so reinfection may be common.

Coccidian Enteritis

EPIDEMIOLOGY

The coccidia (phylum Apicomplexa, class Conoidasida, order Eucoccidiorida), with 43 genera and more than 1700 recognized species, are well-known veterinary pathogens. At least two of the coccidia, *C. cayetanensis* (an eimeriid) and *C. belli* (a sarcocystid), are causative agents of enteritis in humans. These parasites are acquired by ingesting food or water contaminated with feces. The infective oocyst stage is moderately resistant to environmental degradation and may remain viable for weeks. *C. cayetanensis* may have both an animal and a human reservoir, but *C. belli* is thought to be an anthroponosis. Cyclosporiasis is a cause of gastroenteritis in tropical and subtropical areas, with Peru, Mexico, Haiti, the Caribbean countries, and Nepal commonly reporting such cases. Since 1990, at least 11 food-borne outbreaks affecting approximately 3600 persons have been documented in the United States and Canada in those who have eaten contaminated raspberries, fresh basil, snow peas, or mesclun. Cyclosporiasis is occasionally diagnosed in returning international travelers.

PATHOBIOLOGY

Oocysts are passed in feces and must sporulate for at least a day (*C. belli*) or 5 to 11 days (*C. cayetanensis*) before attaining infectivity (i.e., the development of two sporocysts each containing four sporozoites [*C. belli*] or two sporozoites [*C. cayetanensis*]). Sporozoites are liberated in the small bowel and penetrate enterocytes (for *C. cayetanensis*, mainly the jejunum). *C. cayetanensis* appears to have a complicated developmental cycle, with at least two merogonic cycles in the bowel leading to the formation of gametes. The gametes fuse within enterocyte cytoplasm, and an oocyst wall is deposited around the zygote. The sexual cycle begins about a week after infection, with oocysts sloughing into the bowel lumen and subsequently out of the body via feces. Biopsy samples from infected patients demonstrate mononuclear and eosinophilic infiltrates in the lamina propria, as well as alterations in the morphology of villi.

CLINICAL MANIFESTATIONS

After an incubation period of approximately 1 week, either agent produces watery diarrhea, nausea, vomiting, abdominal pain, myalgia, anorexia, and fatigue. The illness is usually self-limited, but symptoms can be prolonged

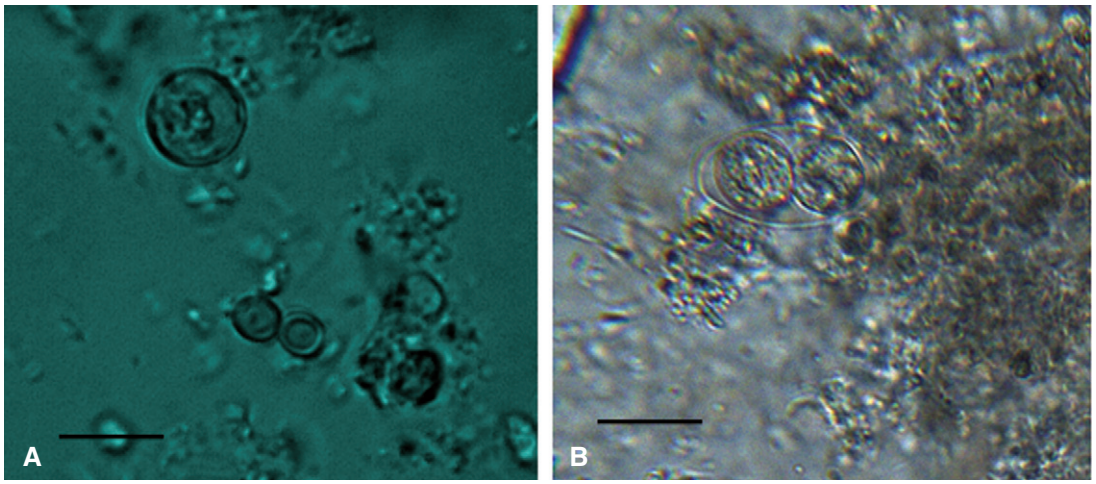

FIGURE 361-4. Diagnosis of coccidian enteritis. A, *Cyclospora cayetanensis* seen on formalin-fixed human feces via bright-field microscopy (×1000) with a green contrast filter. The organism is unsporulated. Note the doublet of yeast cells in the lower right of the photomicrograph. The scale bar is 10 µm. **B,** *Cystoisospora belli* seen by bright-field microscopy (×400) on formalin-fixed human feces. The organism is partially sporulated. The scale bar is 15 µm.

TABLE 361-1 OTHER ENTERIC PROTOZOA

ORGANISM	EPIDEMIOLOGY	MANIFESTATIONS	THERAPY*
Balantidium coli	Primarily an infection of animals, especially pigs, but also affects humans	Asymptomatic or mild and self-resolving; occasionally more severe with abdominal pain, blood, and mucus in stool	Tetracycline (500 mg qid for 10 days). Alternative: metronidazole (750 mg tid for 5 days) or iodoquinol (650 mg tid for 20 days)
Blastocystis hominis	Probably worldwide, including North America; often found concomitantly with *Giardia lamblia*	Pathogenicity is debated	The need for treatment is debated, but symptomatic improvement has been reported with metronidazole (750 mg tid for 10 days), iodoquinol (650 mg tid for 20 days), or trimethoprim-sulfamethoxazole (1 double-strength tablet bid for 7 days)
Dientamoeba fragilis	Worldwide distribution; frequently found concomitantly with the pinworm *Enterobius*	Often asymptomatic; diarrhea reported	Paromomycin (25-35 mg/kg body weight per day in 3 doses for 7 days), tetracycline (500 mg qid for 10 days), metronidazole (500-750 mg tid for 10 days), or iodoquinol (650 mg tid for 20 days)
Microsporidia† (*Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*)	Apparent worldwide distribution	AIDS patients with persistent diarrhea and wasting; self-limited cases in immunocompetent persons	Oral fumagillin (20 mg three times daily for 14 days) has been effective for *E. bieneusi*, but it has been associated with thrombocytopenia. Albendazole (400 mg bid for 21 days) has been effective for *E. intestinalis*. Treatment with HAART may lead to clinical response in HIV-infected patients with microsporidial diarrhea
Sarcocystis species	Common pathogens of animals, rare in humans; acquired by ingesting contaminated beef or pork	Often asymptomatic; nausea, vomiting, abdominal pain, and diarrhea may occur; eosinophilic necrotizing enteritis has been reported	No specific therapy

*Recommendations are based on "Drugs for Parasitic Infections" (*Med Lett Drugs Ther*. 2004;46:1-12. *www. medicalletter.org*). The dosages and durations are for adults.
†Associated with persistent, severe diarrhea in persons with AIDS.
AIDS = acquired immunodeficiency syndrome; HAART = highly active antiretroviral therapy; HIV = human immunodeficiency virus.

(10 to 12 weeks) and be associated with steatorrhea, flatulence, and substantial weight loss in persons who are immunocompromised, especially those with acquired immunodeficiency syndrome (AIDS). Infections may also be asymptomatic.

DIAGNOSIS

The diagnosis is confirmed by identifying coccidia in stool samples stained with modified acid-fast or modified safranin preparations or by phase contrast microscopy or bright-field microscopy (using iodine as a contrast medium) of wet mounts (Fig. 361-4). The unsporulated oocyst of *C. belli* measures 20 to 33 by 10 to 19 µm and usually contains a single sporoblast; that of *C. cayetanensis* measures 8 to 10 µm (similar in morphology to *Cryptosporidium* spp, but more elongate) with two sporocysts. *C. cayetanensis* and *C. belli* may be sensitively detected by fluorescent microscopy of wet mounts. The oocysts are autofluorescent when using a filter set for excitation at 365 nm (oocysts will fluoresce ghostly blue) or 405 nm (bright green); note that standard excitation for fluorescein isothiocyanate (450 to 490 nm) will not induce autofluorescence. PCR assays are specific and can be sensitive, depending on the mode of DNA extraction, but they are available only in research settings.

TREATMENT

Rx

Rehydration is important, as it is for any severe diarrheal disease. Both infections may respond to treatment with 160 mg trimethoprim and 800 mg sulfamethoxazole taken twice daily for 7 to 10 days. HIV-infected patients may require an increased intensive dosing frequency of four times daily for 10 days. Chronic suppressive therapy with 160 mg trimethoprim/800 mg sulfamethoxazole three times weekly is often necessary thereafter in HIV-infected patients. The widespread use of Bactrim prophylaxis for *Pneumocystis* has reduced the incidence of coccidial diarrhea in patients infected with HIV.

PREVENTION

At the community level, preventing the contamination of water and food (mainly vegetables and fruits) by animal or human feces reduces the risk of transmission. Washing vegetables and fruits in water will reduce the potential inoculum but does not eliminate all risk.

PROGNOSIS

Reactive arthritis, Guillain-Barré syndrome, Reiter's syndrome, cholecystitis, and cholangitis have been reported as complications of either form of coccidiosis, mainly in patients with AIDS. Otherwise, treatment appears to eradicate the organism. Whether reinfection may occur is not known. Reports of extraintestinal infection with *C. belli* and *C. cayetanensis* suggest the possibility of reinvasion of the bowel with ensuing recrudescence of signs and symptoms.

Other Enteric Protozoans

A number of other protozoa transmitted by fecal-oral contamination have been associated with enteric disease (Table 361-1). Some reside in the lumen of the bowel, and others invade and multiply within enterocytes. Enteric protozoa should be considered in the differential diagnosis of patients with persistent diarrhea and abdominal symptoms, particularly those with a history of recent international travel. A clinical diagnosis is rarely possible; laboratory tests, mainly for ova and parasites in stool, establish the diagnosis. Expert microscopists are required because these parasites may be confused with fecal debris. Pathogenic protozoa must also be differentiated from commensals such as *Entamoeba coli*, *Endolimax nana*, *Iodamoeba bütschlii*, *Pentatrichomonas hominis*, and *Chilomastix mesnili*. Therapy includes administration of the appropriate antiprotozoal drug and rehydration, as listed in Table 361-1 (also see Chapter 352).

362 CESTODES

A. CLINTON WHITE, JR., AND ENRICO BRUNETTI

DEFINITION

The Pathogens

Cestode parasites are members of the animal kingdom, subphylum Cestoda. The organisms are characterized by several life cycle stages, which typically develop in distinct hosts. The adult stage is the tapeworm, which is acquired by ingestion of uncooked tissues harboring larval forms. After ingestion, the larvae excyst and the scolex attaches to the intestines. Segments, termed *proglottids,* develop at the base of the scolex and are displaced from the scolex by new proglottids to form a chain or tapeworm. The host in which the tapeworm develops is termed the *definitive host.* The proglottids contain male and female sexual organs and produce large numbers of ova. The proglottids or their ova are shed in stools. Humans are the definitive hosts for a number of different tapeworms, including the *Taenia* species, *Diphyllobothrium* species, and *Hymenolepis nana*. Humans can also be an accidental host for the dog and cat tapeworms of the genus *Dipylidium* (Table 362-1).

The intermediate hosts harbor the larval form of the parasite. Infection follows ingestion of the ova. Under the influence of gastric and intestinal fluids, the ova hatch, releasing the invasive larvae (oncospheres), which migrate to tissues, forming tissue forms. The forms in tissue vary between organisms and may include the cysticercus (a bladder containing a single invaginated scolex), the coenurus (a bladder with multiple scolices), the hydatid (a cystic structure with a germinal layer, which forms numerous protoscolices), or the plerocercoid (a solid form seen in *Spirometra* species). Humans can harbor the intermediate forms of *Taenia solium* (cysticercosis), *Echinococcus granulosus* group (cystic hydatid disease), *Echinococcus multilocularis* (alveolar hydatid disease), and rarely other organisms (Table 362-2). Humans can serve as both the definitive host and an intermediate host for two species, *T. solium* and *H. nana*. In the case of *T. solium*, humans are the obligate host for the tapeworm stage (pork tapeworm) but can also harbor the cystic form (cysticercosis). In the case of *H. nana*, both stages typically develop in a single person, with the cysticercoid form in the intestinal wall and the tapeworm in the lumen.

INTESTINAL TAPEWORM INFECTIONS

Diphyllobothrium species (Fish Tapeworm)

Diphyllobothrium tapeworms are large segmented parasites that are acquired by ingestion of undercooked or pickled freshwater fish dishes (sushi, sashimi, ceviche, carpaccio, gefilte fish). The tapeworms develop within a few weeks and can live for more than 10 years.

EPIDEMIOLOGY AND PATHOBIOLOGY

Diphyllobothrium species are found worldwide, including foci in Europe, North and South America, and Asia. Perhaps 20 million people are thought to be infected worldwide. Major foci include Russia, Japan, and South America. Disease was formerly highly endemic in Scandinavia, where it is now rarely diagnosed.

In most cases, infection has little impact on the host. However, one species, *Diphyllobothrium latum*, contains vitamin B_{12} receptors on the surface of the tapeworm, which can out-compete the host, leading to vitamin B_{12} deficiency (Chapter 167). This manifestation has been described only in Scandinavia.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In most of those infected, *Diphyllobothrium* species produce few or no symptoms. Some may complain of gastrointestinal symptoms (abdominal discomfort, nausea, weight loss). The main clinical manifestation is the observation of proglottids being passed in stool. Pernicious anemia with symptoms of anemia or peripheral neuropathy may develop with *D. latum* infection. The diagnosis depends on observation of the characteristic operculated eggs in stool.

TREATMENT AND PREVENTION Rx

A single oral dose of praziquantel (5 to 10 mg/kg) is usually adequate for therapy (Table 362-3). Niclosamide can be used as an alternative (2 g [adults] or 50 mg/kg [children] in a single dose chewed and swallowed), but it is not available in the United States. Parasites in fish can be killed by cooking (>56° C, >5 minutes) or freezing (–20° C, 24 hours). Infected fish may also be identified by inspection.

Hymenolepis nana

Hymenolepis nana is the human dwarf tapeworm. *Hymenolepis diminuta*, a rat tapeworm, can also cause human infection.

EPIDEMIOLOGY AND PATHOBIOLOGY

H. nana is widely prevalent worldwide, with estimates of 50 to 75 million people infected. Infection follows ingestion of ova. The larvae are released, invade, and develop into cysticercoid forms in the intestinal villi. After a few days, the cysticercoids mature, invade the lumen, and are transformed into a scolex, forming small tapeworms (up to 5 cm long), which begin producing eggs within 2 to 3 weeks. Autoinfection either in the intestines or by the fecal-oral route can lead to heavy infection.

TABLE 362-1 COMMON HUMAN TAPEWORM INFECTIONS

ORGANISM	INTERMEDIATE HOST	COMMON NAME	CLINICAL PRESENTATION	TREATMENT
Diphyllobothrium spp	Fish	Fish tapeworm	Passing segments, pernicious anemia	Praziquantel, niclosamide
Hymenolepis nana	Humans	Dwarf tapeworm	Asymptomatic, diarrhea	Praziquantel, niclosamide
Taenia saginata	Cattle	Beef tapeworm	Asymptomatic, passing segments	Praziquantel, niclosamide
Taenia asiatica	Pigs	Asian tapeworm	Asymptomatic, passing worms	Praziquantel, niclosamide
Taenia solium	Pigs	Pork tapeworm	Asymptomatic, passing segments	Praziquantel, niclosamide
Dipylidium caninum	Fleas	Dog tapeworm	Passing segments	Praziquantel, niclosamide

TABLE 362-2 HUMAN LARVAL CESTODE INFECTIONS

ORGANISM	COMMON NAME	ORGANS INVOLVED
Taenia solium	Cysticercosis	Brain, spinal fluid, eye, muscle
Echinococcus granulosus group	Cystic hydatid disease	Liver, lung, other
Echinococcus multilocularis	Alveolar hydatid disease	Liver
Taenia multiceps, *Taenia* spp	Coenurosis	Brain, eyes
Spirometra species	Sparganosis	Subcutaneous tissue, viscera

TABLE 362-3 THERAPY FOR INTESTINAL TAPEWORM INFECTIONS

	PRAZIQUANTEL	NICLOSAMIDE	NITAZOXANIDE
Dosage			
Adults	5-10 mg/kg for all age groups (25 mg/kg for *Hymenolepis nana*)	2 g (4 tablets)	500 mg
Children >34 kg		1.5 g (3 tablets)	200 mg
Children 11-34 kg		1 g (2 tablets)	100 mg
Administration	Taken as a single dose	Taken as a single dose; tablets must be chewed and swallowed	Taken twice a day for 3 days
Side effects	Mild but frequent, including dizziness, myalgias, nausea, vomiting, diarrhea, abdominal pain	Nausea, vomiting, abdominal pain, diarrhea, drowsiness, dizziness, headache, pruritus	
Pregnancy		No known mutagenic effects; considered safe if indicated	

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most infections are asymptomatic. However, some children may be infected by hundreds or thousands of worms, which can cause abdominal pain, loose stools, diarrhea, and malabsorption. Diagnosis depends on observation of the characteristic eggs in stool. More than one specimen may be required.

TREATMENT AND PREVENTION Rx

Praziquantel (15 to 25 mg/kg as a single oral dose) is usually effective in treating *H. nana* infection, but it may need to be repeated in heavy infection (see Table 362-3). Nitazoxanide (100 mg by mouth twice daily for 3 days for children 1 to 3 years of age, 200 mg by mouth twice daily for 3 days for children 4 to 11 years of age, and 500 mg by mouth twice daily for 3 days for older children) is a reasonable alternative therapy; efficacy is about 75 to 82%. Niclosamide can be used as an alternative. Transmission is by the fecal-oral route and could be prevented by improved hygiene. Mass chemotherapy has been used to control infection in some populations.

Dipylidium caninum

Dipylidium caninum is a common tapeworm of dogs and cats. Dogs are infected by ingestion of fleas, which carry the cysticercoid form in their body cavities. The tapeworms can also develop in children who have ingested the fleas. It is widespread worldwide, but human infections are unusual.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Infection may be asymptomatic. In some cases, the motile proglottids may be noted in stool. The proglottids are similar in size and shape to rice grains. Diagnosis depends on identification of the ova in stool or identification of the proglottids.

TREATMENT AND PREVENTION Rx

There are no controlled trials of treatment for *Dipylidium* infection, but infection is likely to respond to regimens used for other tapeworms (see Table 362-3). The main measure for prevention is treatment of pets for fleas and tapeworms.

Taenia saginata

Taeniasis refers to infection with the tapeworm form of one of three *Taenia* species. *Taenia solium* and *Taenia asiatica* are acquired from ingestion of undercooked pork. *Taenia saginata*, called the beef tapeworm, is a common intestinal infection worldwide. Cattle are the intermediate hosts, harboring the tissue cysticerci in their muscle. Humans are the obligate definitive host, harboring the tapeworm form.

EPIDEMIOLOGY AND PATHOBIOLOGY

T. saginata is common worldwide in areas where cattle are raised and human fecal material contaminates the pastures. Approximately 45 to 60 million people are thought to be infected. It is found on most continents. Very high rates (>20% of the population) have been noted in east Africa, Bali, and Tibet. It is also endemic in the Middle East, the Americas, and Europe. *T. saginata* is also common in other parts of Asia, but many of the epidemiologic studies did not differentiate *T. saginata* from *T. asiatica*.

T. saginata tapeworms are acquired by ingestion of undercooked beef. The scolex attaches to the intestinal wall, and proglottids form at the base of the scolex. The proglottids gradually enlarge as they are displaced from the scolex by newer proglottids. The chain of proglottids can reach a length of up to 30 feet. The terminal proglottids are shed periodically in the stool. Terminal proglottids are typically off-white, 2 to 3 cm long, 0.5 to 1 cm wide, and 1 to 2 mm thick.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Mild symptoms (e.g., nausea, abdominal discomfort, anorexia, and pruritus) may be noted. The motile proglottids may cause discomfort as they exit the anus or may be noted in stool.

Ova may be noted in stool. The ova are 40 µm in diameter, surrounded by brown radial striations, and the embryos have six hooks. However, the ova of the three *Taenia* species are morphologically indistinguishable. The proglottids can be distinguished from those of *T. solium* by counting the number of uterine branches (≥14 branches suggests *T. saginata*). However, the proglottids of *T. saginata* cannot be readily distinguished from *T. asiatica*.

TREATMENT, PREVENTION, AND PROGNOSIS Rx

Taeniasis can be treated with praziquantel in a single dose (see Table 362-3). Single doses of niclosamide are also effective. Nitazoxanide has also been used for *T. saginata*. Taeniasis can be prevented by inspection of beef. Also, cooking to 56° C for 5 minutes or freezing at –20° C for 7 to 10 days destroys the infective larvae. Only minor symptoms are noted and are eventually self-limited with or without treatment.

Taenia asiatica

T. asiatica is a cause of taeniasis in Asia, termed *Asian taeniasis.* Infection is acquired by ingestion of undercooked pork. Pigs are infected by ingestion of the ova from tapeworm carriers. *T. asiatica* has been widely described in China, Taiwan, Korea, Indonesia, and Southeast Asia. The clinical manifestations, diagnosis, treatment, and prevention of *T. asiatica* infection are similar to those noted for *T. saginata* infection.

Taenia solium

T. solium, also known as the pork tapeworm, can cause both tapeworm infection and larval infection termed *cysticercosis. T. solium* tapeworm infections are caused by ingestion of infected undercooked pork. The scolex evaginates and attaches to the intestines, forming proglottids. The proglottids gradually mature as they are separated from the scolex by new proglottids. The adult worms are often 10 to 20 feet long. Within the mature proglottids, thousands of microscopic ova develop. The ova are either excreted into the stool or shed with the proglottids. By contrast, ingestion of the ova results in development of larval infection, termed cysticercosis (see later). Thus, the tapeworm carrier poses risk of self-infection as well as infection to other people.

EPIDEMIOLOGY AND PATHOBIOLOGY

T. solium is common worldwide in areas where pigs are raised and where pigs have access to human fecal material. Only a few million people are thought to harbor the tapeworm form. Pork tapeworm infection is highly endemic in Latin America, sub-Saharan Africa, south Asia, and Southeast Asia.

T. solium tapeworms are acquired by ingestion of undercooked pork. The scolex attaches to the intestinal wall and proglottids form at the base of the scolex. The proglottids gradually enlarge as they are displaced from the scolex by newer proglottids. The terminal proglottids are shed periodically in the stool. Terminal proglottids are typically off-white, 2 cm long, 0.5 to 1 cm wide, and 1 to 2 mm thick.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Mild symptoms (e.g., nausea, abdominal discomfort, anorexia, and pruritus) may be noted. The proglottids may be noted in stool. Diagnosis is made by the finding of ova in stool. The ova are 40 μm in diameter, surrounded by brown radial striations, and embryos have six hooks and are morphologically indistinguishable from the other *Taenia* species. The proglottids can be distinguished from those of *T. saginata* and *T. asiatica* by counting the number of uterine branches (<14 branches suggests *T. solium*).

TREATMENT AND PREVENTION Rx

Taeniasis can be treated with praziquantel in a single dose. Single doses of niclosamide are also effective. Taeniasis can be prevented by inspection of pork. Also, cooking to 56° C for 5 minutes or freezing at –20° C for 7 to 10 days destroys the infective larvae. Current control measures include mass chemotherapy for entire populations with praziquantel. Comprehensive control programs include mass chemotherapy to eliminate tapeworm carriers, treatment of porcine cysticercosis with drugs such as oxfendazole, and improved hygiene to limit access of pigs to human fecal material.

TISSUE CESTODE (CYST) INFECTION

Taenia solium (Cysticercosis)

DEFINITION

T. solium is the cause of human larval infection termed cysticercosis. The normal hosts for the larval (cysticercus) forms are pigs. When ingested by pigs, the ova hatch, releasing the invasive larvae (termed *oncospheres*), which invade the intestines, migrate to tissues (especially muscle), and mature into cysticercus forms within the tissues. The cysticercus consists of a thick translucent bladder containing an invaginated scolex, which is poised to form a tapeworm after being ingested by a human host. The ova are also infectious to people, including the tapeworm carrier. The sticky ova attach to the hands of the tapeworm carrier and are transmitted by the oral route to the carrier or close contacts. After ingestion, the ova can migrate to tissues and form cysts (cysticercosis). The presence of cysticerci in the central nervous system is termed *neurocysticercosis.* Neurocysticercosis includes cysticerci in the brain parenchyma (parenchymal neurocysticercosis) and cysticerci in the ventricles, subarachnoid space, spine, and eye (extraparenchymal neurocysticercosis).

EPIDEMIOLOGY

Cysticercosis is found in all regions of the world where pigs are raised with access to human fecal material. Some estimate that 60 million people are infected with *T. solium* cysticerci. However, exact data on incidence and prevalence are available from only a limited number of studies because of the requirement for neuroimaging studies to make a diagnosis. In the 19th century, infection was highly endemic in Europe. However, with improving standards of living, local transmission is now limited to a few rural areas in southern and eastern Europe. Cysticercosis is widespread in rural areas of Latin America. High prevalence rates have been documented in parts of Mexico, Guatemala, Honduras, Ecuador, Peru, Brazil, and Bolivia. In endemic villages, more than 10% of the population may have abnormalities on neuroimaging studies consistent with neurocysticercosis. Studies have highlighted the importance of cysticercosis in sub-Saharan Africa. Cysticercosis is widespread in India, Nepal, Southeast Asia, and parts of China. In India, neurocysticercosis most commonly presents with single enhancing lesions, which are the main lesion associated with seizure disorders in that country. In the United States, approximately 2000 cases are diagnosed each year. Most cases are in immigrants from pig-raising villages in Mexico and Latin America. However, there are also imported cases from Asia and a few locally acquired infections.

PATHOBIOLOGY

For cysticercosis, the pathogenesis and pathophysiology vary with the location of the cysticerci and the host inflammatory response. Cysticerci in the brain parenchyma initially suppress the host inflammatory response. After an incubation period, estimated to be several years, the cysticerci lose the ability to suppress the host inflammatory response, leading to parenchymal inflammation, which typically is manifested by seizures. The cysticerci induce a granulomatous response, which gradually degrades the parasites. In some cases, the lesions resolve. However, in others, degradation leads to formation of calcified granulomas. These calcified lesions intermittently become inflamed (as evidenced by edema or contrast enhancement on magnetic resonance imaging [MRI] scan) and may cause recurrent seizures during a period of years. In some cases, cysticerci develop within the ventricles of the brain and can mechanically cause obstructive hydrocephalus. Cysticerci in the subarachnoid space may cause a chronic arachnoiditis, which can be manifested by vasculitis and stroke, communicating hydrocephalus, basilar meningitis, and, in some cases, mass effect. Cysticerci can also develop in the spine (manifested as radiculitis), eye, subcutaneous tissue, and muscle.

CLINICAL MANIFESTATIONS

The clinical manifestations vary with the location of the cysticerci and the associated host response (Fig. 362-1). All forms of disease may be associated with headaches. In general, parenchymal cysticerci are associated with seizures, whereas ventricular and subarachnoid cysticercosis is associated with hydrocephalus.

SINGLE ENHANCING LESION. A single enhancing lesion is the most common manifestation of cysticercosis in India and the United States. Patients typically present with seizures, which can be focal or focal with secondary generalization. Many will have a single seizure or a few seizures during the period when the cysticercus is degenerating, but it is eventually self-limited in most cases. However, a few go on to develop calcified lesions, which are a risk factor for recurrent seizures.

MULTIPLE PARENCHYMAL CYSTICERCI. In patients with multiple lesions, the main presentation is with seizures, associated with parenchymal inflammation. In contrast to those with single lesions, seizures are more likely to recur.

CALCIFIED LESIONS. Many patients do not present until after they have calcified lesions. Patients with calcified lesions may develop recurrent seizures during a period of years.

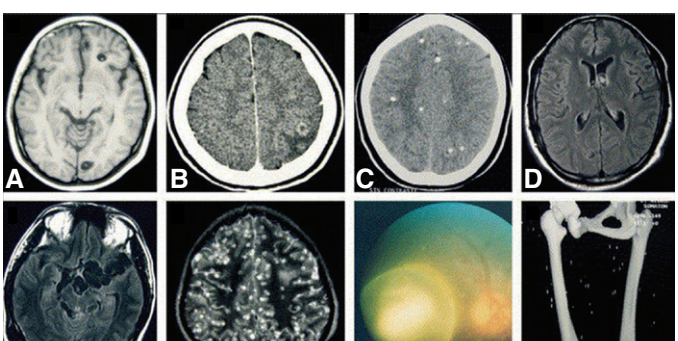

FIGURE 362-1. Human neurocysticercosis can be classified on the basis of neuroimaging studies. A, Multiple cystic lesions. **B,** Single enhancing lesion. **C,** Multiple calcifications. **D,** Intraventricular cysticerci. **E,** Subarachnoid cysticerci. **F,** Diffuse infection with cerebral edema, termed cysticercal encephalitis. **G,** Ocular cysticerci. **H,** Diffuse muscle calcifications. (Reprinted from Garcia HH, Del Brutto OH. Neurocysticercosis: updated concepts about an old disease. *Lancet Neurol.* 2005;4:653-661.)

VENTRICULAR CYSTICERCI. The cysticerci typically are manifested by obstructive hydrocephalus. The patient may present with headache, nausea and vomiting, dizziness, altered mental status, or papilledema with altered vision. This is a medical emergency and can be fatal if it is not treated.

SUBARACHNOID CYSTICERCI. Cysticerci in the basilar cisterns are often accompanied by cysticerci in other locations, including parenchymal cysticerci or calcifications, ventricular cysticerci, and spinal or ocular cysticerci; patients may present with disease attributable to cysticerci at these sites. Cysticerci in the basilar cisterns are particularly prone to cause arachnoiditis. Manifestations of arachnoiditis may include vascular involvement (large- or small-vessel strokes), meningeal signs, or communicating hydrocephalus (headaches, nausea, vomiting, dizziness, and altered mental status).

DIAGNOSIS

The major clinical manifestations of neurocysticercosis (e.g., seizures and hydrocephalus) are not specific, and it is difficult to identify the parasites. The main tools used to diagnose neurocysticercosis are neuroimaging studies. Computed tomography (CT) scans are sensitive for identification of parenchymal calcifications, which appear as 2- to 5-mm nodules. CT may also reveal parenchymal cysticerci or obstructive hydrocephalus. MRI scans are more sensitive for identification of the cysticerci, especially in the subarachnoid space and ventricles. The cysticerci are typically round, 1 to 2 cm in diameter. The cyst fluid is usually isodense with spinal fluid. In uninflamed cysticerci, the walls may not be visible. However, most cases demonstrate enhancement of the cyst walls or surrounding tissues and associated edema. In some cases, the scolex may be visible as a 1- to 2-mm solid nodule, cylinder, or spiral on the side of the cystic lesions. Serologic tests are useful to confirm the diagnosis. Assays using crude antigen, including enzyme-linked immunosorbent assay, are associated with poor sensitivity and specificity. An immunoblot assay using semipurified membrane glycoproteins is highly specific for the diagnosis. The sensitivity is excellent in cases with extraparenchymal or multiple parenchymal cysticerci. However, the sensitivity is poor in those with single enhancing lesions or just calcifications. Antigen detection assays are sensitive and more specific for viable cases but are currently unavailable in the United States.

TREATMENT Rx

Treatment varies with the clinical manifestations and form of infection. Seizures should be treated with antiepileptic drugs (Chapter 410). Phenytoin and carbamazepine are typically used and can control the seizures. Newer antiepileptic drugs may be more effective. There are no viable parasites in those with just calcified lesions, so the main measure is to control symptoms (e.g., antiepileptic drugs for those with seizures). In patients presenting with hydrocephalus, surgery to reestablish cerebrospinal fluid flow is the critical initial step in management. The role of antiparasitic drugs (Chapter 352) varies with the form of infection. Randomized controlled trials have demonstrated more rapid resolution of parenchymal cystic lesions with fewer generalized seizures in those treated with corticosteroids and albendazole (15 mg/kg/day in two daily doses) compared with those treated with placebo. Praziquantel (50 to 100 mg/kg/day in three daily doses) can be used as an alternative. A number of clinical trials in subjects with single enhancing lesions have demonstrated a slightly more rapid radiologic resolution and fewer seizures in those treated with steroids or antiparasitic drugs. However, the effects are not dramatically different from spontaneous resolution and were not significant in one meta-analysis. For patients with cysticerci in the ventricles, management usually involves removal of the cysticerci, which can be best achieved by neuroendoscopy. However, the main alternative approach is placement of a ventriculoperitoneal shunt. Chronic steroids or antiparasitic drugs may decrease the rate of shunt failure, which usually results from clogging of the shunts by the cysticerci or proteinaceous debris. There are no controlled trials on the management of cysticercosis in those with subarachnoid cysticercosis. However, expert opinion supports treatment of subarachnoid cysticercosis with prolonged courses of antiparasitic drugs (e.g., albendazole for >28 days) and chronic anti-inflammatory medications (e.g., prednisone, 1 mg/kg/day). Methotrexate can be used as a steroid-sparing agent. Patients with hydrocephalus should be treated by cerebrospinal fluid diversion (e.g., ventriculoperitoneal shunting). Before treatment with antiparasitic drugs, patients should undergo a funduscopic examination. Intraocular parasites may develop brisk inflammatory responses after treatment with antiparasitic drugs. Because this inflammation could lead to blindness, most authorities recommend extraction of the parasites before antiparasitic therapy. However, there are also reports of treatment of intraocular parasites with antiparasitic drugs.

PROGNOSIS

The prognosis varies significantly between the different forms of neurocysticercosis. Parenchymal enhancing lesions and parenchymal cystic lesions will eventually resolve, but this may take months to years. Patients who have or develop calcifications are at high risk for recurrent seizures lifelong. Patients with ventricular or subarachnoid disease are at high risk for morbidity and mortality. However, a recent case series noted no deaths with optimal management.

Cystic Hydatid Disease (*Echinococcus granulosus* group)

DEFINITION

Cystic echinococcosis (CE), also called cystic hydatidosis, is caused by the larval stage of cestodes of the *Echinococcus granulosus* group of parasites. All of these parasites were initially thought to be caused by a single species, *E. granulosus*. However, molecular studies demonstrate that *E. granulosus* comprises a number of different species and genotypes. In humans, the clinical manifestations range from asymptomatic infection to severe, potentially fatal disease.

Echinococcal cysts consist of a periparasitic host tissue (pericyst or adventitia), which encompasses the larval endocyst, and the endocyst itself. The endocyst has an outer, acellular laminated layer and an inner, or germinative, layer that gives rise to brood capsules and protoscolices. The cyst is filled with clear fluid, numerous brood capsules, and protoscolices. Some cysts may also harbor daughter cysts of variable size. The protoscolices convert to tapeworms in the canine definitive hosts but can also form new cysts when released in mammalian tissues.

EPIDEMIOLOGY

E. granulosus species occur on all continents and in circumpolar, temperate, subtropical, and tropical zones. The highest prevalence of the parasite is found in parts of Eurasia, Africa, Australia, and South America. Within the endemic zones, the prevalence of the parasites varies from sporadic to high, but only a few countries can be regarded as being free of *E. granulosus*.

It is difficult to determine the true incidence of CE because of the slow rate of growth and variable clinical presentation. Most epidemiologic reports are based on hospital- and surgery-based surveys that greatly underestimate the actual rates of infection, especially in low socioeconomic groups with limited access to diagnosis and treatment.

Since the mid-1980s, however, mass community-based surveys using portable ultrasound scanners have been conducted in many remote, rural areas of the world. The sensitivity and specificity of ultrasound have been shown to be superior to those of serology in prevalence surveys. These studies showed the real burden of disease, uncovering population infection rates of up to 6.6%.

E. granulosus exists as a complex of species and strains that differ in a variety of criteria that may have an impact on the epidemiology, pathology, and

control of CE. To date, 10 distinct genotypes (G1 to G10) have been identified. Some distinct species have been identified (*Echinococcus equinus*, *Echinococcus ortleppi*). The great majority of *E. granulosus* isolates from human patients thus far have been of the sheep genotype (G1).

CLINICAL MANIFESTATIONS

The presentation of human CE is protean. Patients seek medical attention when a large cyst has some mechanical effect on organ function or rupture of a cyst causes acute hypersensitivity reactions. The cyst is often diagnosed incidentally during ultrasound examination, chest radiography, or body scanning performed for other clinical reasons. The liver is the most frequent location of echinococcal cysts, representing approximately 70% of cases. The lungs are the second most common location. However, CE can occasionally occur in virtually any other organ.

Common symptoms are upper abdominal discomfort and pain, poor appetite, and a mass in the abdomen. Physical findings are hepatomegaly, a palpable mass on the surface of the liver or other organs, and abdominal distention. Other manifestations include jaundice, colic-like pains, portal hypertension, ascites, and compression of the inferior vena cava. If cysts in the lung rupture into the bronchi, symptoms may include intense cough, a salty taste in the mouth, or vomiting of hydatid material and cystic membranes. Patients may present with a chest mass, chest pain, chronic cough, pneumothorax, eosinophilic pneumonitis, pleural effusion, parasitic lung embolism, hemoptysis, or biliptysis. Cysts in the heart can cause a cardiac mass, pericardial effusion, and embolism. Cysts in the breast must be differentiated from neoplasms. Cysts located in the spine and in the brain can cause serious neurologic symptoms, including paralysis and seizures.

DIAGNOSIS

The diagnosis of CE is based on imaging methods and on serology, but serology has only a confirmatory role. Routine laboratory tests are nonspecific. Cyst rupture into the biliary tree may cause elevation of alkaline phosphatase, sometimes in association with hyperamylasemia and eosinophilia (up to 60%). Otherwise, eosinophilia is low grade or absent.

Imaging

Modern imaging tools (ultrasound, CT, and, to a lesser extent, MRI) are central to the diagnosis and clinical management of CE. Ultrasound is the procedure of choice for diagnosis of asymptomatic CE. Ultrasound is also useful for longitudinal studies, such as monitoring the response of cysts to treatment and recording cyst growth rate. In 2003, the World Health Organization (WHO) Informal Working Group on Echinococcosis proposed a standardized ultrasound classification (Fig. 362-2). This classification defines six cyst stages that are assigned to three clinical groups. The active group comprises developing cysts, which may be unilocular (CE1) or multivesicular with daughter cysts (class CE2) and are usually found to be viable. The transitional group (class CE3) contains cysts that are usually starting to degenerate. There are two types of CE3: the "water lily sign" for floating membranes, which is now known as subclass CE3a; and predominantly solid cysts with daughter cysts, or subclass CE3b. This subdivision is based on their different response to percutaneous treatment (see later) and albendazole, which is generally good for CE3a and poor for CE3b. A study using nuclear magnetic resonance spectroscopy has found that CE3a and CE3b may have different metabolic characteristics. The inactive group (classes CE4 and CE5) exhibits involution and signs of solidification of cyst content with increasing degrees of calcification and is nearly always found to be nonviable.

CT scanning has the advantage of inspecting any organ, detecting smaller cysts located outside the liver, locating cysts precisely, and sometimes differentiating parasitic from nonparasitic cysts. MRI may have some advantages over CT scanning in the evaluation of postsurgical residual lesions, recurrences, and selected extrahepatic infections, such as cardiac infections. Plain radiographs are used for cysts in the lungs, bone, and muscle and for detection of calcified cysts.

Serology

Serologic tests are useful for confirmation of presumptive imaging diagnoses. However, many tests are available, and they are not standardized. Their sensitivity varies with the location of the cysts. Hepatic cysts are more likely to elicit an immune response than are pulmonary, brain, or splenic cysts. Serologic test results are usually positive when the endocyst is detached (CE3a) and in active (CE2) and transitional (CE3b) stages. Serologic test results are generally negative in patients with inactive cysts (CE4 and CE5). Titers tend to slowly decrease when a cyst becomes inactive (CE4, CE5) and after radical surgery. Titers may remain positive after conservative surgery in which the antigen source (the germinal layer) is not completely removed. Antibody titers usually increase immediately after medical or percutaneous treatments because of the mobilization of the antigen following disruption of cyst integrity.

Other Diagnostic Procedures

Fine-needle aspiration biopsy of the cyst performed under ultrasonographic guidance, with a transhepatic approach, under anthelmintic coverage, is useful for differentiation of CE, malignant neoplasms, abscesses, and nonparasitic cysts. The procedure must be carried out in the presence of an anesthesiologist ready to manage the rare but possible anaphylactic reaction.

TREATMENT Rx

The appropriate treatment depends on factors of the individual patient, the characteristics of the cyst, the therapeutic resources available, and the physician's preference. There are few randomized clinical trials evaluating treatment options, so a low level of evidence supports one therapeutic modality over another.

Surgery

Surgery has long been the only option in the treatment of CE. However, in the past two decades, medical treatment, percutaneous procedures, and a

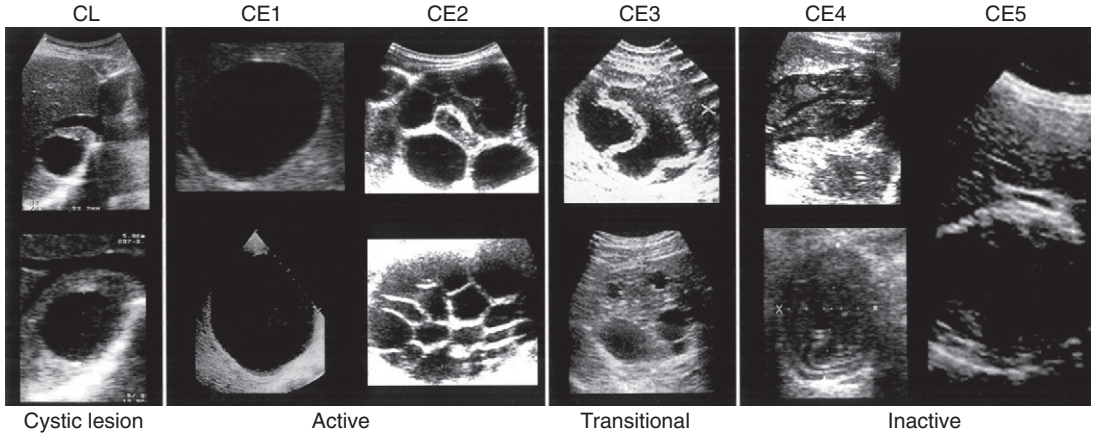

FIGURE 362-2. WHO Informal Working Group on Echinococcosis standardized ultrasound classification of cystic echinococcosis. CL lesions are cystic lesions lacking a distinct wall and may have other diagnoses. CE1 lesions are cystic lesions with a visible wall that may demonstrate protoscolices ("hydatid sand"). CE2 lesions include internal septation. CE3 lesions may be detached from the wall or have daughter cysts with internal thickening. CE4 lesions are heterogeneous lesions with degeneration. CE5 lesions show thick calcification.

"watch and wait" approach have been successfully introduced and replaced surgery as the treatment of choice in selected cases. Surgery remains the main therapy in complicated cysts (i.e., rupture, biliary fistula, compression of vital structures, superinfection, hemorrhage), cysts at high risk of rupture, or large cysts with many daughter vesicles that are not suitable for percutaneous treatments. Surgery can be performed as an open procedure, with either radical and conservative techniques, or laparoscopically, but there are controversies as to the safest and most effective technique and in which cases it should be applied. In all cases, perioperative albendazole prophylaxis, from 1 week before surgery until 4 weeks postoperatively, is recommended as a cautionary measure to minimize the risk of fluid spillage and consequent secondary echinococcosis from seeding of protoscolices in the abdominal cavity. Some authorities treat with praziquantel as well.

Percutaneous Treatments

Percutaneous techniques provide an alternative to surgery and benzimidazole derivatives. These treatment modalities aim either to destroy the germinal layer with scolicidal agents or to evacuate the entire endocyst. The most popular method aimed at destroying the germinal layer is PAIR (puncture, aspiration, injection of a scolicidal agent, and reaspiration). Many modified catheterization techniques are used to evacuate the endocyst and are generally reserved for cysts that are difficult to drain or tend to relapse after PAIR, such as multivesiculated cysts or cysts with predominantly solid content and daughter cysts. A growing number of articles have reported its safety in treating abdominal, especially liver, echinococcal cysts. More than 4000 cysts have been punctured, for either diagnostic or therapeutic purposes, and 16 cases of anaphylactic shock (two of them lethal) have been reported. Prophylactic administration of albendazole for at least 30 days after puncture is a cautionary measure that should always accompany PAIR. PAIR is generally successful at inducing permanent solidification in CE1 and CE3a cysts. A few reports with long-term follow-up indicate that multivesicular cysts (i.e., CE2 and CE3b) tend to relapse repeatedly after PAIR.

Chemotherapy

Albendazole (Chapter 352) is the antiparasitic drug of choice for CE. It is administered orally at a dosage of 10 to 15 mg/kg/day; administration should be continuous without treatment interruptions. However, the optimal dosage and optimal duration of treatment with albendazole have not been formally assessed, and data from the small clinical trials generally fail to take into account the cyst's characteristics. A recent systematic review on the effect of albendazole showed that the efficacy of the drug may have been overstated in previous retrospective, nonrandomized studies. Albendazole induces solidification in small and medium-sized CE1 and CE3a cysts, whereas it has generally little effect on giant (diameter > 10 cm) CE1 and CE3a cysts. It has no effect on most cases of CE2 and CE3b cysts.

Adverse effects of benzimidazoles (Chapter 352) include hepatotoxicity, leukopenia, thrombocytopenia, and alopecia. Increases in aminotransferases may be due to drug-related efficacy or real drug-related toxicity. Whereas teratogenic risks are theoretical, it is nonetheless good practice to avoid use during pregnancy when possible and to delay treatment until after delivery unless it is absolutely necessary.

Watch and Wait

Inactive liver cysts that are free of complications, such as compression on neighboring organs, are increasingly monitored without being treated. Prospective studies need to be carried out to confirm the safety of this option.

Follow-up

Follow-up is crucial to evaluate the efficacy of treatment. Long-term follow-up, generally more than 5 years, is required to evaluate local recurrences, which have been reported up to 10 years after apparently successful treatment. When the combination of imaging and serology is inconclusive, fine-needle aspiration should be performed to ascertain the viability of the cyst contents.

Alveolar Hydatid Disease (*Echinococcus multilocularis*)

Alveolar hydatid disease is caused by the tissue forms of *Echinococcus multilocularis*. In tissues, typically the liver, *E. multilocularis* grows as a budding mass rather than as a large cystic lesion. The tissues resemble lung tissues, hence the name "alveolar." The normal definitive hosts are canines, including wolves and foxes. The normal intermediate hosts are rodents. Humans are accidentally infected by contact with soil containing the ova.

EPIDEMIOLOGY

E. multilocularis is endemic in arctic and alpine areas of the Northern Hemisphere. It is highly endemic in western China, Tibet, and central Asia. In recent years, *E. multilocularis* has emerged as an important problem in Alpine areas of central Europe and adjacent forested areas.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Human *E. multilocularis* infection almost invariably involves the liver, in which it is manifested as a tumor-like mass that gradually expands during decades. The main symptoms are liver discomfort and swelling. Diagnosis is by demonstration of a characteristic mass on imaging studies, with the etiology confirmed by serologic tests.

TREATMENT

Rx

Surgery remains the mainstay of treatment of *E. multilocularis*. When feasible, all infected tissues should be removed. Apparently curative therapy should be followed by a 2-year course of albendazole to decrease the risk of relapse. In some cases, resection is feasible only when it is accompanied by liver transplantation. In cases that are not amenable to surgical resection, prolonged courses of albendazole can suppress growth of the lesion.

Other Larval Cestode Infections

Sparganosis is caused by infection with the larval (plerocercoid) stage of *Spirometra mansonoides*. Infection is acquired by ingestion or application of infected meat (frogs, birds, fish) or exposure of skin to infected flesh (e.g., poultices of infected tissues). After infection, plerocercoids develop in the tissues, typically presenting as subcutaneous or central nervous system nodules or occasionally larva migrans symptoms. Treatment usually involves removal of the nodule.

Coenurosis is a rare larval cestode infection caused by human infection with the larval stage of the dog tapeworms *Taenia multiceps* and *Taenia serialis*. In the tissue, the larva forms a cystic lesion containing multiple scolices (the coenurus). The cystic lesion is usually single and most frequently identified in brain, eye, or soft tissues. Treatment usually involves removal.

Echinococcus oligarthus and *Echinococcus vogeli* have been associated with polycystic hydatid disease in northern South America. *Taenia crassiceps* has been identified in the eye and in tissues of compromised hosts. *Hymenolepis*-like organisms have also been identified in tissues of AIDS patients.

363 SCHISTOSOMIASIS (BILHARZIASIS)

EDGAR M. CARVALHO AND ALDO A. M. LIMA

DEFINITION

Schistosomiasis is one of the most important parasitic diseases of humans and is a global public health problem in the developing world. The disease is caused by trematodes of the genus *Schistosoma,* and it is estimated that 300 million people are infected, another 600 million are at high risk for infection, and 20 million have debilitating disease. Mortality from schistosomiasis is estimated at 280,000 deaths per year and the burden of disease at 1.7 million disability-adjusted life years lost per year.

The Pathogen

Five major species of *Schistosoma* affect humans: *S. mansoni, S. haematobium, S. japonicum, S. intercalatum,* and *S. mekongi.* The sequencing of the *S. mansoni* genome was recently reported. Other *Schistosoma* species that occasionally infect humans include *S. bovis, S. mattheei,* and some avian schistosomes. These species differ biologically from one another and in their geographic distribution and the type of disease that they produce. The schistosomes are digenetic parasitic trematodes (Fig. 363-1). Although they are morphologically distinct, the species of *Schistosoma* that infect humans share some common factors. The large male (0.6 to 2.2 cm × 2 to 4 mm) has a ventral gynecophoric canal in which the female (1.2 to 2.6 cm × 1 to 2 mm) is held during copulation.

EPIDEMIOLOGY

Schistosomiasis occurs mainly in rural agricultural and periurban areas. *S. mansoni* is found in 55 countries, including the Arabian peninsula, Egypt, Libya, Sudan, most countries in sub-Saharan Africa, Brazil, Suriname, and Venezuela. *S. haematobium* is endemic in 53 countries in the Middle East and most of the African continent, including the island of Madagascar and Mauritius. *S. japonicum* is endemic in China, Indonesia, and the Philippines; it has also been reported from Thailand. *S. intercalatum* has been reported from 10 countries in Africa. *S. mekongi* is found in Cambodia and Laos.

The endemicity of schistosomiasis depends on the urban disposal of urine *(S. haematobium)* and feces *(S. mansoni, S. japonicum, S. intercalatum, S. mekongi),* the presence of suitable snail hosts, and human exposure to cercariae. The freshwater snail intermediate hosts are *Biomphalaria* spp in Africa and *Biomphalaria glabrata (Australorbis)* and *Tropicarbis* in South America and the West Indies. In some cases, the endemicity of schistosomiasis may be maintained by animal reservoirs. Such is the case with *S. japonicum,* which infects dogs and cows. Rodents, monkeys, and baboons have been found infected in nature, but the role of these animals as reservoirs does not seem to be epidemiologically important.

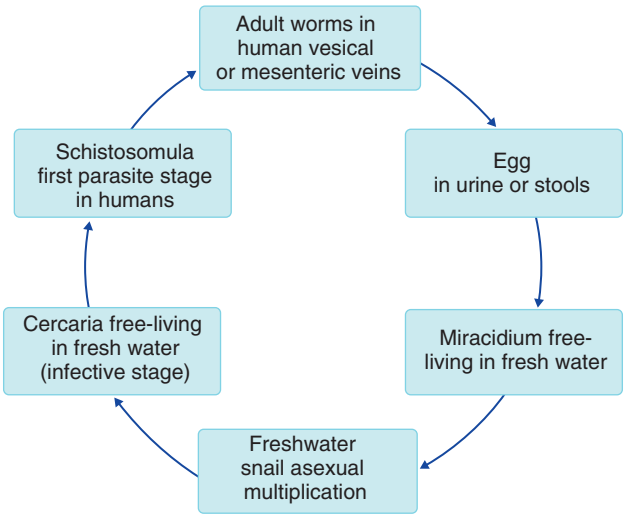

FIGURE 363-1. Schistosome life cycle.

Etiology and Life Cycle

Adult worms live in the mesenteric veins (*S. mansoni, S. japonicum, S. mekongi,* and *S. intercalatum*) or in the venous plexus around the lower ends of the ureters and the urinary bladder *(S. haematobium).* In these sites, they start their sexual reproduction by releasing eggs. Once deposited in the host, eggs may stay in the mesenteric vein, be trapped in the intestines, escape to the intestinal lumen, and migrate by portal blood to the liver *(S. mansoni, S. japonicum).* Eggs of *S. haematobium* may be trapped in the intestines and bladder and may escape to the intestinal or bladder lumen. After being excreted with feces or urine into fresh water, the eggs hatch and release ciliated motile miracidia that penetrate into the snail intermediate host. Following asexual multiplication in the snail, the development of cercariae, the infective forms for humans, takes 4 to 7 weeks. After leaving the snails, the cercariae can survive in fresh water for almost 72 hours. When penetration of the skin in the human host occurs, the cercariae lose their tails and change into schistosomula. Schistosomula migrate to the lungs and, in about 6 weeks, mature to adult worms and descend to their final habitat. Viable eggs can be seen in excretions (i.e., stool or urine) 5 to 9 weeks after cercarial penetration. The lifespan of the worms ranges from 5 to 10 years.

PATHOBIOLOGY

The pathogenesis of acute human schistosomiasis is mainly related to egg deposition and liberation of antigens of adult worms and eggs. A strong inflammatory response characterized by high levels of pro-inflammatory cytokines such as interleukin (IL)–1, IL-6, and tumor necrosis factor-α (TNF-α) and circulating immune complexes participate in the pathogenesis of the acute phase of the disease.

In chronic schistosomiasis, tissue injury is mediated by egg-induced granulomas and the subsequent appearance of fibrosis. Because the habitat of *S. mansoni, S. japonicum, S. mekongi,* and *S. intercalatum* worms is the mesenteric blood vessels, the intestines are involved primarily, and egg embolism results in secondary involvement of the liver. Host genetics, immunologic response, and parasite load measured by egg count in the stool are associated with a greater chance for hepatosplenic involvement. IL-4 and IL-13 have been associated with granuloma formation and liver fibrosis. Enzymes and antigens released from eggs sensitize host lymphocytes, which migrate to areas of egg deposition and recruit other cell types, such as macrophages, eosinophils, and fibroblasts. The size of these granulomas and the resulting fibrosis lead to most of the chronic fibro-obstructive lesions in schistosomiasis. In the liver, the granulomas result in perisinusoidal obstruction of portal blood flow, portal hypertension, splenomegaly, esophageal varices, and portosystemic collateral circulation. Liver cell perfusion is not reduced; consequently, liver function test results remain normal for a long time.

In schistosome-infected populations, the intensity of infection increases during the first 2 decades of life as children accumulate worms and then declines. The susceptibility of younger children to infection is even more evident when intensities of reinfection are studied after the elimination of existing worms by chemotherapy. Although there is a decrease in exposure with age, the lower intensities of infection in older individuals are due in part to acquired resistance. Both T_H1 (interferon-γ) and T_H2 types of immune response, mediated by IgE, may participate in resistance to reinfection. In the *S. haematobium*–infected population, IgE increases progressively with age, and IgE antibodies directed against adult worm antigens are associated with subsequent low intensities of reinfection. Similar associations between high IgE levels or a high IgE/IgG4 ratio and resistance to reinfection have been found among Brazilian and Kenyan subjects exposed to *S. mansoni.* Evidence that a T_H1-type immune response may also be involved in the protection against *S. mansoni* comes from immunologic studies in subjects who are highly exposed to contaminated water but have negative stool examination results. In these subjects, there is evidence of higher interferon-γ production in response to *S. mansoni* membrane extract. The existence of a major codominant gene, called *SM1,* that controls the intensity of infection by *S. mansoni* has been demonstrated. The localization of *SM1* on chromosome 5q31-q33, close to several genes involved in regulation of the immune response, including those for colony-stimulating factor-1 receptor, granulocyte-macrophage colony-stimulating factor, IL-3, IL-4, IL-5, IL-13, and immune regulatory factor-1 and a locus regulating IgE levels, indicates that genetic factors are probably critical to susceptibility and resistance to schistosome infection.

Because modulation of the immune response is a characteristic of chronic schistosomiasis, *S. mansoni* infection has modified the clinical course of autoimmune and inflammatory diseases in experimental models and in humans. *S. mansoni* infection attenuates the clinical manifestations of type 1 diabetes and experimental autoimmune encephalitis in mice. In humans, *S. mansoni* attenuates the clinical manifestations of asthma and is inversely associated with the development of myelopathy related to human T-cell leukemia virus type 1 (HTLV-1) infection. *S. mansoni* infection may impair immunologic response to vaccines and change manifestations of other infectious diseases.

CLINICAL MANIFESTATIONS

Clinical manifestations of schistosomiasis are divided into schistosome dermatitis, acute schistosomiasis, and chronic schistosomiasis. Schistosome dermatitis, or swimmer's itch, is seen mainly when avian cercariae penetrate the skin and are destroyed. It is uncommon, but recognition of this clinical entity is gradually expanding. Schistosome dermatitis is a sensitization phenomenon occurring in previously exposed persons. The cercariae evoke an acute inflammatory response with edema, early infiltration of neutrophils and lymphocytes, and later invasion of eosinophils. A pruritic papular rash occurs within 24 hours after the penetration of cercariae and reaches maximal intensity in 2 to 3 days.

Acute schistosomiasis occurs usually 20 to 50 days after primary exposure. Although asymptomatic in endemic areas, acute schistosomiasis is becoming a frequent and major clinical problem in nonimmune individuals from urban regions who are exposed for the first time to a heavy infection in an endemic area. The clinical syndrome (i.e., fever, chills, liver and spleen enlargement, and marked eosinophilia) originally described for *S. japonicum* infection, and still common for this species, is increasingly being diagnosed in Brazil in individuals with *S. mansoni* infection. Malaise, diarrhea, weight loss, cough, dyspnea, chest pain, restrictive respiratory insufficiency, and pericarditis are important findings in this phase. High levels of TNF-α and circulating immune complexes are found in the patient's serum in this phase of illness, and they correlate with the presence of abdominal pain, diarrhea, and weight loss and with respiratory and pericardial manifestations, respectively. Acute disease is not observed in individuals living in endemic areas of schistosomiasis because of the downmodulation of the immune response by antigens or idiotypes transferred from mother to child.

In chronic schistosomiasis, abdominal pain, irregular bowel movements, and blood in the stool are the main symptoms of intestinal involvement. Colonic polyposis may occur, especially in Egypt.

Hepatosplenic involvement is the most important cause of morbidity with *S. mansoni* and *S. japonicum* infection. Patients may remain asymptomatic until the manifestation of hepatic fibrosis and portal hypertension develops. Hepatic fibrosis is caused by a granulomatous reaction to *Schistosoma* eggs that have been carried to the liver. Hepatic fibrosis in *S. mansoni* infection has been associated with the intensity of infection and the patient's genetic background and immunologic response. Although the severity of infection is clearly linked with liver disease, the immune response, collagen deposition, and genetic factors potentiate disease in some individuals with only moderate infections or inhibit disease in others with heavy infections.

Hematemesis from bleeding esophageal or gastric varices may occur. In such cases, anemia and decreasing levels of serum albumin are observed. A few patients have severe hepatosplenic disease with decompensated liver disease. Jaundice, ascites, and liver failure are then observed. Concomitant infection by *Salmonella* species and, less extensively, other gram-negative bacteria with *S. mansoni* or *S. haematobium* leads to a picture of prolonged fever, hepatosplenomegaly, and mild leukocytosis with eosinophilia. Coinfection with *S. mansoni* and hepatitis C virus is associated with a greater chance of chronic hepatitis. Glomerulonephritis, infantilism, and hypersplenism are other complications associated with hepatosplenic schistosomiasis. The finding of pulmonary hypertension is increasing with the use of more advanced diagnostic technology. Pulmonary hypertension has been detected in 10.7% of patients with liver fibrosis. In countries endemic for *S. mansoni,* up to 30% of the cases of pulmonary hypertension are due to schistosomiasis. In hospitalized adult patients with *S. japonicum* infection, cerebral schistosomiasis occurs in 1.7 to 4.3%. It may occur as early as 6 weeks after infection, and the most common sign is focal jacksonian epilepsy. Signs and symptoms of generalized encephalitis may occasionally be found. In *S. mansoni* infection, neurologic involvement is rare and mainly characterized by transverse myelitis. An association between *S. mansoni* or *S. haematobium* and human immunodeficiency virus (HIV) infection has been documented in areas where both infectious agents are found. Although the immune response of patients with schistosomiasis is altered by HIV, it has not been reported to be associated with any clear changes in the degree of infection or severity of manifestations of schistosomiasis.

In *S. haematobium* infection, the main organ system involved is the urinary tract. The acute granulomatous response to parasite eggs in the early stages causes urinary tract disease, such as urethral ulceration and bladder polyposis. In chronic disease, usually in older patients, granulomas at the lower end of the ureters obstruct urinary flow and may cause hydroureter and hydronephrosis. Bladder fibrosis and calcification are also seen in this phase. Up to 70% of infected individuals have hematuria, dysuria, or urinary frequency. Urine examination reveals proteinuria and hematuria. Radiologic findings include hydronephrosis, hydroureter, ureteral strictures, dilation or distortion, ureteral calcifications, ureterolithiasis, calcified bladder, polyps, reduction in bladder capacity, irregular contraction of the bladder wall, and dilated bladder because of bladder neck fibrosis. An increased incidence of squamous cell carcinoma of the bladder (Chapter 203) has been reported in endemic areas of *S. haematobium* infection, but the mechanism of carcinogenesis is unknown. *S. haematobium* eggs have occasionally been found in the lungs, with subsequent focal pulmonary arteritis and pulmonary hypertension.

DIAGNOSIS

A definitive diagnosis of schistosomiasis can be made only by finding schistosome eggs in feces, urine, or a biopsy specimen, usually from the rectum (Table 363-1). A history of contact with contaminated water and appropriate clinical manifestations are important steps in establishing the diagnosis. Because schistosome eggs may be few, concentration by sedimentation should be performed. All eggs from feces, urine, or tissues should be examined under high power to determine their viability by visualizing the activity of cilia of the excretory flame cells of the enclosed miracidium. Dead eggs may persist for a long time after successful therapy or natural death of the

TABLE 363-1 DIAGNOSIS OF SCHISTOSOMIASIS

SCHISTOSOME	EGGS	DIAGNOSIS
S. haematobium	Mainly found in urine but may be found in stools or rectal biopsy specimens Eggs: 143 × 50 µm; spindle shaped: rounded anterior, conical posterior, tapering to a terminal delicate spine	Obtain urine sample at midday (when eggs are excreted); more than one sample may be needed Examine urine directly or by filtering 10 mL of urine through a Nuclepore membrane Rectal biopsy in suspected cases with normal urine Serologic testing to diagnose early or light infection
S. mansoni	Eggs: 155 × 66 µm; oval with lateral, long spine	Examine stool for eggs Use the Kato-Katz thick smear method for quantification purposes Rectal biopsy or serologic testing to diagnose stool-negative cases, particularly in lightly infected patients
S. japonicum	Found in stool; eggs: 89 × 67 µm; oval or rounded with a lateral, short, sometimes curved spine	Examine stool for eggs Kato-Katz thick smear (for quantitative assessment) Rectal biopsy for those with light infections, especially with less common manifestations (i.e., cerebral schistosomiasis)
S. mekongi	Found in stool; eggs: 60 × 32 µm; smaller than eggs of *S. japonicum*	Examine stool for eggs
S. intercalatum	Found in stool; eggs: 180 × 65 µm; terminal spine	Examine stool for eggs

worms. The presence of only dead eggs does not necessarily require treatment. Because the intensity of infection is associated with morbidity, quantitative techniques are recommended. For *S. mansoni* and *S. japonicum*, the Kato-Katz thick smear method is used. Rectal biopsy may be used for those with light infection. In patients with chronic *S. mansoni* and *S. japonicum* infection and liver disease, the diagnosis is sometimes made by documentation of eggs in liver specimens. Ultrasonography allows determination of the degree of liver fibrosis. *S. mekongi* and *S. intercalatum* infection is diagnosed by examination of the stool for eggs.

Urine examination for *S. haematobium* eggs can be performed by direct or concentration methods. Samples should be obtained at midday, when excretion of eggs is maximal. Rectal biopsy may be performed in patients with light infection and negative urine results. After *S. haematobium* infection is diagnosed, assessment of urinary tract disease by ultrasonography is recommended. Because of an increased incidence of carcinoma of the bladder, cancer surveillance should be performed in patients with *S. haematobium* infection (Chapter 203).

Several serologic tests for detection of IgM, IgG, and IgA antibodies to *Schistosoma* antigens are available. Serologic tests are important in the diagnosis of acute infection because the symptoms are not specific and the finding of eggs in stool may reflect chronic infection.

Quantification of circulating antigens in serum and urine is an alternative for the diagnosis of schistosome infection. However, the sensitivity of the method decreases in patients with light infection (<100 eggs per gram of feces). This test has also been used to monitor the efficacy of antischistosome chemotherapy. A significant decrease in antigen levels or negativity of the test is observed as early as 10 days after therapy.

TREATMENT

Rx

Chemotherapy is by far the major method for control and cure of schistosomiasis. Three compounds are in use—metrifonate, oxamniquine, and praziquantel—and all three are included in the World Health Organization's list of essential drugs. Praziquantel, a pyrazinoisoquinoline derivative, is the drug of choice for the treatment of schistosomiasis for four reasons: high efficacy against all schistosome species and against cestodes, lack of serious short-term and long-term side effects, administration as a single oral dose, and competitive cost.

The standard recommended treatment consists of a single dose of praziquantel, 40 mg/kg, for *S. mansoni, S. haematobium,* and *S. intercalatum* infection. In *S. japonicum* infection, a total dose of 60 mg/kg is recommended, split into two or three doses in a single day. Although no significant difference was found in the overall cure rates between single-dose (40 mg/kg) and double treatment (40 mg/kg with 2-week interval) regimens of praziquantel for *S. haematobium,* the effect of double treatment resulted in significant reduction in infection intensity and microhematuria, which may have an impact on reducing subtle morbidity.[1] *S. mekongi* may require two treatments at 60 mg/kg body weight. With these dosages of praziquantel, recorded cure rates are 75 to 85% for *S. haematobium,* 63 to 85% for *S. mansoni,* 80 to 90% for *S. japonicum,* 89% for *S. intercalatum,* and 60 to 80% for double infections with *S. mansoni* and *S. haematobium.* A decrease in the efficacy of praziquantel has been observed in patients coinfected with HTLV-1.

Praziquantel is well tolerated and effective in patients of all ages and for different clinical forms of schistosomiasis, including advanced hepatosplenic cases *(S. mansoni),* cerebral schistosomiasis *(S. japonicum),* and neurologic syndromes *(S. mansoni* and *S. haematobium),* possibly in association with corticosteroids. However, praziquantel has low prophylactic effect, which reduces its efficacy in areas of high transmission. There have been several reports of persistent schistosome egg shedding after treatment, thus posing concern about the emergence of drug resistance.

The effects of praziquantel on schistosomes can be summarized under three headings: muscle contraction, tegumental damage (i.e., vacuolization and blebbing), and metabolic alterations (i.e., decreased glucose uptake, lactate excretion, and glycogen content). Schistosome calcium ion channels are so far the only molecular targets of praziquantel action identified. The drug may also interfere with adenosine uptake, which is relevant because schistosomes are unable to synthesize purines de novo. Several drugs (e.g., phenytoin, rifampin, azole antifungals) decrease plasma concentrations of praziquantel because they inhibit cytochrome P-450 pathway 3A4. Chloroquine and cimetidine also decrease praziquantel bioavailability. Praziquantel's activity also depends on the patient's immune system. Several studies have reported that praziquantel induces the exposure of worm surface antigens that may function as targets for immune responses.

The most common side effects observed with praziquantel or oxamniquine are related to the gastrointestinal tract: abdominal pain or discomfort, nausea, vomiting, anorexia, and diarrhea. These symptoms can be observed in up to 50% of patients but are usually well tolerated. Other side effects are related to the central nervous system (e.g., headache, dizziness, drowsiness) and the skin (e.g., pruritus, eruptions) or may be nonspecific (e.g., fever, fatigue). In general, the cumulative experience from a large number of studies allows the conclusion that praziquantel is an extremely well tolerated drug that requires minimal medical supervision and is therefore particularly suitable for mass chemotherapy programs. Although a reduction in the intensity of infection and morbidity has been documented after mass chemotherapy, provision of clean water, use of molluscicides, and adequate sanitation should also be implemented to control the disease.

LIVER, INTESTINAL, AND LUNG FLUKE INFECTIONS

EDUARDO GOTUZZO

THE PATHOGENS

Flukes belong to the phylum Platyhelminthes and class Trematoda. The major flukes of medical importance are discussed in this chapter; they belong to the families Fasciolidae, Opisthorchiidae, Heterophyidae, Echinostomatidae, and Troglotrematidae. Approximately 135 million people worldwide are infected with these flukes. With the exception of schistosomes, all flat worms of clinical significance are hermaphroditic. Blood flukes, or schistosomes, are discussed in Chapter 363. The epidemiology, clinical manifestations, diagnosis, and treatment are summarized in Table 364-1.

Liver Flukes

FASCIOLIASIS

Fascioliasis is a zoonosis caused by *Fasciola hepatica* (adult: 30 by 13 mm) or *Fasciola gigantica* (adult: 75 by 20 mm). The most common natural hosts are sheep, cattle, and goats.

EPIDEMIOLOGY

The infection is distributed globally. The highlands of Peru, Bolivia, Ecuador, Egypt, and Vietnam are the most affected regions in the world. Prevalence

rates higher than 60% have been reported in Peru and Bolivia. Estimates of the number of people infected in some countries are 830,000 in Egypt, 742,000 in Peru, 360,000 in Bolivia, 37,000 in Yemen, 20,000 in Ecuador, and 10,000 in Iran. It has been estimated that between 2.4 and 17 million people are infected worldwide.

The life cycle begins when the parasite's eggs in stool are deposited in water; miracidia appear, develop, and hatch in 9 to 14 days and invade many species of freshwater snails (*Lymnaea* spp), in which they multiply as sporozoites, rediae, and cercariae during a period of 4 to 7 weeks. They then leave as free-swimming cercaria that subsequently attach to watercress, water lettuce, alfalfa, mint, parsley, or khat. The main source of infection is consumption of raw vegetables or water contaminated with metacercariae. Women have a higher incidence of the disease, with more severe infections and complications than seen in men.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

After consumption of contaminated vegetables, the larvae excyst in the duodenum and then migrate through the bowel wall to the liver through the peritoneal cavity. In 4 weeks, they reach the liver, penetrate Glisson's capsule, and cause inflammation and pain. During their migration through the liver, the ongoing inflammatory process is accompanied by intense hemorrhage manifested as subcapsular hematoma. Computed tomography (CT), magnetic resonance imaging, or ultrasonography can detect these initial lesions. Furthermore, migration of the parasite leaves a trail or track that can be observed in histologic sections or by imaging (CT). The flukes sometimes die and leave cavities filled with necrotic debris that are eventually replaced by scar tissue and then become calcified. After 3 to 5 months of migration along the liver, the juvenile larvae finally reach the bile ducts. During this invasive, migratory or acute phase the clinical manifestations are prolonged fever, hepatomegaly, abdominal pain, and eosinophilia. Multiple hypodense lesions are seen on CT, similar to metastases, but they change in position, attenuation, and shape in time because the parasites are still migrating. Acute fascioliasis is clinically similar to acute cholecystitis but with the addition of significant eosinophilia. It can occur in travelers with acute subcapsular hematoma or metastatic-like lesions seen on CT of the liver. Hyperbilirubinemia is notably absent in this phase. Other manifestations are anorexia, weight loss, nausea, vomiting, cough, diarrhea, urticaria, lymphadenopathy, and arthralgias. Occasionally, the juvenile larvae reach other ectopic or extrahepatic locations, such as subcutaneous tissue, the pancreas, the eye, the brain, and the stomach wall, among others. In endemic areas, the acute phase manifestation can be superimposed on chronic infection.

Arrival of the parasite in the bile ducts marks the beginning of the chronic phase. Mature flukes consume hepatocytes and duct epithelium and reside for years in the hepatic and common bile ducts and sometimes in the gallbladder. In this chronic phase, the liver contains large dilated, thick-walled, and calcareous bile ducts with yellowish brown bile. The bile ducts have a thickened hyperplastic wall with marked fibrosis. Symptoms usually reflect biliary obstruction with colicky pain in the right upper quadrant and epigastric area. Eosinophilia is absent in half of the chronic cases. Bacterial superinfection of these cysts and consequent cholangitis can develop. Other complications are hemobilia and liver fibrosis. Alkaline phosphatase is commonly elevated because of biliary obstruction, which sometimes requires surgical intervention. On imaging, the initial lesions may be strongly confused with hepatic metastases. Other findings on CT are hepatomegaly, tracklike hypodense lesions in subcapsular locations, multiple hypodense nodular areas (abscess-like lesions), or low-density, serpiginous, tortuous, tunnel-like branching lesions ranging from 2 to 10 mm. CT can also show subcapsular hematoma, enhancement of Glisson's capsule, necrotic granuloma, and cystic calcifications. After maturation, the adult flukes start laying eggs, which are passed from the sphincter of Oddi to the intestines and evacuated to the environment along with stool. Adult parasites can live in the bile ducts for many years, up to 13. In endemic populations, chronic infection has been reported as mildly symptomatic, whereas in travelers or temporary residents, it has been reported to cause biliary obstruction, with adult parasites being seen on endoscopic retrograde cholangiopancreatography (ERCP).

CLONORCHIASIS AND OPISTHORCHIASIS

Clonorchiasis is the disease caused by *Clonorchis sinensis*, also called the Chinese or oriental liver fluke (adult: 10 to 25 mm by 3 to 5 mm). Opisthorchiasis is caused by *Opisthorchis viverrini* (adult: 5 mm to 10 mm by 1 mm to 2 mm) and *Opisthorchis felineus* (adult: 7 to 12 mm by 2 to 3 mm). The most common natural hosts are dogs, cats, pigs, and some small wild mammals.

EPIDEMIOLOGY

The global estimate of the number of people infected is 46.2 million: 35 million with *C. sinensis* (15 million in China), 10 million with *O. viverrini* (8 million in Thailand and 2 million in the Lao People's Democratic Republic), and 1.2 million with *O. felineus*. There are 601 million and 79.8 million people

at risk for infection with *Clonorchis* and *Opisthorchis*, respectively. Both infections are endemic in the Far East, Southeast Asia, and Eastern Europe. *C. sinensis* is endemic in northeast China, southern Korea, Japan, Taiwan, northern Vietnam, and the far eastern part of Russia, whereas *O. viverrini* is endemic in Laos, Thailand, Vietnam, and Cambodia. *O. felineus* infection is prevalent in Russia, Ukraine, and Kazakhstan.

The life cycle starts when the adult worm deposits fully developed eggs, which are then passed to the environment through feces. They hatch in water and the miracidia infect their first intermediate host, a freshwater snail (*Bithynia* spp or *Parafossarulus* spp), where they transform into sporocysts, rediae, and cercariae. Cercariae are released from the snail and then penetrate freshwater fish, which are the second intermediate host (*Cyclocheilichthys* spp, *Puntius* spp, *Hampala dispa*); the cercariae encyst as metacercariae in the muscles or under the scales. In general, the infection is acquired by eating raw or uncooked cyprinoid fish products in rural areas or dishes such as koi-pla. The metacercariae pass through the stomach and reach the small intestine unharmed. Then, through the ampulla of Vater, they reach the bile ducts, where they mature into adult worms within 4 weeks and deposit yellow, operculated eggs. The parasites may live for up to 45 years in a human host.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Clonorchiasis as an acute infection caused by *C. sinensis* is usually asymptomatic, but some patients may have fever, rash, malaise, and right upper quadrant abdominal discomfort. Chronic infections may be manifested as recurrent pyogenic cholangitis, cholecystitis, obstructive jaundice, hepatomegaly, cholecystitis, multiple hepatic tumors, cholelithiasis, pancreatitis, and cholangiocarcinoma.

Opisthorchiasis as an acute infection caused by *O. viverrini* can cause right upper quadrant abdominal pain, flatulence, fatigue, and a hot sensation over the abdomen. In the chronic phase, mild hepatomegaly occurs, mainly in more heavily infected patients (egg counts >10,000 per gram). Jaundice and splenomegaly are not observed. Intrahepatic duct stones and recurrent suppurative cholangitis are common manifestations of opisthorchiasis. Whenever jaundice and ascending cholangitis are detected, fluke-related cholangiocarcinoma should be suspected.

In opisthorchiasis caused by *O. felineus*, infestation usually follows the consumption of raw, slightly salted, and frozen fish ("stroganina"), and acute symptoms occur 2 to 4 weeks later, including high-grade fever, nausea, vomiting, abdominal pain, malaise, arthralgias, lymphadenopathy, and rash. Peripheral eosinophilia is a common finding, especially during the initial 2 to 6 weeks of the infection, together with raised liver enzyme levels. In chronic infection, the eosinophilia is usually milder. Patients may have suppurative cholangitis and liver abscesses because of biliary obstruction. Ultrasonography or CT demonstrates the pathologic changes in the liver, including intrahepatic duct dilation and periductal changes.

The pathologic and clinical consequences of these flukes are related to the intensity and duration of cumulative infestations. In general, they cause inflammation around the biliary tree, severe hyperplasia of epithelial cells, metaplasia of mucin-producing cells in the mucosa, and progressive periductal fibrosis. There are clear associations between *O. viverrini* infection and cholangiocarcinoma. Several *N*-nitroso compounds and their precursors occur at low levels in fermented food, such as preserved mud fish paste (*pla ra*), a condiment that is a ubiquitous component of the cuisine of northeastern Thailand and Laos.

Intestinal Flukes

The most common human intestinal trematode is *Fasciolopsis buski* (adult: 20 to 75 mm by 8 to 20 mm). It is found mainly in the central and southeast parts of Asia. *F. buski* is a common parasite in pigs. Others are *Heterophyes heterophyes* (adult: 1 to 2 mm in length), *Metagonimus yokogawai* (adult: 1 to 2.5 mm by 0.4 to 0.75 mm), and *Echinostoma* species (adult: 6.5 by 1 to 2 mm).

EPIDEMIOLOGY

More than 50 species of intestinal trematodes from the Far East, Middle East, and North Africa have been reported to cause human infection. *H. heterophyes* can also be found in the Nile delta region of Egypt. An estimated 40 to 50 million people are infected with one or several species of intestinal flukes. Their life cycles are similar. The adult worm, attached to the intestinal wall of humans, produces eggs that are passed in feces. The eggs reach water, and miracidia develop and penetrate the first intermediate host—snails. During the course of 6 to 7 weeks inside the host snails, they develop into sporocysts, rediae, and cercariae. The cercariae leave the snails to encyst in the second intermediate host, which can be freshwater snails, fish, tadpoles, or vegetables. Humans are infected by the ingestion of raw stems, leaves (especially bamboo shoots), watercress, or water chestnuts with encysted metacercariae. In the human duodenum, the metacercariae attach to the walls and become adult worms in approximately 3 months.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Despite the fact the majority of intestinal fluke infections are asymptomatic, they may cause inflammation, ulceration, and mucus secretion at the site of attachment, particularly in the duodenum and jejunum. In fact, gastrointestinal hemorrhage, perforation, and abscesses have been observed. In heavy infection, intestinal obstruction, protein-losing enteropathy, malabsorption, impaired vitamin B_{12} absorption, hypoalbuminemia, and anasarca have been reported. The adult worm causes traumatic, toxic, and obstructive damage to the intestinal mucosa. Some cases have been diagnosed by direct visualization of the adult parasite via esophagogastroduodenoscopy.

Pulmonary Flukes

Paragonimiasis is a zoonosis caused by *Paragonimus* spp (adult size: 10 by 5 mm). Reservoir hosts include felids, canids, viverrids, mustelids, some rodents, and pigs. At least 10 species of *Paragonimus* are known to cause human disease; of these, *Paragonimus westermani* is the most common.

EPIDEMIOLOGY

An estimated 22 million people are infected worldwide with *Paragonimus* spp, and 293 million are at risk. Human paragonimiasis is distributed mainly in Southeast Asia, Japan, Korea, China, and the Philippines, where *P. westermani* is the main species. In other areas of low endemicity, other species have been reported, such as *Paragonimus mexicanus* in Latin America, *Paragonimus kellicotti* in North America, *Paragonimus heterotremus* in India, and *Paragonimus africanus* and *Paragonimus uterobilateralis* in West Africa. The life cycle starts when the eggs are excreted unembryonated in sputum, or alternatively they can be swallowed and passed in stool. In the external environment the eggs become embryonated, and miracidia hatch, seek the first intermediate host, a snail (families Pleuroceridae and Thiaridae), and penetrate its soft tissues. Within the snail, asexual reproduction occurs for several weeks with transformation into sporocysts, rediae, and cercariae; the last emerge from the snail and invade the second intermediate host, a crustacean such as a crab or crayfish, where they encyst and become metacercariae. This is the infective stage for the mammalian host. Human infection occurs by eating inadequately cooked or pickled crab or crayfish that harbor metacercariae of the parasite. The metacercariae excyst in the duodenum, penetrate the intestinal wall, and migrate through the peritoneal cavity toward the lungs. During migration through the peritoneum and diaphragm, the inflammatory process causes abdominal pain and dry cough. When invading the lungs, they become encapsulated and develop into adults. Infections may persist for 20 years in humans.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Paragonimiasis typically results from the consumption of raw or improperly cooked crustaceans, especially crabs. Recently, in the United States some autochthonous cases have been reported in the Midwest in people who consumed raw crayfish while camping during the summer. Most of the infected people are asymptomatic and have subclinical disease. During the first month of infection, abdominal pain may represent the juvenile larvae migrating through the abdominal cavity before reaching the lungs. Irritation of the diaphragm or pleura may cause dry cough. Fever, chest pain, fatigue, and urticaria may follow, as well as eosinophilia. Pleural effusions may be seen at this stage, with significant eosinophilia noted on analysis of pleural fluid, which can be the first clue to the diagnosis. In fact, pleural manifestations predominate early in the disease process, whereas lesions of the pulmonary parenchyma predominate later in the course of disease. Moreover, pneumothorax and mild eosinophilia may occur only 1 month after the initiation of infection. The migrating worms may cause bronchiectasis, interstitial pneumonitis, transient hemorrhage, or bronchopneumonia. Again, pulmonary lesions and eosinophilia raise the possibility of paragonimiasis. Cough and recurrent hemoptysis are common clinical findings in this phase. The chronic stage occurs when the worms are paired in a cyst in the pulmonary parenchyma. Eggs are produced 6 weeks after infection, and if there is communication with the bronchial tree, eggs may be seen in a sputum

sample under microscopy, or they can be swallowed and passed with stool. The rusty discoloration of sputum is caused by the presence of the tan- to brown-pigmented *Paragonimus* eggs; the sputa of these patients have been classically described as resembling "iron filings." Charcot-Leyden crystals can be seen.

Peripheral blood eosinophilia and elevated total serum IgE levels are observed in approximately 80% of patients. Common findings on CT are pleural effusion, hydropneumothorax, pulmonary nodules or consolidation of air spaces, and cysts. The most common ectopic form is cerebral paragonimiasis, which is manifested as eosinophilic meningitis or meningoencephalitis, brain tumor, or just residual calcifications from a past infection.

Management of Liver, Intestinal, and Lung Fluke Infections

DIAGNOSIS

In general, transmission of food-borne trematodiases is restricted geographically, and their distribution is one of the most important factors in suspecting this diagnosis. In the appropriate clinical setting, laboratory and imaging data can add information to narrow the differential diagnosis. Acute fluke infections require a high level of suspicion. Serologic tests, direct visualization of the migrating larvae, or empirical therapy with a significant clinical response (including reduction of eosinophilia) are major criteria to confirm the diagnosis. In the chronic phase, the diagnosis is usually made by visualization of the eggs in stool or, in the case of *Paragonimus*, in sputum. A sedimentation technique must be performed on a series of at least three stool specimens from alternate days or even weeks. Some of the sedimentation or concentration parasitologic techniques used for these infections include the Lumbreras rapid sedimentation technique, the Kato-Katz technique, and the ether-formalin concentration technique. Immunodiagnostics is an excellent tool, particularly for patients who do not have demonstrable eggs in clinical specimens.

If acute fascioliasis is strongly suspected, serology would be the next step. Cathepsin L1–based antibody enzyme-linked immunosorbent assay (ELISA) has a sensitivity of 92% and a specificity of 84%. If negative, the diagnosis is unlikely. If serology is not available, CT of the liver can visualize the characteristic tracklike lesions. However, because the parasitic lesions are very similar to metastases, liver biopsy may be necessary. If serology or CT is not available, a trial of triclabendazole with clinical (including eosinophilia) resolution is the major criterion for diagnosis. In chronic fascioliasis, the Lumbreras rapid sedimentation technique is the method of choice to detect the eggs in stool. At least three stool examinations are preferred. If negative, serology can be helpful. Ultrasonography and CT have low sensitivity in this phase. ERCP usually finds the adult parasites in the bile duct when performed for other reasons. Nonetheless, ERCP can be useful to eliminate the adult parasites causing biliary obstruction.

In opisthorchiasis, serology or stool examinations can be performed to approach the diagnosis. The Ov-CP-1–based ELISA has a sensitivity of 95% and a specificity of 96%. For *C. sinensis*, ELISA has a sensitivity between 81.3 and 96% and a specificity between 92.6 and 96.2%. For detection of eggs and to measure the intensity of infection, the Kato-Katz technique is preferred. Intestinal fluke eggs can be detected by performing a sedimentation stool technique, preferably in consecutive stool samples.

For paragonimiasis, an immunoblot assay performed with a crude antigen extract of *P. westermani* has been in use at the Centers for Disease Control and Prevention; the sensitivity of the test is 96%, and its specificity is 99%. This would be the ideal first step to confirm the diagnosis. In the acute phase, the precise location of the migrating larva is unknown and a biopsy may not necessarily target the parasite. When serology is negative (or not available), a trial of praziquantel or triclabendazole with a positive clinical response in 48 to 72 hours is a major criterion for diagnosis. In the chronic phase, several sputum samples have to be examined by a sedimentation technique to increase sensitivity. Stool examinations are complementary because the eggs can be swallowed by the host and then passed through stool. If a pulmonary cyst contains adult parasites with eggs but they do not have communication to the main bronchi, serology is indicated to confirm the diagnosis. If not available, biopsy is warranted.

Under the light microscope, the morphologic characteristics and size of the eggs may be sufficient to identify the specific fluke. For *Fasciola*, the egg is large, ellipsoid, and oval with an indistinct operculum and thin shell. The *F. hepatica* egg measures 120 to 150 µm by 63 to 90 µm, the *F. gigantica* egg measures 160 to 190 µm by 70 to 90 µm, and the *F. buski* egg measures 130 to 159 µm by 78 to 98 µm. *Opisthorchis* eggs are elongated with an operculum on the anterior end and a pointed terminal "knob" on the posterior end (26 to 30 µm by 11 to 15 µm). *C. sinensis* eggs (27 to 35 µm by 11 to 20 µm) are small, ovoid, or elongated with broad rounded posterior ends, a convex operculum resting on "shoulders," and a small "knob" on the posterior ends. *H. heterophyes* and *M. yokogawai* eggs are similar in size, 26 to 30 µm by 15 to 17 µm. *Echinostoma* eggs are brownish and operculated and measure 83 to 116 µm by 58 to 69 µm. *Paragonimus* eggs measure 68 to 118 µm by 39 to 67 µm, are reddish brown and ovoid or elongated, and have a thick shell; the operculum is slightly flattened and fits into the shoulder area of the shell, and the posterior end is thickened. The egg is often asymmetrical, with one side slightly flattened.

TREATMENT

Rx

The general principles and details of antiparasitic therapy are provided in Chapter 352. For fascioliasis, 10 mg/kg of triclabendazole once or twice has a cure rate higher than 90%, and it is the treatment of choice.■ Cure is achieved if stool examinations remain negative for at least 3 months. Serology can usually take more than a year to resolve. In treatment of the chronic phase, the dead parasites can occasionally cause biliary obstruction, which may need surgical consultation. For *O. viverrini*, a single dose of praziquantel (40 to 50 mg/kg) has a cure rate of 91 to 97%. For clonorchiasis, the recommended dose of praziquantel is 25 mg/kg three times for 1 day (total dose of 75 mg/kg), which has a cure rate of 83 to 85%. For intestinal flukes, praziquantel, 25 mg/kg by mouth three times a day for 1 day, is recommended. For paragonimiasis, praziquantel, 25 mg/kg by mouth three times a day for 3 days, or triclabendazole, 10 mg/kg by mouth once or twice, is highly effective.■ For ectopic cases, surgery may be necessary. In follow-up, negative stool examinations in the ensuing weeks can confirm cure. However, because the rate of reinfection is high in subjects from endemic areas, a suddenly positive stool examination is highly suggestive of a new infection rather than failure to respond to treatment.

PREVENTION

Prevention of infection with these flukes depends on several factors, including recognizing their geographic distribution and avoiding the consumption of raw vegetables, fish, crayfish, or contaminated water in endemic areas. Proper medical advice must be given to individuals traveling or planning to reside in endemic areas, not only to prevent fluke infection but also to inform them about the risk for coinfection with other parasites. Control of these flukes in animals is impractical because of wild animal reservoirs. However, control of human infections is challenging because it involves changing long-established cultural, dietary, and sanitary habits. Massive chemotherapy in highly endemic populations may reduce the infection in humans and in selected animals.

INTESTINAL NEMATODE INFECTIONS

DAVID J. DIEMERT

DEFINITION

Nematodes are nonsegmented roundworms that belong to the phylum Nematoda. Most species are free-living in soil or water but a few parasitize humans. These infections are some of the most prevalent and affect millions worldwide. Nematodes are complex multicellular organisms with specialized organs that include a protective outer coating or cuticle, a complete and functional gastrointestinal tract, and muscular, nervous, and reproductive systems.

Nematodes of medical importance can be divided into those that primarily affect the gastrointestinal tract, where adult worms become established and cause disease, and those that affect other tissues and organ systems. The former group is covered in this chapter and includes the roundworm *Ascaris lumbricoides*, the hookworms (*Ancylostoma duodenale*, *Necator americanus*), the pinworm *Enterobius vermicularis*, the whipworm *Trichuris trichiura*, and the threadworm *Strongyloides stercoralis*. Zoonotic intestinal nematodes such as *Trichostrongylus* and *Anisakis* also occasionally infect and cause disease in the gastrointestinal tract of humans. Nematodes that invade and cause disease primarily in tissues outside the gastrointestinal tract include those that cause lymphatic filariasis (*Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*), *Onchocerca volvulus*, *Loa loa*, the guinea worm *Dracunculus medinensis*, *Trichinella spiralis*, and *Angiostrongylus* species.

Nematodes that infect humans vary from several millimeters to more than a meter in length and can often survive for months to years within their host. With the exception of *S. stercoralis* and *Capillaria philippinensis*, adult worms cannot replicate within the host. Instead, eggs or larvae are produced after the mating of sexually mature adult worms.

Nematode infections are rarely acutely fatal; they more commonly result in chronic morbidity such as iron deficiency anemia caused by hookworm infection or elephantiasis caused by lymphatic filariasis. For most nematodes, the severity of the clinical manifestations of infection are proportional to the worm burden in a given host; although light infections with only a few worms are usually asymptomatic, pathologic features appear with heavier worm burdens.

Nematode infections are highly prevalent in the temperate and tropical regions of Africa, Asia, and Latin America. They are transmitted by the oral ingestion of embryonated eggs or by penetration of infective larvae through the skin, either by direct contact with contaminated soil or by blood-feeding arthropod vectors. The prevalence of nematode infections is highest in areas with poor sanitation, where the environment is contaminated by human waste, or in climates that are conducive to survival of the insect vector.

In communities located in endemic areas, the distribution of infections is overdispersed such that most individuals harbor low numbers of worms whereas a minority have relatively high worm burdens and contribute disproportionally to both transmission and morbidity.

ASCARIASIS

The Pathogen

A. lumbricoides, also known as roundworm, is acquired by the oral ingestion of embryonated eggs. After the egg's protective outer shell is dissolved by gastric acid, larvae are released into the small intestine, where they penetrate the intestinal wall; migrate to the liver and then the pulmonary vasculature, where they break into the alveolar spaces; and ascend the bronchial tree and are swallowed to re-enter the small intestine, where they develop into adult, egg-laying worms (if female) approximately 9 to 11 weeks after egg ingestion. Adult worms (Fig. 365-1) are the largest intestinal nematodes and range in length between 15 and 50 cm and can survive in the host for approximately 18 months. A female adult *Ascaris* worm produces approximately 240,000 eggs per day, which are passed in feces. Fertilized unembryonated eggs require warm, moist, shady soil for embryonation to occur, after which they become infective (Fig. 365-2). Eggs in the environment are extremely hardy and resistant to extreme temperatures and desiccation.

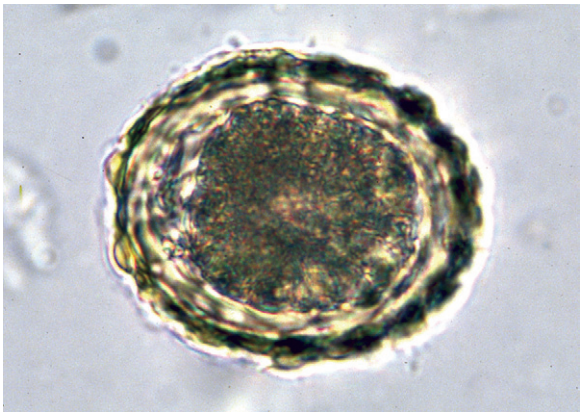

FIGURE 365-2. Fertilized, unembryonated egg of *Ascaris lumbricoides*. (Reproduced with permission from Dickson Despommier.)

EPIDEMIOLOGY

A. lumbricoides is the most prevalent nematode infection worldwide, with approximately a billion people chronically infected. Infection is common in sub-Saharan Africa, south and Southeast Asia, and Latin America, especially in rural areas of high population density with inadequate sanitation or treatment of sewage and where untreated human feces are used as fertilizer. Climate is also an important determinant of disease in that warm temperature and adequate moisture are required for embryonation of eggs in the soil. In endemic areas, the prevalence and intensity of infection with *A. lumbricoides* increase dramatically during the first 2 to 3 years of life; it remains high between the ages of 4 and 15 years and then declines during adulthood.

CLINICAL MANIFESTATIONS

Infection with *A. lumbricoides* is most commonly asymptomatic. Clinical manifestations are usually associated with heavy worm burdens and can be classified into those associated with larval migration through the lungs and into acute and chronic manifestations resulting from parasitism of the gastrointestinal tract by adult worms.

When migrating through the lungs, *Ascaris* larvae can induce an intense reaction that is due to both the physical disruption that their migration causes and the dramatic inflammatory hypersensitivity response to secreted antigens. This phenomenon is more common in areas in which transmission is seasonal, such as on the Arabian peninsula, where outbreaks of pneumonitis typically follow the rainy season because of resumption of transmission. Symptoms may last for 2 to 3 weeks and include a sudden onset of wheezing, dyspnea, paroxysmal nonproductive cough, and high fever. Respiratory symptoms may coincide with or be preceded by urticarial rash, angioedema, abdominal pain, and vomiting. These symptoms are usually self-limited and resolve spontaneously.

With moderate or heavy infestations, intestinal signs and symptoms can result from obstruction caused by a mass of worms in the small intestine or migration of worms to unusual sites such as the biliary tree, pancreatic duct,

or appendix. Intestinal obstruction is more common in young children because of their smaller lumen size and is characterized by colicky abdominal pain and vomiting that may progress to signs of perforation. Hepatobiliary and pancreatic ascariasis is more common in adults, presumably because their biliary tree is large enough to accommodate a migrating worm. Chronic intestinal infection can also have more insidious effects, especially in children, including decreased protein and fat absorption, deficiencies of vitamin A and C, and lactose intolerance, which in turn lead to stunted growth and impaired cognitive development.

DIAGNOSIS

The diagnosis of ascariasis is usually made by microscopic examination of a sample of feces for characteristic thick-shelled *A. lumbricoides* eggs. Pulmonary ascariasis cannot be diagnosed on the basis of identification of ova in feces because adult worms have not yet matured and begun producing eggs; instead, larvae, as well as eosinophils or Charcot-Leyden crystals (formed from the breakdown of eosinophils), may be visualized on microscopic examination of sputum. Pulmonary disease is also usually marked by peripheral eosinophilia and transient infiltrates on chest radiographs. The diagnosis of intestinal or biliary obstruction caused by *A. lumbricoides* relies increasingly on radiologic evaluation with ultrasound or endoscopic retrograde cholangiopancreatography (ERCP).

TREATMENT Rx

Intestinal ascariasis is usually treated with a single oral dose of albendazole (Table 365-1). Alternatives include mebendazole or pyrantel pamoate. No specific treatment is recommended for pulmonary ascariasis because the condition is self-limited. In severe cases of biliary obstruction, such as those with cholangitis, ERCP with or without resection of the ampulla of Vater has proved highly successful and may reduce the need for surgical intervention.

PREVENTION

The major means of preventing *Ascaris* infection is improvement of hygiene and proper disposal of human waste. In endemic communities where this is not feasible, control efforts center on regular (at least annual) mass administration of an anthelmintic medication such as albendazole or mebendazole.

HOOKWORM

The Pathogen

Hookworm infection in humans is due almost exclusively to two species: *N. americanus* and *A. duodenale*. Humans may also be incidentally infected by the zoonotic hookworms *Ancylostoma caninum*, *Ancylostoma braziliensis*, *Bunostomum phlebotomum*, and *Uncinaria stenocephala*, which can cause self-limited dermatologic lesions in the form of cutaneous larva migrans (Fig. 365-3). Additionally, *Ancylostoma ceylanicum*, normally a hookworm infecting cats, has been reported to cause intestinal hookworm disease in humans, especially in Asia, whereas *A. caninum* has been implicated as a cause of eosinophilic enteritis in Australia.

Infection occurs when exposed skin comes in contact with infective filariform larvae in contaminated soil or grass. Larvae are able to penetrate the skin, enter the afferent circulation, and migrate to the pulmonary vasculature, where they break into the alveolar spaces, ascend the bronchial tree to the trachea, and are swallowed into the gastrointestinal tract. Larvae undergo two molts to mature into adult worms approximately 5 to 9 weeks after skin penetration. Adult hookworms reside in the lumen of the upper part of the small intestine, where they attach to the mucosa by means of cutting teeth in the case of *A. duodenale* or a rounded cutting plate in the case of *N. americanus*. After mating in the host intestinal tract, each female adult worm produces thousands of eggs per day, which then exit the body in feces; *A. duodenale* female worms lay approximately 28,000 eggs daily, whereas the output from *N. americanus* worms is considerably less, averaging around 10,000 a day. Hookworm eggs hatch in warm, moist soil and give rise to larvae that can infect another host. Humans are the only major definitive host for these two parasites, and there are no intermediate or reservoir hosts. *A. duodenale* survives on average for 1 year in the human intestine, whereas *N. americanus* generally lives for 3 to 5 years.

EPIDEMIOLOGY

More than 500 million people are infected with hookworms worldwide. *N. americanus* is the most widespread hookworm globally, whereas *A. duodenale* is more geographically restricted in distribution. The highest prevalence of infection occurs in rural areas of tropical and less developed countries, where environmental and socioeconomic conditions favor transmission. Climate is an important determinant of hookworm transmission, with adequate moisture and warm temperature being essential for larval development in soil. An equally important determinant of infection is poverty and inadequate sanitation and supply of clean water. In endemic areas, prevalence increases with age in young children and reaches a plateau by around 10 years of age, whereas the intensity of infection rises at a slower rate during childhood, reaches a plateau by around 20 years, and then increases again in the elderly. Whether such age dependency reflects differences in exposure, acquired immunity, or a combination of both is controversial.

Although cutaneous larva migrans is found throughout the tropics, in the United States it is diagnosed primarily in tourists who have recently returned from a vacation to a tropical beach destination, especially in the Caribbean, Brazil, Mexico, and Southeast Asia. Occasionally, autochthonous cases (originating where found) have been reported in the United States, usually from southeastern coastal states such as Florida and South Carolina. Most commonly, cutaneous larva migrans occurs when exposed skin comes in contact

TABLE 365-1 TREATMENT OF INTESTINAL NEMATODES

NEMATODE	TREATMENT
Ascaris lumbricoides	Albendazole, 400 mg once. Alternative: mebendazole, 100 mg bid for 3 days
Hookworm	Albendazole, 400 mg once. Alternatives: mebendazole, 500 mg once or 100 mg bid for 3 days, or pyrantel pamoate, 11 mg/kg for 3 days with the maximum daily dose not to exceed 1 g
Trichuris trichiura	Mebendazole, 100 mg bid, or albendazole, 400 mg daily, for 3 days
Enterobius vermicularis	Pyrantel pamoate, 11 mg/kg once, with a second dose 2 wk later; maximum dose of 1 g. Alternatives: mebendazole, 100 mg once, or albendazole, 400 mg once, repeated in 2 wk
Strongyloides stercoralis	Uncomplicated infection: ivermectin, 200 μg/kg daily for 2 days.* Alternative: albendazole, 400 mg daily for 7 days
Trichostrongylus spp	Pyrantel pamoate, 11 mg/kg once; maximum dose of 1 g. Alternatives: albendazole, 400 mg once, or mebendazole, 100 mg bid for 3 days
Capillaria philippinensis	Albendazole, 400 mg daily for 10 days. Alternative: mebendazole, 200 mg bid for 20 days

*Treatment may need to be extended in immunocompromised patients with disseminated disease.

FIGURE 365-3. Typical lesion of cutaneous larva migrans. An erythematous, serpiginous track caused by intradermal migration of a dog (*Ancylostoma caninum*) or cat (*Ancylostoma braziliense*) hookworm larva is apparent. (Reproduced with permission from Gregory L. Zalar.)

with the larval stages of the dog or cat hookworm *A. caninum* or *A. braziliense*, respectively, present in moist soil or sand (especially on beaches) contaminated with animal feces. Other animal hookworms such as *U. stenocephala* and *B. phlebotomum* are less common causes.

PATHOBIOLOGY

The major pathology of hookworm infection is due to the associated gastrointestinal blood loss and the resulting iron deficiency anemia. Hookworms attach to the intestinal mucosa and secrete enzymes that enable them to invade submucosal tissues and ingest villous tissue and blood. Hemoglobinases within the hookworm's digestive canal enable degradation of human hemoglobin for use as an essential nutrient source. The amount of blood loss is directly related to the total worm burden. *A. duodenale* causes more blood loss than *N. americanus* does, with each *N. americanus* worm producing a daily blood loss of 0.03 to 0.1 mL and the corresponding figure for *A. duodenale* being between 0.15 and 0.26 mL.

CLINICAL MANIFESTATIONS

The clinical features of hookworm infection can be separated into acute manifestations associated with larval migration through the skin and other tissues and acute and chronic manifestations resulting from parasitism of the gastrointestinal tract by adult worms. Repeated exposure to hookworm larvae can result in a hypersensitivity reaction known as "ground itch," a pruritic local erythematous and papular rash that appears most commonly on the hands and feet. In contrast, when zoonotic hookworm larvae penetrate the skin to produce cutaneous larva migrans, most commonly on the feet, thighs, and buttocks, they are unable to complete their life cycle in the human host and eventually die after causing a typical clinical syndrome of intensely pruritic erythematous linear tracks with a serpiginous appearance (see Fig. 365-3). Tracks appear after an incubation period of a few days, can be single or multiple, and advance by millimeters to a few centimeters each day. Vesiculobullous or papular lesions may develop along the tracks, as can secondary bacterial infection as a result of scratching. Lesions usually heal spontaneously within weeks to months after the larvae die in the skin.

Migration of hookworm larvae through the lungs may induce mild and transient pulmonary symptoms consisting of a dry cough, sore throat, wheezing, and low-grade fever. Acute symptomatic disease may also result from the oral ingestion of *A. duodenale* larvae, referred to as the Wakana syndrome, which is characterized by nausea, vomiting, pharyngeal irritation, cough, dyspnea, and hoarseness.

Abdominal symptoms and signs caused by hookworm infection are rare. Instead, the manifestations of hookworm disease occur when blood loss via infection exceeds the nutritional reserves of the host and results in iron deficiency anemia. Usually only moderate- and high-intensity (≥2000 eggs per gram of feces) hookworm infections in the gastrointestinal tract produce clinical manifestations, which resemble those of iron deficiency anemia secondary to other causes (Chapter 162). In addition, the protein losses associated with heavy hookworm infection can result in hypoproteinemia and anasarca. The anemia and protein malnutrition that result from chronic intestinal parasitism cause long-term impairments in childhood physical, intellectual, and cognitive development. As iron deficiency anemia develops and worsens, an infected individual may have weakness, palpitations, fainting, dizziness, dyspnea, mental apathy, and headache. Uncommonly, there may be constipation or diarrhea with occult blood in the stool or frank melena, especially in children; there may also be an urge to eat soil (pica). Overwhelming hookworm infection may cause listlessness, coma, and even death, especially in infants. Because children and women of reproductive age have reduced iron reserves, they are at particular risk with hookworm disease. The severe iron deficiency anemia that may arise from hookworm disease during pregnancy can result in adverse consequences for the mother, her unborn fetus, and the neonate.

DIAGNOSIS

The diagnosis of hookworm infection is made primarily by microscopic identification of characteristic eggs in the stool. The eggs of *N. americanus* and *A. duodenale* cannot be distinguished because both are colorless and have a single thin hyaline shell with blunted ends; they range in size from 55 to 75 µm by 36 to 40 µm. Egg concentration techniques, such as the formalin–ethyl acetate sedimentation method, can be used to detect even light infections, although a direct wet mount examination is adequate for detecting moderate to heavy infections. In addition, eosinophilia is a common finding with persistent infection and also during larval migration through the lungs.

TREATMENT Rx

A single oral dose of albendazole, 400 mg, is the recommended treatment of intestinal hookworm infection (see Table 365-1).[1] Alternatives include mebendazole and pyrantel pamoate. For cutaneous larva migrans, although the disease is self-limited and will resolve spontaneously within weeks to a few months, treatment with a single dose of ivermectin will lead to rapid resolution of the symptoms and skin manifestations. Albendazole is an alternative treatment of cutaneous larva migrans.

PREVENTION

The ideal method for preventing hookworm infection is improvement in hygiene and proper disposal of human waste. In endemic communities where this is not feasible, control of disease centers on the regular (at least annual) mass administration of an anthelmintic medication such as albendazole or mebendazole. For cutaneous larva migrans, tourists should be advised to wear shoes or sandals when walking to and on beaches and to avoid beaches frequented by stray cats and dogs.

TRICHURIASIS

The Pathogen

Infection with *T. trichiura*, also known as whipworm, does not have a tissue migratory phase like *A. lumbricoides* and hookworm, and its entire life cycle in the host is limited to the gastrointestinal tract. After embryonated eggs are ingested orally, larvae are released into the small intestine where they undergo a series of molts before being carried passively to the transverse and descending colon. The narrow anterior end of adult worms embeds in the columnar epithelium, with the posterior portion protruding into the lumen, thereby allowing eggs to be released into feces, which are then passed into the environment where they must embryonate in warm, moist soil to complete the life cycle. Adult worms can measure up to 50 mm in length and can survive in the host for approximately 1.5 to 2 years. The period between ingestion of eggs and detection of eggs in feces is about 90 days.

EPIDEMIOLOGY

Like the other soil-transmitted helminths, trichuriasis is most common in poor, mostly rural areas of the tropics and subtropics where disposal of human waste is inadequate. The estimated prevalence worldwide is 800 million. Children are more frequently infected than adults and more likely to have higher worm burdens. Humans are the only host for this parasite.

CLINICAL MANIFESTATIONS

The majority of *T. trichiura* infections are asymptomatic. Most disease is seen in children because the majority of heavy infections (>10,000 eggs per gram of feces) occur in this age group. Heavy infections can be accompanied by acute dysentery or chronic colitis resembling inflammatory bowel disease and result in abdominal pain and diarrhea. The chronic mucosal inflammation and edema of the colon and rectum can lead to protracted tenesmus and resulting rectal prolapse. Chronic *Trichuris* colitis can also lead to malnutrition, impaired growth, and anemia.

DIAGNOSIS

Infection is diagnosed by identification of the typical barrel-shaped eggs with bipolar plugs in direct or concentrated smears of fecal specimens.

TREATMENT Rx

Although *T. trichiura* responds less effectively than *A. lumbricoides* or hookworm to treatment with albendazole or mebendazole, a 3-day course of one of these two benzimidazole drugs is the recommended therapy, as listed in Table 365-1. The addition of ivermectin (200 µg/kg) to either drug increases the response rate significantly.[2]

ENTEROBIASIS

The Pathogen

E. vermicularis, or pinworm, is transmitted by the fecal-oral route. Embryonated eggs on fingernails, bed clothing, or bedding are ingested and hatch in the upper part of the small intestine, where they develop into adults before taking residence in the large intestine. Adult worms measuring between 2 and

5 mm live freely in the lumen of the colon, where they mate. Gravid female worms migrate nightly out of the rectum and deposit large numbers of eggs (11,000 per worm) on the perianal and perineal areas. The eggs rapidly embryonate within 6 hours after being laid. If they are still on the skin, infective larvae are released that can migrate back through the anus into the rectum (retroinfection). In infected females, larvae may also migrate into the genital tract and establish an ectopic infection.

EPIDEMIOLOGY

E. vermicularis is the most prevalent nematode infection found in temperate climes, but it is also found worldwide. Transmission is especially frequent in primary schools and daycare centers where children are in close contact. Up to a quarter of all children worldwide are estimated to be infected with pinworm.

CLINICAL MANIFESTATIONS

Although most pinworm infections are asymptomatic, perianal pruritus is the most common symptom and is caused by an allergic response to worm proteins. The pruritus can be intense and result in chronic sleep deprivation. Rarely, *E. vermicularis* may cause appendicitis, and when hatched larvae migrate into the female genital tract, vulvovaginitis, salpingitis, or peritonitis may develop.

DIAGNOSIS

Pinworm infection is diagnosed by identifying eggs on a piece of cellophane tape applied to the perianal region immediately after waking and before bathing. Characteristic *E. vermicularis* eggs are oval and slightly flattened on one side. It is unusual to find eggs in feces or adult worms in the perianal area. Repeated examination may be necessary.

TREATMENT

Rx

Pinworm infection is treated with a single dose of pyrantel pamoate, mebendazole, or albendazole, which must be repeated 2 weeks later because the drugs do not kill eggs or developing larvae (see Table 365-1). Given the high rate of transmission, all household members and individuals in close contact with the patient (e.g., other children attending the same daycare center) should be treated as well. Bedding and underclothes should be thoroughly washed with hot water to remove and kill the eggs.

STRONGYLOIDIASIS

The Pathogen

S. stercoralis, or threadworm, infection is endemic in warm climates worldwide, including parts of the United States. Infection occurs when exposed skin comes in contact with free-living filariform larvae living in contaminated soil. After penetrating the skin, larvae enter the afferent circulation and travel to the pulmonary vasculature, where they rupture into the alveolar spaces, ascend the respiratory tree, and are swallowed into the gastrointestinal tract. Further development into adult worms occurs in the upper part of the small intestine, where parasites live embedded in the columnar epithelium. Unlike most nematodes, *S. stercoralis* reproduces by parthenogenesis, with no apparent parasitic male worm present in human infection. Female worms begin laying eggs within 25 to 30 days after infection. The embryonated eggs hatch rapidly in the lumen of the small intestine and release rhabditiform larvae that migrate to the colon and are passed in feces. Alternatively, larvae may directly penetrate the colonic mucosa or perianal skin after migrating out of the anus and enter the circulation directly, a mechanism known as autoinfection. This phenomenon can lead to maintenance of parasitism in the host for decades.

Infective filariform larvae develop in the soil by direct transformation from rhabditiform larvae or indirectly from eggs produced by free-living adult worms that have developed from rhabditiform larvae in warm, moist, sandy soil.

A less common type of strongyloidiasis, called swollen belly syndrome, has been attributed to infection with *Strongyloides fuelleborni* in infants living in sub-Saharan Africa and Papua New Guinea.

EPIDEMIOLOGY

S. stercoralis infection is endemic in the tropical and subtropical regions of sub-Saharan Africa, Asia, Latin America, and areas of eastern and southern Europe, with a worldwide prevalence of between 30 and 100 million. In the United States, infection is diagnosed most frequently in immigrants, commonly from Southeast Asia, although strongyloidiasis is still endemic in parts of rural Appalachia.

PATHOBIOLOGY

In immunologically competent individuals, infection is usually asymptomatic or is associated with mild gastrointestinal symptoms. The main complications of infection with this parasite, however, occur in individuals with cell-mediated immunodeficiency such as those chronically taking corticosteroids, renal transplant recipients, patients with Hodgkin's disease and other lymphomas, leukemic patients, and those infected with human T-cell lymphotropic virus type 1. In these individuals, the autoinfection cycle of the *S. stercoralis* life cycle can become amplified and lead to a hyperinfection syndrome with a large increase in the total worm load in the infected person. Hyperinfection can lead to life-threatening dissemination of larvae and adult worms to aberrant sites such as the brain, pancreas, and kidneys. For unknown reasons, advanced acquired immunodeficiency syndrome has not been associated with hyperinfection syndrome or with disseminated strongyloidiasis. Disseminated strongyloidiasis is frequently accompanied by bacterial sepsis, probably as a result of translocation of enteric organisms carried by migrating larvae.

CLINICAL MANIFESTATIONS

As mentioned previously, most *S. stercoralis* infections, especially in immunocompetent hosts, are asymptomatic or, at most, associated with mild gastrointestinal manifestations such as abdominal pain, bloating, and watery diarrhea. Gastrointestinal bleeding, manifested by hematochezia or melena, occurs in less than 20% of those infected. Rare causes of morbidity related to intestinal *S. stercoralis* infection are small bowel obstruction, paralytic ileus, and a malabsorption syndrome (especially in children).

During the migratory phase of larvae through the lungs, symptoms are rare in immunocompetent patients, although infection may be accompanied by peripheral eosinophilia. However, pulmonary signs and symptoms in immunocompromised persons with hyperinfection syndrome can be severe and resemble those of adult respiratory distress syndrome with an acute onset of dyspnea, productive cough, and hemoptysis accompanied by fever, tachypnea, and hypoxemia.

Migration of filariform larvae from the anus can lead to a dermatologic manifestation known as larva currens, which is characterized by serpiginous erythematous maculopapular tracks and occasionally urticarial lesions on the skin of the buttocks, upper aspect of the thighs, and lower part of the abdomen.

Autoinfection leading to exceptionally high worm loads (i.e., hyperinfection) and disseminated strongyloidiasis can occur in persons with deficient cell-mediated immunity. Because *S. stercoralis* may persist and the person may remain asymptomatic for decades after exposure, it is important to remember that a change in immune status associated with conditions such as the administration of immunosuppressive drugs following solid organ transplantation may result in hyperinfection syndrome even though the infection was previously asymptomatic. Massive increases in the number of *Strongyloides* larvae because of hyperinfection can be manifested as acute enteritis with severe diarrhea and ulcerative disease of the small and large intestine. During disseminated infection, larvae and sometimes adult worms penetrate the intestinal mucosa, migrate to aberrant sites, including the central nervous system, and result in metastatic abscesses and gram-negative meningitis as a result of the enteric bacteria carried by the migrating parasites. Less common complications of disseminated disease include glomerulonephritis and minimal-change nephrotic syndrome, acute respiratory distress syndrome, and alveolar hemorrhage. Mortality from hyperinfection and disseminated disease can be high, although early diagnosis and prompt initiation of treatment are associated with improved outcomes.

Infants with swollen belly syndrome caused by *S. fuelleborni* are often seen acutely with abdominal ascites that is not accompanied by diarrhea or fever. The ascites is due to gastrointestinal protein loss; it can be significant enough to cause respiratory impairment and is associated with a high rate of mortality.

DIAGNOSIS

Definitive diagnosis of *S. stercoralis* infection relies on microscopic identification of larvae in feces or other fluids (such as sputum) or tissues. Detection of filariform larvae in feces implies active autoinfection. Intestinal

strongyloidiasis can be diagnosed by identification of larvae in direct smears of freshly passed stool, although the sensitivity of examining a single fecal sample is as low as 30%. Sensitivity can be increased by examining multiple fecal specimens, by using concentration techniques, and by plating feces on an agar plate and inspecting for tracks of colonies created by bacteria being dragged by migrating larvae. Incubating stool mixed with bone charcoal can also enhance recovery (the Harada-Mori culture technique).

Hyperinfection syndrome and disseminated strongyloidiasis can be diagnosed by detection of filariform larvae in duodenal fluid obtained by endoscopy, in sputum, or in bronchoalveolar lavage specimens. Larvae have also been recovered from cerebrospinal fluid, urine, peritoneal washings, skin, and the brains of immunocompromised persons.

Fluctuating eosinophilia is common with uncomplicated intestinal strongyloidiasis, especially during the pulmonary migration phase of initial infection. However, eosinophilia may be absent in patients with hyperinfection and dissemination. In fact, those with hyperinfection and eosinophilia appear to have a better prognosis than do those without eosinophilia.

Serologic diagnosis using an enzyme-linked immunosorbent assay (ELISA) that detects antibodies to filariform larval antigens is both sensitive and specific, even in immunocompromised hosts with disseminated strongyloidiasis.

TREATMENT

Rx

Uncomplicated intestinal strongyloidiasis can be treated effectively with ivermectin (200 µg/kg body weight daily for 2 days), with cure rates in excess of 90%. Albendazole is an alternative treatment (see Table 365-1). Decreases in serologic antibody titer and eosinophilia indicate a treatment response in the absence of continued exposure. After 6 months, antibody titers should fall significantly.

In immunocompromised patients with hyperinfection or disseminated disease, daily treatment should be extended. Some experts recommend continuing treatment until 2 weeks after fecal examinations have become negative (i.e., for one autoinfection cycle). For severely ill patients who are unable to tolerate oral therapy, parenteral veterinary and enema ivermectin preparations have been used. Combination therapy with ivermectin and albendazole may also be used to treat disseminated strongyloidiasis, but data on whether this improves prognosis over monotherapy are lacking.

PREVENTION

In endemic areas, the risk for infection can be reduced by minimizing skin contact with contaminated soil, although elimination of this infection will occur only with improvements in sanitation and treatment of human waste. To prevent hyperinfection in individuals already infected, diagnosis should be attempted before the onset of immunosuppression if possible, such as before organ transplantation or cancer chemotherapy. Anyone who has resided in or traveled to an endemic area should undergo screening for asymptomatic infection, preferably by ELISA or, if not possible, by examination of at least three fecal samples for the presence of larvae. Patients with positive screening test results should be treated empirically with ivermectin. Individuals with negative screening test results but unexplained eosinophilia and a history of exposure should also be considered for empirical treatment. In those undergoing hematopoietic stem cell transplantation, documentation of cure with at least three consecutive negative fecal examinations is recommended before proceeding with transplantation.

UNCOMMON INTESTINAL NEMATODIASES

Humans may serve as accidental hosts for several nematodes that ordinarily parasitize the intestines of other mammals.

Trichostrongylus

Human infection with several different species of the genus *Trichostrongylus* has been reported in Iran, the Far East, and Australia. Humans are incidentally infected when larvae are ingested with leafy vegetables that have been contaminated with soil containing the feces of herbivorous animals. *Trichostrongylus* worms are similar to hookworms in their morphology, appearance of their eggs on fecal examination, and the pathology that they induce. Heavy infections may be accompanied by diarrhea and anemia. Drugs recommended for treatment are pyrantel pamoate, albendazole, or mebendazole (see Table 365-1).

Anisakiasis

Anisakiasis results from ingestion of the larvae of nematodes that normally infect sea mammals such as dolphins, whales, and seals. Larvae of the genera *Anisakis*, *Phocanema*, and *Pseudoterranova* infect the flesh of a number of saltwater fish species as intermediate hosts. Consumption of raw or undercooked fish, often in the form of sushi or sashimi, results in release of the infective larvae into the stomach, followed by invasion of the stomach or duodenal wall, which causes upper abdominal pain that can sometimes be intense. Anisakid worms cannot further develop in humans and die within a few days; an eosinophilic granulomatous reaction is provoked that may mimic a gastric tumor. Diagnosis and treatment are accomplished by endoscopic removal of the parasite. Infection is prevented by cooking or freezing seafood before consumption. Of note, salting, smoking, and marinating fish do not kill anisakid larvae.

Capillaria philippinensis

C. philippinensis can cause a serious intestinal infection that has been reported primarily in the Philippines and Thailand, although it has also been observed in Japan, Taiwan, Korea, and Egypt. Adult worms resemble those of *T. spiralis*, although biologically they mimic *S. stercoralis* in that they have an autoinfectious cycle of reproduction in which larvae can develop into adult worms within the host. Even though the life cycle is not completely known, this nematode probably parasitizes waterfowl that feed on fish and crustaceans, which serve as intermediate hosts. Humans become infected by eating raw or undercooked infected shrimp or fish. Adult worms travel to the mucosal crypts of the small intestine, where they deposit living larvae, sometimes resulting in overwhelming infection. Clinical disease consists of severe diarrhea associated with anorexia, vomiting, and weight loss. Mortality rates as high as 10% have been reported, with death resulting from severe malabsorption and protein-losing enteropathy. Diagnosis depends on finding eggs or larvae in feces. The treatment of choice is albendazole or mebendazole (see Table 365-1).

Other Intestinal Nematode Infections

Several nematodes that normally parasitize the intestine of nonhuman primates very rarely infect the human gastrointestinal tract. *Oesophagostomum bifurcum* infections have been reported from Africa, Asia, and South America and result from the oral ingestion of infective larvae. Adult worms can result in the formation of nodules in the intestinal wall that may be manifested as abdominal masses. Finally, infection with *Ternidens diminutus* has been reported to result in colonic ulcerations and nodular lesions in people living in southern Africa.

366 TISSUE NEMATODE INFECTIONS

DAVID J. DIEMERT

The tissue nematodes can be broadly divided into those that normally infect animals but can incidentally infect humans and those for which humans serve as the principal host (the filariases). Several zoonotic nematodes, such as *Toxocara canis*, *Trichinella spiralis*, and *Angiostrongylus cantonensis,* can infect humans through accidental oral ingestion of helminth eggs or larvae but are unable to complete their life cycle in the host. Clinical manifestations are primarily due to the aberrant migration of larvae through various tissues.

TOXOCARIASIS

DEFINITION

Accidental ingestion of embryonated eggs of the dog roundworm *Toxocara canis,* or less frequently of the cat roundworm *Toxocara cati,* can lead to the clinical syndromes of visceral larva migrans and ocular larva migrans. Symptoms are caused by the aberrant migration of larvae through the body, invading organs to cause serious disease and even death.

EPIDEMIOLOGY

Toxocara infections in animals are ubiquitous in their distribution throughout the world and are more common in younger animals than in adults. In humans, children are most frequently infected, probably because they are more likely to ingest soil contaminated with feces of dogs and cats, such as when playing in sandboxes or playgrounds. Although robust epidemiologic data are lacking, recent evidence suggests that this infection may be one of the most common helminthic diseases in North America and Europe, particularly in inner-city urban areas. Visceral larva migrans occurs most commonly in children younger than 5 years, whereas ocular larva migrans typically affects older children between the ages of 5 and 10 years.

PATHOBIOLOGY

The life cycle of *Toxocara* in its normal animal host resembles that of *Ascaris* in humans; larvae penetrate the intestinal wall after being released into the lumen from ingested eggs, migrate through the vasculature to the lungs, enter into the alveolar space, and ascend the bronchial tree until they are swallowed back into the gastrointestinal tract, where they develop into adult worms that can produce eggs. However, when embryonated *Toxocara* eggs are ingested by humans, the released larvae migrate throughout the body (most commonly the lungs, the liver, the central nervous system [CNS], and occasionally the eyes) but cannot develop into adult worms. Ultimately, the larvae die, inducing significant immediate-type and delayed-type hypersensitivity reactions that result in eosinophilic granuloma formation. Visceral larva migrans and ocular larva migrans seem to be mutually exclusive, suggesting that different *Toxocara* strains may have different tissue tropisms. Alternatively, visceral larva migrans may result from repeated infections, whereas ocular larva migrans may be a manifestation of infection in children who have not been previously sensitized.

CLINICAL MANIFESTATIONS

Most *Toxocara* infections in humans are asymptomatic. Visceral larva migrans is characterized by low-grade fever, pulmonary symptoms including cough and wheeze, and less frequently hepatosplenomegaly accompanied by right upper quadrant pain. Symptoms have a gradual onset and resolve during 4 to 8 weeks. Myocarditis, nephritis, and CNS disease are less common. CNS involvement can result in seizures, encephalopathy, neuropsychiatric symptoms, or an eosinophilic meningoencephalitis. A more subtle syndrome referred to as *covert toxocariasis* has been described that may result from less dramatic migration of larvae through organs. For example, *T. canis* has been suggested as an environmental risk factor for asthma in inner-city populations.

Ocular larva migrans typically presents as unilateral visual impairment that is sometimes accompanied by strabismus. The degree of vision loss is dependent on the particular ocular structure involved, and permanent blindness can occur. Ocular larva migrans involving the retina can be difficult to distinguish from other causes of focal intraretinal lesions, such as retinoblastoma or tuberculosis.

DIAGNOSIS

Toxocariasis can be presumed on the basis of a compatible clinical presentation and history of exposure to dogs or cats. Eosinophilia and hypergammaglobulinemia may be present. Serologic diagnosis by an enzyme-linked immunosorbent assay (ELISA) that employs antigens secreted by second-stage larvae to measure anti-*Toxocara* antibodies may be informative. Although establishment of sensitivity and specificity is difficult because of the inability to make a definitive parasitologic diagnosis, it is estimated that when a titer cutoff of 1:32 is used, the sensitivity of the ELISA is 78% for visceral larva migrans but lower for ocular larva migrans; specificity for both syndromes is greater than 90%. Biopsy of tissues to document the presence of larvae is not recommended because of its low sensitivity.

Computed tomography and fluorescein angiography may be helpful in the diagnosis of ocular larva migrans, especially to differentiate it from retinoblastoma and other causes of intraocular space-occupying lesions. Anti-*Toxocara* antibodies can be detected in aqueous and vitreous humor fluid, and elevated levels relative to serum are suggestive of ocular larva migrans.

TREATMENT Rx

Albendazole (400 mg given twice daily for 5 days) is the treatment of choice for toxocariasis (Table 366-1). Mebendazole is not recommended because of its poor oral bioavailability. In patients with severe pulmonary, cardiac, or neurologic involvement, corticosteroids may be used to reduce symptoms and to shorten the duration of the illness. Ocular larva migrans is treated by vitrectomy, albendazole, or corticosteroids.

See also Chapter 352.

PREVENTION

Visceral larva migrans and ocular larva migrans may be prevented by periodic treatment of dogs and cats with anthelmintics, cleaning up after pets and properly disposing of their feces, covering sandboxes, washing hands after playing with dogs or cats, and keeping children from playing in places where pets have defecated.

TABLE 366-1 TREATMENT OF TISSUE NEMATODE INFECTIONS

NEMATODE INFECTION	TREATMENT
Toxocariasis	Albendazole, 400 mg twice daily for 5 days
Trichinellosis	Albendazole, 400 mg twice daily for 8-14 days*
Angiostrongyliasis	Treatment with albendazole or mebendazole is controversial but may relieve symptoms.
Gnathostomiasis	Surgical removal Alternatives: albendazole, 400 mg daily for 3 weeks; ivermectin, 200 µg/kg/day for 2 days
Lymphatic filariasis	Diethylcarbamazine, 6 mg/kg/day divided in 3 doses for 12 days† Alternative: doxycycline, 100-200 mg/day for 4-8 weeks
Onchocerciasis	Ivermectin, 150 µg/kg once, repeated every 6-12 months until resolution of symptoms
Loiasis	Diethylcarbamazine, 6 mg/kg/day divided in 3 doses for 12-21 days†,‡
Mansonella perstans	Doxycycline, 200 mg/day for 6 weeks
Mansonella ozzardi	Ivermectin, 200 µg/kg once
Mansonella streptocerca	Diethylcarbamazine, 6 mg/kg/day divided in 3 doses for 12 days Alternative: ivermectin, 150 µg/kg once
Dracunculiasis	Extraction of the adult worm

*Treatment is effective only if it is initiated during the intestinal phase of infection.
†Start at a dose of 50 mg on the first day, 50 mg three times/day on the second, 100 mg three times/day on the third, and then 6 mg/kg/day on day 4 onward.
‡Repeated treatment after 6 months is often necessary if symptoms and eosinophilia persist.

BAYLISASCARIASIS

Baylisascariasis is a rare zoonosis caused by infection with the ascarid *Baylisascaris procyonis,* which is primarily a nematode parasite of raccoons and other small carnivores. In North America, infection is most commonly associated with contact with raccoons or environments contaminated with their feces and occurs predominantly in infants and young children who ingest the embryonated eggs while playing with soil. Clinically, disease is manifested as neural larva migrans because of the larval invasion of the CNS after release from ingested eggs in the gastrointestinal tract. Characteristic findings include fever and altered mental status accompanied by focal neurologic deficits and seizures; examination of the cerebrospinal fluid (CSF) reveals eosinophilic meningitis. *B. procyonis* has also been associated with ocular larva migrans, usually in otherwise healthy adults. Infection can be fatal or result in significant permanent neurologic or visual impairment. Once neural larva migrans is present, response to treatment with anthelmintics is poor, although corticosteroids may be helpful. Successful use of photocoagulation in ocular larva migrans has been reported. Prophylactic albendazole (25 mg/kg/day for 20 days) started within days of an exposure may prevent clinical disease.

TRICHINELLOSIS

DEFINITION

Trichinella normally infects a range of mammalian hosts, with the domestic pig serving as the most important reservoir worldwide. Humans are infected on eating raw or undercooked pork or other meats of domestic or wild animals that are contaminated with larvae that are encysted in muscle tissue. Although larvae develop into adults in the human intestinal tract, mate, and produce offspring larvae, clinical disease is characterized not so much by the intestinal infection as by the newborn larvae that penetrate through the intestinal wall and disseminate throughout the body.

EPIDEMIOLOGY

Several different species of *Trichinella* can cause disease in humans, although *Trichinella spiralis* is the most important etiologic agent. *T. spiralis* is enzootic throughout the world in omnivorous and carnivorous wild animals, including bears, boars, and rats. *Trichinella nativa* affects predominantly carnivores (e.g., walruses, polar bears, and seals) living in the Arctic and subarctic regions of North America, Europe, and Asia. *Trichinella* is introduced into domestic animal populations, usually pigs or horses, by giving them unprocessed feed containing meat scraps of infected animals, most commonly rats. Because of regulations banning this practice in the United States, Canada, and the European Union, human infection by consumption of undercooked or smoked pork products or beef contaminated with the encysted larvae has been virtually eliminated, although it still occurs throughout the rest of the world. Instead, ingestion of the flesh of poorly cooked wild game, especially bear or boar meat, is now the most common source of infection in these places. An important source of infection with *T. nativa* in Alaskan and Canadian Arctic native populations is eating of uncooked walrus meat.

PATHOBIOLOGY

Infection with *Trichinella* is initiated by ingestion of striated muscle containing encysted infective larvae. Larvae are released from muscle tissue by digestive enzymes in the stomach and then migrate to the upper two thirds of the small intestine, where they rapidly develop into sexually mature adult worms after only 2 days. Adults live embedded in the columnar epithelium, where they grow to a length of 3 mm (females) or 1.5 mm (males). Females begin producing newborn larvae within 5 days of mating. Adult worms remain viable for an additional 3 to 5 weeks, after which acquired immunity develops that leads to their expulsion from the host.

Newborn larvae possess a sword-like stylet in their oral cavity that permits them to penetrate the lamina propria and enter the lymphatic and blood vessels of the host, allowing them to be distributed throughout the body. Larvae enter all types of cells, where they usually die, with the exception of striated skeletal and cardiac muscle cells. Unique among nematodes, mature *Trichinella* larvae have an intracellular phase, developing and transforming muscle cells into "nurse cells" that support the growth and development of the larvae (Fig. 366-1). In nurse cells, parasite larvae can survive for decades. Although nurse cells do not result in any disease in most mammals, they can induce an eosinophilic granulomatous reaction in humans that may result in significant tissue damage and dysfunction.

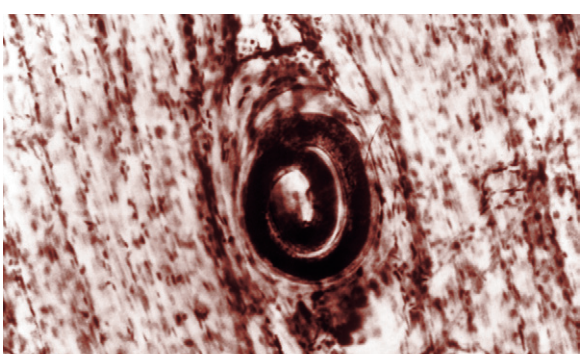

FIGURE 366-1. Nurse cell in muscle tissue containing a larva of *Trichinella spiralis.* (Courtesy of Dr. I. Kagan, Centers for Disease Control and Prevention.)

CLINICAL MANIFESTATIONS

Clinical disease in humans can be divided into an initial intestinal phase followed by a systemic or muscle phase. The initial phase of infection that occurs within days after ingestion of larvae may be associated with mild gastrointestinal signs and symptoms such as diarrhea, abdominal pain, and vomiting. This phase is self-limited and usually resolves spontaneously within 10 days.

The systemic dissemination of *Trichinella* larvae can result in myocardial damage, pulmonary infiltration, and focal neurologic damage caused by migrating larvae, although usually only in the most heavily infected persons. This systemic phase of infection usually begins 2 to 3 weeks after ingestion of infective larvae and may persist for several weeks. Clinical manifestations typically include fever, periorbital or facial edema, a diffuse inflammatory myositis (Chapter 429) that is characterized by myalgias and muscle tenderness, and petechial hemorrhages most easily observed in the subungual skin and conjunctivae. Larval invasion of the myocardium can lead to myocarditis (Chapter 60) that may result in heart failure or arrhythmias.

As with most nematodes, the severity of symptoms is related to the total worm burden. Because adult worms are incapable of reproducing within the host, the number of encysted larvae ingested is the most important determinant of the number of larvae that invade muscle and other tissues.

DIAGNOSIS

A diagnosis of trichinellosis should be suspected in individuals with a compatible clinical presentation, a history of eating raw or undercooked meat, eosinophilia, and increased muscle enzymes such as creatine kinase and lactate dehydrogenase. Definitive diagnosis depends on visualization of nurse cells in a muscle biopsy specimen or detection of *Trichinella*-specific DNA by the polymerase chain reaction (PCR) technique, although this tool is not widely available. Findings on muscle biopsy may be normal even in heavily infected patients because of sampling error. Detection of anti-*Trichinella* antibodies can be very useful in making a diagnosis; ELISA is the most commonly used method. Antibodies can usually be detected as early as 12 days after initial infection.

TREATMENT

Rx

If patients present during the intestinal phase of infection, albendazole is recommended at a dosage of 400 mg given twice daily for 8 to 14 days to kill the adult worms and thus to prevent release of more newborn larvae (see Table 366-1). Although it is not known if albendazole is effective against newborn larvae, administration of this drug during the systemic phase of infection could potentially worsen symptoms by exacerbating the host inflammatory response to dying larvae. Treatment of severe systemic disease, including myocarditis and neurologic disease, should be directed toward reducing inflammation, most commonly with corticosteroids. Symptomatic treatment with antipyretics and analgesics should also be considered.

See also Chapter 352.

PREVENTION

Trichinella infection is prevented by thoroughly cooking meat products to kill the encysted larvae. Freezing meat solid at −20° C for at least 3 days will kill *T. spiralis* but not all other species of *Trichinella*. Of note, curing and smoking techniques do not reliably kill this nematode.

TABLE 366-2 FILARIAL PARASITES OF HUMANS

			Microfilariae		
SPECIES	**DISTRIBUTION**	**VECTOR**	**PRIMARY LOCATION**	**PERIODICITY**	**PRESENCE OF SHEATH**

ANGIOSTRONGYLIASIS

DEFINITION

Angiostrongylus cantonensis and *Angiostrongylus costaricensis* are nematodes that normally infect rodents, primarily rats. The adult worms of *A. cantonensis*, or rat lungworm, inhabit the pulmonary arteries of rodents; larvae are produced that migrate to the pharynx, are swallowed, and then are passed in the feces. Mollusks such as snails, slugs, and prawns serve as intermediate hosts until they are ingested by definitive hosts. Released larvae migrate to the brain, where they develop into immature adult worms before traveling to the pulmonary vasculature to become sexually mature adults. Humans are incidentally infected after eating poorly cooked or raw intermediate mollusk hosts; larvae can migrate to the CNS but cannot develop further. Fresh vegetables may also serve as a vehicle of human infection if they are contaminated with parts of mollusks containing infective larvae. The life cycle of *A. costaricensis* is similar except that the adult worms reside in the arterioles of the small intestine and release eggs and larvae into the intestinal tissue, causing an intense eosinophilic granulomatous reaction.

EPIDEMIOLOGY

Human infections with *A. cantonensis* occur mainly in Southeast Asia and the South Pacific and less frequently in Africa and the Caribbean. Abdominal angiostrongyliasis due to *A. costaricensis* has been reported in Costa Rica, mostly in young children.

CLINICAL MANIFESTATIONS

In human cases of *A. cantonensis* infection, ingested larvae penetrate the intestinal wall and migrate to the brain, the meninges, and less commonly the spinal cord and eye. Fever, severe headache, meningismus, nausea, vomiting, seizures, and focal neurologic deficits may develop. As opposed to *A. cantonensis*, the larvae of *A. costaricensis* can develop into sexually mature adult worms in the local lymphatics and mesenteric arterioles of humans after penetrating the intestinal wall. Clinically, *A. costaricensis* infection can mimic appendicitis with right-sided abdominal pain, vomiting, and fever. Less frequently, gastrointestinal bleeding may occur.

DIAGNOSIS

Diagnosis of *A. cantonensis* infection is based on a history of ingestion of potentially contaminated food, the presence of peripheral eosinophilia, and detection of eosinophils and rarely larvae in the CSF. In neither meningeal nor intestinal angiostrongyliasis are larvae or eggs found in the feces, although both may be seen in specimens removed at surgery.

TREATMENT AND PREVENTION

Rx

Most patients infected with either species of *Angiostrongylus* recover completely after approximately 2 weeks. The use of anthelmintics (Chapter 352) is controversial, with only a few reports of benefit with albendazole or mebendazole, usually administered in combination with analgesics and corticosteroids to relieve symptoms. Periodic removal of CSF can relieve symptoms of raised intracranial pressure caused by infection with *A. cantonensis*. Proper cooking of food and washing of vegetables can prevent this infection.

GNATHOSTOMIASIS

Gnathostoma spinigerum is an intestinal nematode of dogs and cats; intermediate hosts include tiny crustaceans (copepods), amphibians, fish, and birds. Accidental human infection occurs throughout the Far East, Thailand, and parts of Mexico on eating of raw or undercooked invertebrate hosts harboring larvae in their tissues. Larvae are released in the intestine and subsequently migrate through the body but are unable to complete their normal life cycle in humans. The most common clinical presentation is migrating painful and pruritic subcutaneous swellings. Eosinophilic meningitis and ocular larva migrans may also occur, with potentially devastating results, including paralysis, subarachnoid hemorrhage, and permanent visual loss. Peripheral eosinophilia, often high, is usually present; with meningitis, eosinophils are also present in the CSF. There is no commercially available serologic test for this infection. Surgical removal is both diagnostic and curative. Alternatively, either a 3-week course of albendazole or a 2-day course of ivermectin (200 μg/kg/day) is recommended (see Table 366-1). The infection may be prevented by thoroughly cooking fish.

FILARIASES

DEFINITION

The filariases are a group of arthropod-borne nematode infections that are endemic mostly in tropical areas of the world. Instead of residing in the intestine, mature adult filarial worms characteristically live in the lymphatics or in connective tissue (Table 366-2). Eight filarial species infect humans: *Wuchereria bancrofti, Brugia malayi, Onchocerca volvulus, Brugia timori, Loa loa, Mansonella streptocerca, Mansonella perstans,* and *Mansonella ozzardi.* The first three are the most common filariases worldwide. Although not usually fatal, these infections can result in significant disability and disfigurement, such as irreversible limb lymphedema in the case of *W. bancrofti* and *B. malayi* or blindness in the case of *O. volvulus.* Most of the filariases require prolonged exposure for disease to be manifested and are therefore uncommon in short-term travelers to endemic areas. The one exception is loiasis, which can occur in returned travelers and expatriates who have spent extended periods in endemic regions.

For all of the filarial nematodes, infection begins with the bite of an infected arthropod vector that deposits infective larvae called *microfilariae* into the skin or blood. During several months, microfilariae mature into adult worms capable of mating to produce more microfilariae that can be ingested by another arthropod vector to complete the life cycle. Adult worms can survive for 5 to 17 years in the human host; microfilariae live for between 5 months and 5 years. For most of the filarial nematodes except *B. malayi* and *M. perstans*, humans are the only definitive host.

Clinical manifestations of infection are varied and are caused by either the adult worm or the migrating microfilariae. Severity of disease is in most cases directly proportional to the worm burden harbored by an individual, with relatively light infections commonly being asymptomatic. For several of the filariases, the host inflammatory response to infection becomes apparent only on the death of the adult worm or microfilariae. This may be triggered by exposure to filarial antigens that were previously hidden from the immune system or by release of bacterial endosymbionts of the genus *Wolbachia* that live inside several of the filariae and that are critical to the viability and

fertility of the worm. *Wolbachia* are of the order Rickettsiales and are found in the hypodermis of adults worms and in oocysts, embryos, and microfilariae; they play an essential role in worm fertility and survival.

Diagnosis of filarial infections usually depends on the microscopic examination of either blood or skin specimens for characteristic microfilariae (see Table 366-2). Microfilariae of the different filarial species measure between 170 and 320 μm in length and can be distinguished on the basis of the tissue source of the specimen, the presence or absence of a sheath, and the arrangement of nuclei in the tail. For some filarial species, microfilariae are present in the blood only during certain periods of the day to coincide with biting habits of the arthropod vector, which must be taken into account in timing blood sampling for diagnosis based on microscopy. Serology is not very useful in endemic areas because a positive result does not distinguish between previous and current infection, and there is considerable antigenic cross-reactivity between the filariae and other nematodes. Detection of antifilarial antibodies may, however, be useful in returned long-term travelers or expatriates who are not originally from endemic areas but are suspected of having a filarial infection.

Diethylcarbamazine (DEC), ivermectin, and albendazole are the principal antifilarial drugs, although they have varying efficacies against the different filarial species (see Table 366-1). DEC is macrofilaricidal (active against the adult worm) for *W. bancrofti*, *Brugia* species, and *L. loa*, although prolonged or repeated courses are required for this effect. More commonly, the goal is to suppress microfilaria production by adult female worms, which can be achieved by single doses of antifilarial drugs administered alone or in combination annually or biannually. Reduction of microfilariae in the blood or skin can in some cases ameliorate symptoms or prevent progression of disease as well as interrupt the transmission cycle. Recently, evidence has emerged that targeting the *Wolbachia* endosymbionts of some filarial species with extended courses of antibiotics such as doxycycline can be macrofilaricidal.

Lymphatic Filariasis

DEFINITION

The three etiologic agents of lymphatic filariasis, *W. bancrofti, B. malayi,* and *B. timori,* are transmitted to humans through the bite of an infected mosquito. Microfilariae deposited at the bite wound subsequently migrate through the subcutaneous tissue to the lymphatic system, where adult worms develop after approximately 4 to 12 months. The worms reside coiled in lymph nodes and may extend into afferent lymph vessels and surrounding subcutaneous tissue. The lymphatics of the lower and upper extremities and male genitalia are most commonly affected. After mating, females, which measure between 4 and 10 cm in length, twice the length of males, release more than 10,000 microfilariae a day that migrate into the blood stream until ingestion by mosquito intermediate hosts taking a blood meal. In most endemic areas, microfilariae are present in the peripheral blood only at night, when mosquito vectors are most likely to bite. Adult filariae live between 5 and 8 years within the host, although infections lasting for decades have been reported.

EPIDEMIOLOGY

An estimated 120 million people are affected by lymphatic filariasis worldwide; most cases are caused by *W. bancrofti,* and only approximately 10 to 20 million are due to *B. malayi*. *B. timori* is of minor importance, being restricted to southeastern Indonesia. *W. bancrofti* is widely distributed in the tropics, especially in Southeast Asia, the Indian subcontinent, Africa, South America, the Caribbean, and the South Pacific. Most strains of *W. bancrofti* exhibit nocturnal periodicity, with peak levels of microfilariae in the blood stream detectable between 10 PM and 2 AM. An exception is those strains found in the Pacific Islands, where microfilariae circulate at all hours but with peak levels in the late afternoon. The major vectors of bancroftian filariasis are *Culex* mosquitoes in urban areas, anopheline mosquitoes in rural areas of Africa, and *Aedes* species in the Pacific. Humans are the only definitive host for *W. bancrofti*.

B. malayi, on the other hand, can be zoonotic, with both monkey and feline species serving as reservoir hosts. Brugian filariasis is found primarily in India, Malaysia, and other restricted areas in Southeast Asia. Zoonotic strains of *B. malayi* are transmitted to humans by *Mansonia* mosquitoes in Malaysia and Indonesia and are subperiodic, with microfilariae circulating in the blood at all times of day. A nocturnally periodic form, which has no animal reservoir, is transmitted by *Mansonia* and *Anopheles* species in India and parts of Southeast Asia.

PATHOBIOLOGY

The pathologic process due to filarial infections is primarily due to blockage of lymphatic circulation resulting from damage caused by adult worms. Although the worms themselves do not seem to cause obstruction, they induce a local inflammatory lymphangitis, with cell-mediated, cytokine, and humoral components leading to hypertrophy of the vessel walls. It was initially thought that only dead or dying worms induced such an inflammatory response, but more recent evidence suggests that changes to the lymphatic architecture are induced even by living worms. The first pathologic event appears to be lymph vessel dilation resulting from an inflammatory response to filarial antigens and those of endosymbiotic *Wolbachia* bacteria that live within *W. bancrofti* and *B. malayi* adult worms. *Wolbachia* are of the order Rickettsiales and are found in the hypodermis of adults worms, oocysts, embryos, and microfilariae and play an essential role in worm fertility and survival.

The initial inflammatory response leads to endothelial and connective tissue proliferation and vessel dilation, which reduces normal lymphatic function and results in lymphedema that is initially reversible. However, worm death results in a granulomatous reaction to released worm and *Wolbachia* antigens. The infiltration of giant cells as well as plasma cells, eosinophils, and neutrophils can completely occlude the lumen of the lymphatic vessel. Over time, fibrosis and obstruction of lymph flow result in irreversible edema and enlargement of the affected limb or body part. Although recanalization and collateralization of lymph vessels may occur, lymphatic function remains compromised.

There is evidence that repeated secondary bacterial and fungal infections may contribute significantly to the pathology of lymphatic filariasis. In individuals with altered lymph vessels due to lymphatic filariasis, these secondary infections with extrinsic microorganisms trigger heightened inflammation and lymphangiogenesis that can hasten the progression from subclinical lymphatic abnormalities to chronic lymphedema.

CLINICAL MANIFESTATIONS

The clinical manifestations of lymphatic filariasis cover a wide spectrum from asymptomatic infection to severe chronic lymphatic obstruction accompanied by lymphedema (referred to as elephantiasis). Other common clinical outcomes include acute episodic lymphadenitis (also called *filarial fever*) and tropical pulmonary eosinophilia. Most infected individuals living in endemic regions are clinically asymptomatic, although microfilariae can be observed in their blood. Despite the absence of a significant inflammatory response, these individuals may nevertheless exhibit dilation of the affected lymphatics on ultrasound, which is thought necessary to precede the onset of clinically apparent disease.

For unknown reasons, newly exposed individuals may develop acute inflammatory reactions that can rapidly progress to chronic or irreversible changes compared with those born in endemic areas. Severe episodes of lymphadenitis, often with genital involvement, may lead to the relatively rapid development of lymphedema and elephantiasis within a year of arrival. Findings usually resolve quickly if the individual is promptly removed from the endemic area. Microfilariae are usually not detected in these patients.

Acute Lymphadenitis

Acute episodes of retrograde lymphadenitis occur most commonly in adolescents in endemic areas, often in response to a dying adult worm. Painful, erythematous enlargement of an affected lymph node, most commonly inguinal, precedes the onset of lymphangitis and is accompanied by fever and chills. Episodes usually last for about a week, frequently recur, and can be incapacitating. Defervescence is abrupt and associated with desquamation of the overlying skin. In men, inguinal lymphadenitis can be complicated by epididymitis and orchitis. Patients with filarial fevers may be microfilaremic but often are not.

Elephantiasis

Repeated episodes of lymphadenitis eventually lead to dilation of the lymphatic vessels, resulting in chronic lymphedema during the course of months to years (Fig. 366-2), with the prevalence of chronic manifestations increasing with age in affected communities. The extremities, breasts, and genitalia are most commonly affected, although with *B. malayi* infection, usually only the lower parts of the legs are involved. The edema is initially pitting in nature, but the subcutaneous tissue eventually loses its elasticity, resulting in woody edema with thickening of subcutaneous tissue and hyperkeratosis. Secondary

FIGURE 366-2. Elephantiasis, or chronic lymphedema due to infection with *Wuchereria bancrofti.* (Courtesy of the Centers for Disease Control and Prevention.)

bacterial or fungal infection is now recognized to occur more frequently than previously acknowledged and may contribute significantly to the chronic pathologic process of elephantiasis.

In bancroftian filariasis, development of hydrocele is a common manifestation of chronic filariasis in men and can sometimes become massive and debilitating; lymphedema of the vulva is less commonly seen in women. Involvement of the retroperitoneal lymphatics can lead to their rupture to produce intermittent chyluria or chylocele.

Tropical Pulmonary Eosinophilia

Tropical pulmonary eosinophilia develops in a small minority of individuals with filarial infections. The syndrome is most commonly seen in young men living in southern India, although it also occurs in Pakistan, Sri Lanka, Southeast Asia, and Brazil. Characteristic clinical findings include nocturnal paroxysmal cough, wheeze, and low-grade fever that is accompanied by weight loss and prominent peripheral eosinophilia. Levels of both total IgE and antifilarial antibodies are typically high. Chest radiographs generally show diffuse interstitial infiltrates or mottled opacities in the middle and lower lung fields. Without treatment, chronic restrictive lung disease may develop.

Tropical pulmonary eosinophilia is thought to occur as a result of an immune-mediated reaction to microfilariae when they pass through the vasculature of the lung. Eosinophils accumulate in the lungs and can sometimes be observed in sputum or bronchial lavage fluid. Respiratory symptoms result from IgE-mediated and inflammatory reactions to the cleared microfilariae.

DIAGNOSIS

Definitive diagnosis usually relies on microscopic examination of a Giemsa-stained blood sample for microfilariae. Although thick blood smears are relatively insensitive except in cases of high microfilaremia, concentration or filtering techniques can increase diagnostic yield. In the latter case, blood is passed through a 3- to 5-μm pore size membrane filter that is then stained with Giemsa and examined under a microscope. Characteristic microfilariae are 250 to 320 μm in length. Collection of blood should be timed according to the known periodicity of the microfilariae.

Blood can also be assayed by a highly sensitive and specific commercially available rapid immunochromatographic card test that detects circulating *W. bancrofti* antigen (there is no equivalent test for *Brugia* infections). This test has the advantage of not requiring nocturnal collection of blood because it detects antigen of the adult worm and not microfilariae. PCR methods have also been developed to detect filarial antigens in blood, although these are not widely available. Serologic detection of antifilarial antibodies is of limited value because of extensive antigenic cross-reactivity with other nematodes. Furthermore, actively infected individuals cannot be distinguished from those previously infected, and those merely exposed but not infected may also have positive serologic test results.

Ultrasound examination of the lymphatic vessels of the spermatic cord of men can be used to visualize the "filarial dance sign," which is pathognomonic for a nest of filarial parasites.

Individuals with elephantiasis may be amicrofilaremic. Diagnosis therefore depends on a compatible clinical history and physical examination in the context of the appropriate epidemiology, and it may be supported by a positive antigen test result or, in men, by a suggestive scrotal ultrasonogram.

TREATMENT Rx

Management of lymphatic filariasis differs according to whether disease control or curative treatment of an individual patient is the aim. In endemic areas, annual mass drug administration of entire susceptible populations with a combination of two antifilarial drugs has been instituted to break the transmission cycle by reducing the number of microfilariae in the blood available to biting mosquitoes. These programs use different combinations of single-dose DEC, ivermectin, and albendazole, administered once a year. DEC is administered with albendazole except in areas where onchocerciasis or loiasis is also found, in which case ivermectin plus albendazole is used.

It is recommended that all individuals with active infection by a lymphatic filarial parasite, whether symptomatic or asymptomatic, be treated with an antifilarial medication (see Table 366-1). The treatment of choice is DEC (6 mg/kg/day in three divided doses for 12 days). In the United States, DEC is available only through the Centers for Disease Control and Prevention (CDC) drug service *(http://www.cdc.gov/ncidod/srp/drugs/drug-service.html)*. For patients with high levels of microfilariae in the blood, treatment can be started at a low dose of 50 mg daily and scaled up during the first 3 days to reduce side effects of treatment such as fever, headache, dizziness, nausea, vomiting, transient rashes, myalgias, and arthralgias. These normally resolve after a few days of treatment and can be treated with antipyretics, antihistamines, and, if symptoms are severe, corticosteroids.

DEC is both microfilaricidal and partially macrofilaricidal. In individuals who will not be returning to endemic areas, repeated treatments with DEC are often attempted to kill the adult worms instead of just reducing the levels of microfilariae in the blood. Typically, courses of DEC are repeated every 6 to 12 months. Although the adult worm burden is reduced in most treated individuals, all parasites are eliminated in less than a quarter. In men with dancing live adult worms visible by ultrasound in the scrotal lymphatics, serial studies may be performed to monitor the effects of therapy.

Unfortunately, lymphedema due to lymphatic filariasis is usually not reversible with DEC treatment, except in the very early stages. Nevertheless, several management modalities can be employed to limit the chronic sequelae of lymphatic filariasis. Critical among these is the prevention of secondary bacterial and fungal infection through meticulous hygiene and prompt treatment of suspected infections with antimicrobials. Limb elevation, physiotherapy, and use of elastic stockings may slow the worsening of lymphedema. Surgery is usually not indicated except for cases of hydrocele.

Interestingly, treatment directed against the *Wolbachia* endosymbiont has recently been shown to be effective in killing adult *W. bancrofti* and *Brugia* worms. Doxycycline, 100 or 200 mg daily for 4 to 8 weeks, has been shown to reduce female worm fertility with a resulting suppression of microfilaremia for up to a year and to reduce the number of live adult worms.[1] Given the duration of treatment, these regimens are obviously not ideal for disease control programs in endemic countries.

DEC is highly effective in the treatment of tropical pulmonary eosinophilia. Treatment with 6 mg/kg/day for 14 to 21 days results in resolution of symptoms within a week, although relapse may occur even after an interval of years.

See also Chapter 352.

PREVENTION

Annual mass treatment with single doses of two antifilarial drugs can significantly reduce the prevalence of infection within a community. In some areas, DEC-fortified table salt has been used to reduce the levels of microfilaremia in affected communities to interrupt the transmission cycle. Vector control through use of insecticide-treated bed nets and residual indoor spraying of insecticides may have some efficacy.

Onchocerciasis

DEFINITION

Onchocerciasis, or river blindness, caused by the nematode *Onchocerca volvulus,* is transmitted to humans by *Simulium* species blackflies. Infective microfilariae develop into male and female adult worms during several months and live for 8 to 10 years coiled within subcutaneous fibrous nodules (onchocercomas). Adult females measure between 20 and 70 cm in length and remain confined to the nodules; males are only 3 to 5 cm long and freely migrate through the subcutaneous tissues. Mature female worms produce about 700 microfilariae per day, which leave the nodule to migrate primarily through the skin and ocular tissues. Microfilariae can survive within the host for approximately 3 to 5 years unless they are ingested by a blackfly taking a blood meal.

EPIDEMIOLOGY

Onchocerciasis is endemic in 30 countries, predominantly in equatorial Africa, with small foci in six Latin American countries (Guatemala, southern

Mexico, Venezuela, Brazil, Colombia, and Ecuador) and in Yemen. More than 17 million people are estimated to be infected, 500,000 of whom have significant visual impairment and 270,000 of whom are blind. More than 99% of cases occur in sub-Saharan Africa, with Nigeria being the most highly endemic country. Because *Simulium* blackflies require fast-flowing, well-oxygenated water for egg laying and reproduction, onchocerciasis is concentrated around streams and rivers, often in the most fertile farming areas. In communities bordering such waterways in endemic areas, up to 50% of the population can be affected.

Blindness caused by *O. volvulus* results in significant morbidity, long-term disability, and reduced economic productivity. In addition, onchocerciasis has been associated with a reduced life expectancy of at least 10 years compared with uninfected individuals in the same area, an effect that appears to be independent of the blindness that develops.

PATHOBIOLOGY

The pathologic changes of onchocerciasis are primarily due to an inflammatory reaction elicited by microfilariae. The skin, eyes, and lymph nodes are most affected. Adult worms contained in nodules are relatively isolated from the host immune response. Tissue damage results mainly from a cell-mediated immune response to dying microfilariae, which becomes more pronounced as infection persists. The degree of tissue damage is directly related to the intensity of infection as well as the magnitude of the host response. Sclerosing keratitis, the major cause of blindness, is caused by a lymphocytic inflammatory reaction to dying intraocular microfilariae that appears to be dependent on T helper cell type 2 (T_H2) cytokines. With time, neovascularization and scarring of the cornea lead to corneal opacification and eventual blindness. In the skin, similar immune responses result in pruritus and angioedema. Ongoing low-grade inflammation in the skin eventually leads to loss of elasticity and atrophy. Chronic inflammatory changes and fibrosis are also seen in lymph nodes.

Like the nematodes responsible for lymphatic filariasis, *O. volvulus* adult worms contain endosymbiotic *Wolbachia* bacteria that are obligatory for the development, survival, and fertility of these worms. Pro-inflammatory *Wolbachia* proteins released by dying microfilariae may be responsible for a significant amount of the immunopathologic process associated with onchocerciasis. For example, an endotoxin-like *Wolbachia* product has been shown to interact with the innate immune system through a Toll-like receptor 4–mediated mechanism.

CLINICAL MANIFESTATIONS

Onchodermatitis

Onchocerciasis commonly presents with a diffuse papular dermatitis that is intensely pruritic. In heavily infected individuals in endemic areas, the pruritus is intractable, leading to scratching and excoriation to the point of bleeding and even suicide. Hypersensitivity reactions, scabies, insect bites, and atopic or contact dermatitis should be considered in the differential diagnosis of the acute papular dermatitis seen with onchocerciasis. The skin of affected areas becomes edematous and thickened, losing its elasticity and taking on an orange-peel texture. A lichenified dermatitis (referred to as *sowdah*) may occur; it consists of an intensely pruritic eruption limited to one extremity, usually a leg, with hyperpigmented papules and plaques accompanied by edema of the entire limb. Over time, the skin will atrophy and fine wrinkles appear, especially over the buttocks. Pruritus is uncommon at this point. Areas of depigmentation may occur most commonly over the shins, a phenomenon called *leopard skin*.

Subcutaneous Nodules

Subcutaneous onchocercomas containing adult worms are most often palpable over bone prominences. In Africa, the nodules are most commonly found over the hips and lower limbs; in Latin America, they are often located on the head and upper part of the body. Nodules usually measure between 0.5 and 3 cm in diameter and are freely mobile. In lightly infected individuals, such as expatriates, nodules are usually not detectable.

Ocular Lesions

Initial ocular involvement is characterized by conjunctivitis, excess tearing, and photophobia in response to dying microfilariae. At this time, the corneal disease consists of a punctate keratitis or snowflake corneal opacities. During 20 to 30 years, this leads to sclerosing keratitis, neovascularization, and corneal opacification. The anterior chamber of the eye may also be involved, with iritis, iridocyclitis, and secondary glaucoma. Posterior ocular disease can be manifested as chorioretinitis, optic neuritis, and optic atrophy.

Lymphadenopathy

Lymphadenopathy is frequently found in the inguinal and femoral areas in Africa and in the head and neck in Latin America. Advanced disease in the inguinal region can result in the so-called hanging groin, with elongated atrophic skin containing nontender and fibrotic lymph nodes.

DIAGNOSIS

Definitive diagnosis has traditionally been made by observing motile microfilariae released from superficial skin snips. Microfilariae of *O. volvulus* do not have a sheath and measure 200 to 300 µm in length. To take a skin snip, a thin piece of skin overlying a bone prominence that has been tented up with a needle is sliced with a scalpel blade, or a corneal-scleral punch instrument is used to obtain a small piece of skin without drawing blood. Avoidance of blood contamination is critical to avoid confusion with blood-borne microfilariae in cases in which patients are coinfected with other filariases. Because microfilariae of *M. streptocerca* are also found in the skin, it is necessary to fix the skin and to stain it with Giemsa if a patient has been in an area endemic for this nematode. Typically, six snips are taken, one from over each scapula, iliac crest, and lateral aspect of each calf, and then incubated with warm physiologic saline and examined microscopically for motile microfilariae after at least 30 minutes of incubation, although longer periods of up to 24 hours may be necessary. Multiple skin snips have a higher yield than a single one, although sensitivity is usually low even then, especially in areas of low transmission. Newer techniques include PCR amplification of filarial DNA directly from skin snips that are far more sensitive than direct visualization. With ocular disease, free microfilariae may be visible by slit lamp examination in the anterior chamber or aqueous humor.

Subcutaneous nodules can be sampled or examined by ultrasound to demonstrate the presence of adult worms. Serologic tests are usually positive for antifilarial antibodies but are not specific because of extensive antigenic cross-reactivity with other nematodes. Eosinophilia is a common but inconsistent finding.

In the past, the Mazzotti test was used to diagnose onchocerciasis. In this test, a challenge dose of DEC was administered to patients suspected of having onchocerciasis; with *O. volvulus* infection, an intense pruritic skin reaction would develop within hours. However, in patients with high-intensity infections, the Mazzotti reaction could be severe and even worsen ocular disease, resulting in permanent visual loss. Therefore, this test is no longer recommended, although some instead suggest the application of a small amount of DEC to the skin to provoke a localized Mazzotti reaction.

TREATMENT Rx

Ivermectin is the treatment of choice for onchocerciasis (see Table 366-1). Administration of a single dose of ivermectin (150 µg/kg) is effective in ameliorating ocular and dermatologic disease by destroying microfilariae and suppressing their release from female worms. Because ivermectin is not active against the encapsulated adult worms, treatment must be repeated every 6 to 12 months, probably for at least 10 years in those without further exposure. For unknown reasons, pruritus in lightly infected expatriates may require more aggressive and frequent treatment for the first 2 years. Within 24 hours of treatment with ivermectin, fever and pruritus may occur in reaction to the dying microfilariae or released *Wolbachia* antigens, especially in those with high pretreatment levels of microfilariae. Use of ivermectin in areas where *L. loa* (see later) is co-endemic should be undertaken with caution as treatment may precipitate severe reactions including encephalopathy in those with high microfilaremia. DEC should never be used for treatment of onchocerciasis because of frequent unacceptable reactions to dying microfilariae ranging from urticaria and angioedema to hypotension and death. Although the drug suramin (available from the CDC drug service) is active against adult *O. volvulus* worms, because of its excessive toxicity and potentially life-threatening effects, it is used only in rare situations. Surgical removal of palpable nodules has been successful in resolving the infection in some areas, notably in Central America.

Doxycycline, 100 mg/day administered for 4 to 6 weeks, followed by single-dose ivermectin, has been shown to deplete *Wolbachia* endosymbionts from adult worms and to suppress *O. volvulus* embryogenesis and production of microfilariae for up to 18 months. Some experts now recommend this regimen for patients with onchocerciasis who have left an endemic area and will not be re-exposed.

See also Chapter 352.

PREVENTION

Regular mass administration of ivermectin to affected communities forms the core of the global eradication strategy for onchocerciasis. Implementation of this program has been made easier because the drug is donated by the manufacturer. In addition to benefiting infected individuals, mass drug administration reduces the microfilariae available to vectors and thus interrupts the transmission cycle. For travelers to endemic areas, use of insect repellent may be beneficial.

Loiasis

DEFINITION

Loiasis is caused by infection with the filarial nematode *Loa loa,* otherwise known as the *African eye worm*. *L. loa* are transmitted by flies of the genus *Chrysops* during a blood meal. Adult worms develop during a period of 1 to 4 years and live for up to 17 years. They migrate freely in the subcutaneous tissue, including the subconjunctiva or sclera of the eye. Adult females measure between 50 and 70 mm in length; males are shorter, measuring between 25 and 35 mm. After mating, females release microfilariae into the blood. *L. loa* microfilariae exhibit a diurnal periodicity coinciding with the feeding habits of *Chrysops,* with microfilaremia peaking around noon.

EPIDEMIOLOGY

Loiasis is endemic in the rain forest regions of central and west Africa. Although accurate numbers are not available, loiasis appears to be most prevalent in Gabon, Cameroon, the Democratic Republic of the Congo, Nigeria, and the Central African Republic. More so than other filarial infections, loiasis seems to require a shorter period of exposure and can be seen in returning travelers or expatriates who have spent extended periods in Africa.

PATHOBIOLOGY

Neither adult *L. loa* worms nor microfilariae have any direct pathologic effects. In a subset of infected individuals, a hypersensitivity response, termed a *Calabar swelling*, develops to secretions from adult worms or released microfilariae, resulting in recurrent localized angioedema that often precedes the migrating worm. Interestingly, this reaction is more commonly observed in visitors to endemic areas rather than in native residents. These patients have very high serum levels of IgE antibodies and eosinophilia. Unlike other filariae, *L. loa* does not contain *Wolbachia* endosymbionts.

CLINICAL MANIFESTATIONS

Most individuals with loiasis are asymptomatic despite being microfilaremic. Clinical manifestations of infection are more common in long-term visitors to endemic areas than in people native to the regions. Recurrent Calabar swellings are the most common finding in these individuals, who are not usually microfilaremic. They are nonerythematous swellings measuring 5 to 20 cm in diameter that typically occur on the extremities and the face and last for a few days. The onset is often preceded by pruritus and pain. On occasion, adult worms may migrate across the subconjunctiva or sclera of the eye in both groups of patients, causing severe pain and inflammation (Fig. 366-3). Rare complications of infection include nephropathy and encephalitis, the latter usually developing in patients with high levels of microfilariae after receiving DEC or ivermectin treatment for other filarial infections. Endomyocardial fibrosis resulting from eosinophilic infiltration of the myocardium has been reported in association with loiasis.

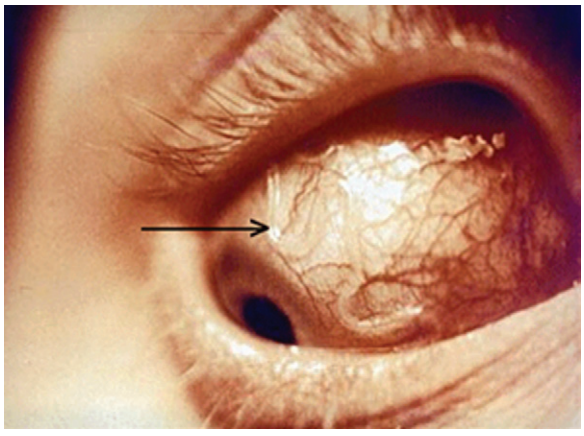

FIGURE 366-3. Adult *Loa loa* worm migrating across the eye *(arrow)*.

DIAGNOSIS

Definitive diagnosis depends on microscopic examination of a Giemsa- or Wright-stained blood film for characteristic sheathed microfilariae. Blood should be collected between 10 AM and 2 PM because of the diurnal periodicity of the microfilariae. Because individuals who are not native to endemic areas are usually not microfilaremic, diagnosis relies on a compatible history, clinical findings, peripheral eosinophilia, and elevated antifilarial antibody levels. Adult worms can sometimes be surgically removed while migrating across the eye or through subcutaneous tissues. Calabar swellings must be distinguished from onchocercomas and other causes of angioedema.

TREATMENT Rx

DEC (6 mg/kg/day for 12 to 21 days) is active against both adult *L. loa* worms and microfilariae (see Table 366-1). Treatment is usually increased from a dose of 50 mg/day on the first day to the full dose on the fourth day to minimize the likelihood of treatment-associated complications, the most serious of which are glomerulonephritis and a potentially fatal encephalopathy. Treatment-associated complications are more common with high pretreatment microfilarial levels and result from host allergic reactions to dying microfilariae. Antihistamines and corticosteroids may be employed to reduce allergic side effects. Alternatively, apheresis can be used to remove circulating microfilariae before initiation of DEC in these individuals. Albendazole, which is microfilaricidal but has no activity against adult worms, has also been used to reduce microfilaria levels before treatment with DEC. Repeated courses of DEC may be necessary in about half of patients before clinical manifestations completely resolve. Persistent or increasing eosinophilia or levels of antifilarial antibodies 6 months after treatment should also prompt re-evaluation for repeated treatment. Adult worms in the eye should be surgically removed.

Ivermectin is microfilaricidal but has no macrofilaricidal effect and may cause toxic encephalopathy in individuals with high microfilaria levels. In areas where onchocerciasis is co-endemic, this infection should be ruled out before the initiation of DEC for loiasis to prevent toxicity from dying *O. volvulus* microfilariae.

See also Chapter 352.

PREVENTION

Weekly chemoprophylaxis with DEC administered as a 300-mg dose is effective in preventing loiasis in long-term residents of endemic areas.

Less Common Filarial Infections

MANSONELLA PERSTANS

M. perstans infection occurs throughout central Africa, in northeastern South America, and in parts of the Caribbean. Microfilariae are transmitted by midges and develop into adult worms that live in serous body cavities, such as the pleural, pericardial, and peritoneal spaces, as well as in mesenteric and retroperitoneal tissues. Most infections are asymptomatic, although painless conjunctival nodules with eyelid edema have been reported. Transient angioedema and Calabar-like swellings, fever, headache, arthralgias, and neurologic manifestations may also occur. Microfilariae do not exhibit periodicity and can be observed on stained blood films. Eosinophilia is common. *M. perstans* harbor *Wolbachia* endosymbionts, and treatment with doxycycline, 200 mg/day for 6 weeks, has been shown to be highly effective in suppressing microfilaremia for up to 3 years, suggesting that the treatment is macrofilaricidal.[2]

MANSONELLA OZZARDI

Infections with *M. ozzardi* occur only in Central and South America and parts of the Caribbean, especially Haiti. Vectors include *Simulium* blackflies and midges. Adult worms locate to the peritoneal and thoracic cavities or the lymphatics; microfilariae circulate in the blood without periodicity. Infection usually results in asymptomatic eosinophilia, although arthritis and allergic symptoms such as urticaria and lymphadenopathy may occur. Administration of ivermectin as a single dose of 200 μg/kg has been reported to provide long-term suppression of microfilaremia and improvement of symptoms. Neither DEC nor the benzimidazoles are effective.

MANSONELLA STREPTOCERCA

M. streptocerca is endemic in the tropical forest zone of west and central Africa and is transmitted by biting midges. Similar to *O. volvulus*, adult worms live in the subcutaneous tissues, as do microfilariae. In contrast to onchocerciasis, however, microfilariae do not invade the eye. Infection is usually asymptomatic, although a pruritic dermatitis with depigmentation similar to onchodermatitis can affect the trunk and upper extremities. Associated axillary or inguinal adenopathy is common. Microfilariae have characteristic hooked tails and can be visualized in skin snips. In areas where onchocerciasis is co-endemic, skin specimens must be stained to differentiate *M. streptocerca* from *O. volvulus*. DEC is microfilaricidal and macrofilaricidal and is given as 6 mg/kg/day for 12 days. Ivermectin is effective against microfilariae but not adult worms.

ZOONOTIC FILARIAL INFECTIONS

A rare accidental filarial infection of humans with the dog heartworm *Dirofilaria immitis* occurs worldwide. Transmitted by mosquitoes, *D. immitis* microfilariae cannot reach maturity in humans but embolize to the lung after dying in the right ventricle. Most infections are asymptomatic, but some people experience cough, chest pain, and hemoptysis consistent with lung infarction. Chest radiographs demonstrate typical coin lesions that may be mistaken for carcinoma. Other animal filariae, including *Dirofilaria repens* of dogs and *Dirofilaria tenuis* of raccoons, can infect humans and result in subcutaneous nodules that may be migratory. Eosinophilia and antifilarial antibodies are not usually present in zoonotic filarial infections. Surgical removal of lesions is both diagnostic and curative.

DRACUNCULIASIS

Dracunculiasis is a disfiguring disease caused by the nematode *Dracunculus medinensis,* also known as the *guinea worm*. Although previously found in India, Pakistan, and Latin America, it is now endemic in only four countries in sub-Saharan Africa (Sudan, Ghana, Mali, and Ethiopia) because of concerted efforts at eradication. Currently, fewer than 5000 cases are thought to exist, with the largest concentration being in southern Sudan. Transmission to humans occurs through ingestion of tiny crustacean intermediate hosts called *copepods* that harbor infective larvae. Released larvae penetrate the intestinal wall and migrate to the subcutaneous tissues, where they develop into adult worms. After approximately a year, female worms induce vesicular skin lesions, usually on the lower extremities, that eventually ulcerate. On direct contact with fresh water, the female worm releases thousands of motile larvae that can then complete the transmission cycle by infecting copepods in the water. Adult worms can measure up to a meter in length. Fever and allergic symptoms, including wheezing and urticaria, may precede rupture of the blister or occur with attempts to extract the worm. Secondary bacterial infection of the skin lesions is frequent. Although not usually fatal, dracunculiasis can result in significant disability.

Traditionally, emerging worms are extracted by slowly winding a few centimeters of the parasite on a stick each day, taking care not to break it. Surgical removal can also be attempted but may exacerbate allergic symptoms. There is no effective chemotherapy for this infection. Prevention efforts have been highly successful in breaking the transmission cycle and have led to eradication of the parasite from many countries. Strategies include filtering of drinking water through finely woven cloth, education of infected individuals not to enter fresh water, treatment of water sources with larvicides, and provision of safe drinking water from wells.

ARTHROPODS AND LEECHES

DIRK M. ELSTON

ARTHROPODS

The Pathogens

Arthropods are invertebrates characterized by an exoskeleton and jointed legs. They commonly act as disease vectors or may cause human injury by means of the direct toxic effects of their venom or through an immune response to their antigens (Tables 367-1 to 367-4). Immediate reactions to

stings may be related to histamine, serotonin, formic acid, or kinins contained within the venom. Delayed reactions to bites and stings generally represent a host response to proteinaceous allergens contained within venom or saliva.

Whereas many diseases are spread by a single vector, others have multiple potential vectors. For example, tularemia is commonly acquired from ticks or handling of infected carcasses, but it may also be spread by deer flies and horseflies. Rickettsiae are spread by both ticks and fleas. The vector may influence manifestations of the disease. For example, *Bartonella* transmitted by a flea may produce bacillary angiomatosis, whereas the same organism transmitted by a louse is much more likely to be manifested as endocarditis. Disease manifestations may also reflect the underlying immune status of the host, previous sensitization, or associated comorbidities. For example, hypersensitivity reactions to insect stings are more common in those with an atopic diathesis, and anaphylaxis may be a manifestation of underlying mastocytosis. Exaggerated bite reactions (Fig. 367-1) may be a manifestation of an underlying lymphoproliferative disease.

Scabies

DEFINITION

Human scabies is caused by the mite *Sarcoptes scabiei* var *hominis,* an obligate human pathogen, belonging to the class Arachnida, subclass Acari, order Astigmata, and family Sarcoptidae. Animal mange or scab is caused by related *Sarcoptes* or *Psoroptes* mites. These zoonotic mites can produce transient symptoms in exposed humans but are rarely capable of producing sustained infestation. *S. scabiei* var *hominis* is round to oval with a small anterior portion, dorsal spines, and hairlike projections on the rudimentary legs.

PATHOBIOLOGY

After mating on the skin surface, the female mite begins to burrow and lay eggs at a rate of one to three per day. The eggs mature and hatch during 3 to 4 days. The larvae pass through protonymph and tritonymph stages before molting into adults. The entire life cycle ranges between 30 and 60 days. All stages of the mite are capable of penetrating the stratum corneum through secretion of enzymes. In immunosuppressed individuals, mite populations may reach staggering proportions within thick, white, highly infectious crusts.

In immunocompetent patients, scabies mites induce a strong host response characterized by a superficial and deep perivascular inflammatory infiltrate composed of lymphocytes, histiocytes, and eosinophils. There is marked production of interleukin (IL)–6 resulting in proliferation of keratinocytes, activation of T_H1 $CD4^+$ cells causing production of IL-2, and activation of T_H2 $CD4^+$ cells causing production of IL-4. Disease manifestations relate to the complex balance of the immune response.

CLINICAL MANIFESTATIONS

Immunocompetent adults present with severe pruritus and a symmetrical erythematous papulovesicular eruption. There is a predilection for involvement of the interdigital web spaces, the wrists (Fig. 367-2), the anterior

TABLE 367-4 CAUSES OF DIRECT TOXIC INJURY BY ARTHROPODS AND LEECHES

ORGANISM	TYPE OF INJURY	DISTRIBUTION AND POPULATION AFFECTED
Australian funnel web spiders (*Hadronyche* and *Atrax)*	Neurotoxin producing tingling around the mouth, muscle twitching, nausea, vomiting, profuse sweating, coma, myocardial injury	Australians
Blister beetles	Bullous reactions	Widely distributed but more common in hot climates
Brazilian wandering spider (*Phoneutria* spiders)	Neurotoxin resulting in paralysis	Brazilians
Brown *Loxosceles* spiders	Dermonecrotic reactions	Contact through attics and woodpiles
Centipedes	Neurotoxin that may produce pain, paresthesia, erythema, edema, and profuse bleeding; rarely, coronary ischemia, rhabdomyolysis, proteinuria, and renal failure	Most toxic species in Asia
Hymenopterids	Anaphylactic reactions	Wide distribution
Leeches	Bleeding	Fresh water exposure
Lepidopterids *Lonomia* caterpillars	Rash, ophthalmia nodosa, keratoconjunctivitis Fatal bleeding diathesis	Wide distribution Brazil
Millipedes	Chemical burns	Most toxic species in Australia and Africa
Pacific funnel web spider *(Tegenaria agrestis)*	Dermonecrotic reactions	Basements in the Pacific Northwest
Scorpions *Centruroides sculpturatus* Buthid scorpions	Mild systemic symptoms, sometimes severe in children; severe cardiac toxicity	 Southwestern United States Asia, Africa, and Latin America
Tarantulas	Contact urticaria and ophthalmia nodosa	Hot climates
Widow spiders *(Latrodectus)*	Neurotoxin mimicking acute abdomen	Contact through outhouses and woodpiles

FIGURE 367-2. Scabies infestation in children commonly presents with burrows (shown here between the thenar and hypothenar eminences), papulovesicles, and crusts involving the wrists and flexures.

axillary folds, the periumbilical skin, the areolae in women, and the penis and scrotum in men. In infants, the face and scalp are commonly involved. Crusted scabies in immunosuppressed individuals presents with silver to white crusts involving any portion of the body but with a predilection for the hands and ears. In elderly patients, the manifestations may be subtle, with mild pruritus and prurigo-like papules on the trunk and extremities. In patients with human T-lymphotropic virus type 1 infection, scabies often presents with linear hyperkeratotic lesions on the dorsal hands and feet.

The most pathognomonic findings are burrows and genital nodules. The burrow is a short serpiginous gray to white keratotic line measuring 1 to 4 mm in length. Burrows are most common on the hands and feet, particularly on the finger web spaces, the thenar and hypothenar eminences, and the wrists. Genital nodules may involve the glans, scrotum, or labia majora. A history of itch in other family members or sexual partners is highly suggestive of the diagnosis.

DIAGNOSIS

The diagnosis is established by identification of the female mite, ova, or feces in a scraping from a burrow (Fig. 367-3). When the diagnosis is missed initially, it may ultimately be made by transmission to other patients and health care providers. This is particularly true in the case of crusted scabies, when hundreds of individuals may become infested. A high degree of suspicion is required in immunosuppressed and elderly patients, in whom the manifestations may be mild and atypical. Scabies may mimic bullous pemphigoid and Langerhans cell histiocytosis, both clinically and histologically.

TREATMENT

Rx

Commonly employed topical agents include permethrin 5% and precipitated sulfur 2 to 10% in petrolatum. Lindane (gamma benzene hexachloride) 1% was widely used in the past, and topical agents used worldwide include benzyl benzoate 10 to 25%, monosulfiram 5 to 25%, malathion 0.5%, and esdepallethrin 0.63%. Crotamiton 10% has relatively weak antiscabetic activity but is sometimes used for its antipruritic effect. Oral ivermectin has also been used at a single dose of 200 μg/kg (about 12 mg for an average adult).

Proper application of any topical must include the umbilicus, the genitalia, under the nails, and the skin up to the edge of all body orifices. Fomites are important in the spread of crusted scabies, with hospital linens being of particular concern. Caregivers involved in bathing or lifting, sexual partners, and family members are at high risk of infection and should be treated at the same time as the patient regardless of symptoms. It has been estimated that 15 to 20 minutes of close contact with an infected individual is required for transfer of the mites from one person to another. Clothes and bed linens should be machine washed at 60° C, followed by heated drying.

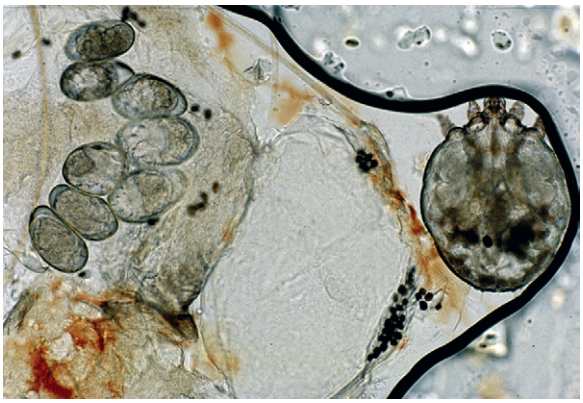

FIGURE 367-3. Scabies preparation demonstrating an adult mite, ova, and feces.

Other Mites

Mites are ubiquitous in the environment and are a frequent cause of dermatitis. The most common medically important mites are listed in Table 367-3.

The majority of mites are free-living, but thousands of species are obligate parasites of animals or plants. Like ticks, mites mature through various life stages. Typically, there is a single six-legged larval stage, followed by several nymphal stages and an adult stage. Both nymphs and adults typically have eight legs. Whereas most mites lay eggs, the spiny rat mite *(Laelaps echidninus)* is viviparous, and the straw itch mite *(Pyemotes tritici)* protects its young internally throughout their life cycle until they emerge as sexually mature adults. Manifestations of mite infestations are protean and include papular, vesicular, urticarial, and morbilliform eruptions. Chigger mites most often affect the lower legs, the edges of underwear, and the genitalia. Summer penile syndrome is a manifestation of chigger mite infestation. It presents with tender to itchy papules of the glans and scrotum and may mimic scabies infestation. Chigger (Trombiculid) mites in Asia are vectors for scrub typhus; house mouse mites in New York City transmit rickettsialpox. The presence of an eschar at the site of the bite suggests rickettsial disease.

The primary treatment is to identify and remove the source of infestation. Many mite-induced rashes represent a "bite and run" injury and can be treated with topical corticosteroids or camphor and menthol lotion for symptomatic relief. Other mites remain attached by a feeding tube and can be removed by scraping or tape stripping of the affected skin. Mite identification can be helpful in establishing the most likely source of the infestation.

Ticks

Ticks are important disease vectors, and *Dermacentor* ticks can cause fatal tick paralysis in children. Tick paralysis presents as progressive ascending paralysis. As the tick attaches to the scalp, it frequently goes unnoticed, and death occurs in more than 10% of affected children. Nodular lesions are commonly pseudolymphomatous histologically.

Rickettsial illnesses typically present with fever and a headache, and treatment with a tetracycline should never be withheld because of absence of a rash. Any delay in the initiation of antibiotic therapy may prove fatal, and empirical treatment should never be delayed until confirmatory test results are available. Doxycycline is generally recommended in both adults and children.

Rickettsial diseases, including Rocky Mountain spotted fever, continue to emerge in much of the world, especially in South America. Recently recognized rickettsial pathogens include *Rickettsia parkeri*. Most of these agents produce milder syndromes similar to Rocky Mountain spotted fever.

Exclusion of animal hosts from recreational areas can be helpful in control of tick-borne illness. Oral agents, including avermectin-laced feed corn, can be used to kill ticks that feed on deer. Removal of leaf debris leads to a reduction in tick numbers through dehydration of adults and ova. Permethrin, a pyrethroid insecticide, is widely marketed as a topical acaricide to be applied to clothing. It is stable through several wash cycles. Some North African *Hyalomma* ticks have demonstrated high-level resistance, and permethrin may produce a pheromone-like attachment response in these ticks. Resistance in North American ticks can be esterase based or related to sodium channel gene mutations, and permethrin resistance has been linked to outbreaks of bovine babesiosis and anaplasmosis.

A veterinarian should be consulted concerning control of ticks in pets and livestock. Topical fipronil is commonly used in dogs. Collars can be impregnated with amitraz and pyriproxyfen, and oral agents are also available.

Antibiotic prophylaxis after tick bites is justified only in the case of endemic disease vectors that are heavily engorged. In some cases, the risk-to-benefit ratio may weigh in favor of prophylactic treatment. If the dose is sufficient and the antibiotic is given at the appropriate time, prophylaxis can prevent tick-borne disease. In the case of Rocky Mountain spotted fever, single-dose prophylaxis should be avoided as it may only delay the onset of clinical symptoms when it is administered too early in the course of incubation. If the decision is made to administer a prophylactic antibiotic, a full 10-day course of therapy is preferable to single-dose prophylaxis. A controlled trial comparing 10 days of oral doxycycline (with or without intravenous ceftriaxone) with 20 days of oral doxycycline for the treatment of early Lyme disease found a similar response rate in all three treatment groups.

Spiders

Toxic spiders are found worldwide. The most feared include the funnel web spiders of Australia and *Phoneutria* wandering spiders in Brazil, which can be fatal. In North America, brown recluse spiders can produce a severe dermonecrotic reaction, but most spider bites result only in a mild local cutaneous reaction.

Black and brown widow spiders have a worldwide distribution. *Latrodectus mactans* is the most common black widow spider in North America. *Latrodectus curacavienis* is common in South America and *Latrodectus tredecimguttatus* in Europe. Both black *(Latrodectus indistinctus)* and brown *(Latrodectus geometricus)* widow spiders are found in Africa and Madagascar; Australia and New Zealand have red-black spiders *(Latrodectus mactans hasselti)*.

Widow spiders are commonly encountered in woodpiles, and bites commonly involve the hand. Latrotoxins act by increasing intracellular calcium concentrations, depolarizing neurons, and stimulating uncontrolled release of neurotransmitters. Divalent cation–dependent tetramers of α-latrotoxin produce membrane pores in mammalian cells. Symptoms include local pain as well as systemic symptoms suggestive of an acute surgical abdomen. Both benzodiazepines and intravenous calcium gluconate have been used to treat associated tetany. Antivenin can produce rapid relief of unresponsive tetany and priapism.

Brown *Loxosceles* spiders are found throughout the world; the most famous is the brown recluse spider, *Loxosceles reclusa* (Fig. 367-4). The resulting necrosis can be severe (Fig. 367-5), but most bites do not result in skin necrosis, and those of related spiders, including *Loxosceles rufescens, Loxosceles deserta,* and *Loxosceles arizonica,* are even milder. Brown recluse spiders are most common in the south central United States, from Tennessee and Missouri to Oklahoma and Texas. They are quite shy, and bites are uncommon. Most skin reactions diagnosed as "brown recluse bites" represent furuncles or pyoderma gangrenosum. The diagnosis can be confirmed by an enzyme immunoassay or a passive hemagglutination inhibition test.

Sphingomyelinase D is the major toxin in brown recluse venom, and hyaluronidase allows the eschars to spread in a gravity-dependent fashion. Systemic reactions include disseminated intravascular coagulation and Coombs'-positive hemolytic anemia, but these reactions are rare as well. Most bites can be treated with rest, ice, and elevation. Intradermal injection of polyclonal anti-*Loxosceles* Fab fragments or antivenin may reduce the ultimate size of the necrotic area but is not readily available. Studies with dapsone, colchicine, hyperbaric oxygen, and prednisone have generally been disappointing. Dapsone produces hemolysis, especially in individuals who have inherited glucose-6-phosphate dehydrogenase deficiency (Chapter 164). On the basis of limited animal data and anecdotal human data, intralesional triamcinolone appears to be appropriate for patients with rapidly expanding areas of necrosis.

Tegenaria agrestis is found in basements in the Pacific Northwest. In Europe, it exists as a rural spider; *Tegenaria gigantea* and *Tegenaria domestica* are more likely to be found in homes. Most reactions are mild, although some dermonecrotic reactions have been attributed to these spiders. Australian *Hadronyche* and *Atrax* spiders can produce severe pain and bleeding. Severe myocardial injury has been reported. Tarantulas can cause contact urticaria and ophthalmia nodosa related to hairs that become embedded in the cornea.

Scorpions

Local and systemic symptoms of scorpion stings are typically out of proportion to cutaneous signs. *Centruroides sculpturatus* produces somewhat more severe envenomation in the American Southwest, but the most dangerous Buthid scorpions are not found in the United States. Most fatalities involve children younger than 10 years. Toxic Buthid scorpions occur in Asia, Africa, and Latin America. Prazosin reverses the autonomic storm characteristic of the Indian red scorpion *(Mesobuthus tamulus)* and is superior to antivenin.

Tongue Worm (Pentastomiasis)

Pentastomiasis is a zoonotic infestation that sometimes affects humans. The pentastomids *Armillifer* and *Linguatula* are wormlike arthropods endemic to Asia and Africa. They commonly infest the respiratory tracts of birds, reptiles, and small mammals. In humans, severe inflammation associated with the infestation can result in coughing, hemoptysis, lacrimation, coryza, and facial edema. Rarely, asphyxiation has been reported. This syndrome is known as halzoun or marrara, meaning suffocation.

Centipedes and Millipedes

Centipedes have powerful jaws that inject a neurotoxic venom. Centipede bites may produce pain, paresthesia, erythema, edema, and profuse bleeding. Rarely, bites have been associated with coronary ischemia, rhabdomyolysis, proteinuria, and renal failure. Millipedes do not bite but cause arcuate chemical burns by a caustic substance that they secrete when threatened. They may be found in line-dried clothing, and the resulting burns may mimic child abuse.

Crustaceans as a Source of Infection

Copepods are tiny aquatic crustaceans that serve as the intermediate hosts for nematodes including the guinea worm *Dracunculus medinensis* and the sushi worm *Gnathostoma spinigerum.* They may also transmit the cestodes *Spirometra mansonoides* and *Diphyllobothrium latum.*

Pediculosis

Pediculosis is the result of infestation by sucking lice of the phylum Arthropoda, class Insecta, order Phthiraptera, suborder Anoplura, family Pediculidae or family Pthiridae. Three types of lice infest humans: *Pediculus humanus*

FIGURE 367-4. Brown recluse spiders are characterized by a dorsal violin-case pattern.

FIGURE 367-5. Dermonecrotic reactions from brown recluse spiders can be severe, but most are mild conditions. Furuncles or pyoderma gangrenosum are commonly misdiagnosed as brown recluse bites. (Image courtesy of Larry Becker, MD.)

capitis (the head louse), *Pediculus humanus humanus* (the body louse), and *Pthirus pubis* (the crab louse).

Head Lice

EPIDEMIOLOGY

Head lice affect 6 to 12 million people per year in the United States alone. Worldwide, much of the human population is affected, with highest prevalence among children between the ages of 3 and 12 years. Transmission occurs by means of direct contact or close contact of hats and scarves.

DIAGNOSIS

Head louse infestation should be suspected in any child with scalp pruritus and cervical adenopathy. Visual inspection can demonstrate nits, especially in the retroauricular area. Small bites and crusts of blood are common on the scalp.

TREATMENT Rx

Combinations of pyrethrins and piperonyl butoxide are available over-the-counter and have commonly been used before the patient seeks treatment from a physician. Pyrethrins are naturally occurring neurotoxins derived from chrysanthemums. Piperonyl butoxide prevents pyrethroid catabolism, producing a synergistic effect.

Permethrin is a synthetic pyrethroid that acts in a similar manner by inhibiting sodium transport in neurons and causing paralysis of the lice. Permethrin is also available over-the-counter. Permethrin is pregnancy category B and is often used in pregnant patients, but recent data suggest a possible association with childhood leukemia.

Lindane is an organochloride compound that is still available by prescription. Central nervous system toxicity appears rare but together with environmental concerns resulted in banning of the product in California. Malathion is a prescription organophosphate that acts by interfering with acetylcholinesterase. In the United States, it is marketed in a flammable vehicle that contributes substantially to its efficacy. There is relatively little resistance to this agent, but the trend is away from the use of neurotoxins in children and toward agents that kill lice by occlusion of the respiratory spiracles. One such agent (Ulesfia lotion) uses benzyl alcohol to stun the spiracle open and allow occlusion. A recently reported multicenter trial for difficult-to-treat head lice infestation in children showed that oral ivermectin (400 µg/kg), given twice at a 7-day interval, had superior efficacy compared with topical 0.5% malathion lotion, suggesting that it could be an alternative treatment.■

Body Lice

EPIDEMIOLOGY

Body louse infestation is common in refugee situations, during war, and among the homeless in urban areas. In this setting, lice act as a vector for *Bartonella* endocarditis. Worldwide, body lice are important vectors for epidemic typhus, louse-borne relapsing fever, and trench fever.

CLINICAL MANIFESTATIONS

Early infestation produces a widespread dermatitis that may mimic atopic dermatitis, allergic contact dermatitis, or a viral exanthem. In patients with widespread excoriations, the most likely differential diagnosis is scabies. The diagnosis is made by finding bluish maculae ceruleae (Fig. 367-6), prompting a search for body lice or nits in the seams of clothing.

TREATMENT Rx

Washing and hot drying of clothing or ironing will kill lice. Permethrin has also been used on clothing.

Crab Lice

PATHOBIOLOGY

Crab louse infestation is spread as a sexually transmitted disease. Roughly 30% of patients will have another concurrent sexually transmitted disease, and adolescents with pubic lice are twice as likely as uninfested adolescents to have chlamydial or gonorrheal infection.

FIGURE 367-6. Maculae ceruleae are bluish red spots that represent sites where body lice have fed.

CLINICAL MANIFESTATIONS

Patients present with intense itching, and both lice and nits may be found on pubic hairs as well as on the hair of the chest, abdomen, and legs. Pubic lice may occasionally cause scalp infestation in patients with thick curly hair. They may also infest the eyelashes. Maculae ceruleae may be present as in body louse infestation. These are bluish gray macules at the sites of louse bites. Underwear will commonly be stained by minute droplets of blood.

TREATMENT Rx

Treatment is by means of shaving or with topical agents used to treat head lice. Oral ivermectin has also been used as for scabies at a single dose of 200 µg/kg.

Beetle-Related Dermatitis

Blister beetles (order Coleoptera) are widespread throughout the world and include members of the families Meloidae and Staphylinidae. Members of the family Oedemeridae are classified as "false" blister beetles but can produce similar skin manifestations. Cantharidin accumulates during the larval stages of the beetle and gives it protection from predatory birds. When threatened, the beetles protect themselves by exuding a cantharidin-containing liquid. Contact with blister beetles results in vesicles and bullae. "Nairobi eye," or rove beetle dermatitis, in northern Kenya is caused by *Paederus eximius*. Rove beetles were implicated in a recent epidemic of pustular eruption among U.S. forces in Pakistan. Treatment for all manifestations of blister beetles is largely symptomatic.

Fleas

Fleas (order Siphonaptera) are ubiquitous among pets and wild animals. They serve as vectors for endemic typhus, bubonic plague, brucellosis, melioidosis, and erysipeloid. The most common flea on dogs is the cat flea, *Ctenocephalides felis*. *Pulex irritans,* the human flea, can be found on dogs and became a major plague vector during the great epidemics. Flea bites cluster on the lower legs and present as intensely pruritic papulovesicles. Tungiasis is caused by the jigger or sand flea, *Tunga penetrans.* It typically presents with a necrotic pustule adjacent to the great toenail.

A veterinarian should be consulted about agents for flea control, including lufenuron and fipronil. Beach areas should restrict pets to prevent infestation.

Flies

Mosquitoes and other flies belong to the order Diptera and represent major disease vectors. *Anopheles* mosquitoes bite mostly at night and are the major vectors of malaria. They also transmit filariasis. *Aedes* mosquitoes bite during the day and transmit dengue, viral encephalitis, yellow fever, and filariasis.

FIGURE 367-7. Bedbugs are red-brown and about the size of small ticks.

FIGURE 367-8. Bedbug bites are often arranged in a characteristic "breakfast, lunch, and dinner" pattern.

Culex mosquitoes bite at night and transmit West Nile encephalitis, filariasis, and viral encephalitis. *Culex* mosquitoes also bite at dusk or early evening. Many arthropod diseases have a principal vector but can also be spread by alternative vectors; for example, whereas *Culex* mosquitoes are the major vector for West Nile fever in the United States, *Aedes* and *Anopheles* species can also spread the disease. *Simulium* flies (blackflies, humpback flies, buffalo gnats, turkey gnats) transmit onchocerciasis. *Lutzomyia* and *Phlebotomus* sand flies transmit leishmaniasis, *Bartonella bacilliformis,* and sandfly fever. Biting midges (punkies, gnats, no-see-ums) are small enough to pass through screens and cause papulovesicular and nodular reactions in sensitive individuals. Tabanid flies include the horseflies, deer flies, and greenheads. As a group, they are large and colorful and deliver painful bites. *Chrysops* deer flies transmit loiasis in Africa and tularemia in the United States. *Glossina* tsetse flies transmit trypanosomiasis.

Furuncular myiasis caused by the botfly is common in Latin America. *Dermatobia hominis* glues its eggs to a mosquito, which serves as an intermediate vector. *Cordylobia anthropophaga*, the mango fly, tumbu fly, putzi fly, or skin maggot fly, is native to Africa and lays its eggs on drying clothing. It produces plaque-type myiasis with many maggots. *Cochliomyia hominivorax,* the screwworm, lays its eggs on wounds or mucous membranes. Screwworms are feared because they leave necrotic flesh and continue to travel through viable tissue. Sarcophagid flies deposit their living larvae on the hosts, where they produce a type of larva migrans. Myiasis is treated by means of mechanical removal with tweezers or by incision of the wound. Covering the embedded larvae with an occlusive substance, such as surgical lubricant, petrolatum, or bacon, encourages them to move upward, facilitating removal.

Prevention of vector-borne disease requires control of standing water, use of screening and mosquito netting, and personal protection with repellents. Screening impregnated with pyrethroids is more effective than untreated screening. Secondary prevention includes malaria chemoprophylaxis and early treatment of illness. Other interventions include insecticidal sprays and gas-powered mosquito traps. Most types of mosquito traps generate carbon dioxide and use chemical attractants such as octenol and butanone. Some *Culex* mosquitoes are repelled by octenol.

N,N-Diethyl-3-methylbenzamide (DEET) remains the most widely used insect repellent, although picaridin is widely used in Europe and is gaining market share in the United States. DEET has a long safety record but can occasionally cause bullous dermatitis, anaphylaxis, or toxic encephalopathy. The American Academy of Pediatrics recommends slow-release products below 30% concentration. A soybean oil–based product (Bite Blocker for Kids) is available for those who wish to avoid chemical repellents. Whereas neem oil products perform reasonably well against various mosquitoes, citronella has limited efficacy.

Hemiptera: True Bugs

Bedbugs have become pandemic and are increasingly recognized in suburban homes, in hotels, and, especially, on college campuses. They are reddish brown and about the size of small ticks (Fig. 367-7). The wings are vestigial. *Cimex lectularius* and *Cimex hemipterus* (the tropical bedbug) parasitize birds and bats, who introduce them into buildings. They also spread readily by luggage. The characteristic skin lesions are a string of bites termed breakfast, lunch, and dinner (Fig. 367-8).

Triatome reduviids are important vectors for American trypanosomiasis (Chagas' disease). Their wings overlap and are sclerotic proximally. The striped abdomen is visible lateral to the wings. Unilateral eyelid swelling (Romaña's sign) is caused by a conjunctival reaction to the bite and to triatome feces infected with trypanosomes.

Hymenoptera Stings

Hymenoptera include membranous winged insects such as wasps, bees, and fire ants. They all result in painful stings and present a potential for anaphylactic reactions. Unexpected stings occur frequently; therefore, allergic individuals must always carry a source of epinephrine, such as an EpiPen auto-injector. Bees are eviscerated during the sting, and the venom gland continues to inject additional venom. Therefore, bee stingers should be removed as rapidly as possible, with little concern for the exact method of removal. Venom immunotherapy can improve quality of life. Rush immunotherapy (a method for rapidly desensitizing patients to allergens) should be performed for those with severe reactions. Omalizumab has been used in conjunction with immunotherapy, but its exact role remains to be determined.

Lepidopterids

Moths and caterpillars may have toxic hairs that may contain histamine, kinins, plasminogen activators, and other proteinaceous toxins. The reactions are usually toxic rather than allergic in nature. Clinical manifestations include pain, erythema, swelling, and hemorrhage. Systemic reactions may include renal failure. *Lonomia* caterpillars may cause a fatal bleeding diathesis with intracranial hemorrhage. Ocular reactions to hairs include ophthalmia nodosa, keratoconjunctivitis, subconjunctival nodules, iritis, and vitreoretinal involvement. Children who ingest caterpillars may develop edema of the lips, tongue, and buccal mucosa. Esophageal and tracheobronchial involvement occurs less commonly.

Delusions of Parasitosis

These patients present with an unshakable belief that they are infested. It is difficult to help them. A careful evaluation should exclude formications secondary to cocaine addiction and pruritus related to systemic diseases such as renal failure and hyperthyroidism. Whereas delusions of parasitosis have traditionally been treated with pimozide, newer atypical antipsychotic agents such as olanzapine and risperidone are better tolerated and reduce the need for electrocardiographic monitoring of drug-induced cardiotoxicity.

LEECHES AND OTHER ANNELIDS

Leeches occur in fresh water and may be associated with *Pseudomonas* or *Aeromonas* wound infections. Leeches contain anticoagulants, and the attachment sites may bleed freely when the leech is removed. More serious coagulation disorders with massive bleeding have been reported. Saturated salt solutions have been used to facilitate leech removal but do not reduce the risk of infection.

ANTIVIRAL THERAPY (NON-HIV)

JOHN H. BEIGEL

Although some viral infections are self-limited, others can cause significant morbidity and mortality. Effective therapy is available for many of these infections. Emerging viral diseases such as coronavirus and influenza, concern about viral agents of bioterrorism, and treatment of chronic viral diseases such as hepatitis B and hepatitis C have reinvigorated the search for new antiviral agents. This chapter reviews currently available antiviral agents for the treatment of infections caused by viruses other than human immunodeficiency virus (HIV). Not all agents discussed are presently licensed in all countries.

MECHANISM OF ACTION

Currently available agents can be classified into those that directly inhibit viral replication at the cellular level (antivirals), those that modify the host response to infection (immunomodulators), and those that directly inactivate viral infectivity (antibodies, virucides, or microbicides). Antiviral agents can be further classified into two general mechanisms. First—and most numerous—are nucleic acid analogues that inhibit viral DNA or RNA synthesis by competing with endogenous nucleic acids for incorporation into the viral genome by viral DNA polymerase or RNA transcriptases. The second mechanism is inhibition of the functions of other essential viral enzymes or proteins, including those responsible for attachment to or release from cells. For example, the principal antivirals for influenza viruses inhibit viral proteins responsible for either uncoating (M2 protein) or release and spread (neuraminidase).

Antiviral strategies that are not covered in this chapter include local destructive measures that destroy both host tissues and virus simultaneously, such as cryotherapy, laser, and podophyllin treatment of warts. Although effective, such measures are useful only for discrete or localized mucocutaneous infections.

ANTIVIRALS FOR HERPESVIRUS INFECTIONS

Acyclovir and Valacyclovir

Acyclovir, which is an acyclic analogue of the nucleoside guanosine, is converted to its active form through initial monophosphorylation by a virus-encoded thymidine kinase (TK). Although normal human cells possess TK, the affinity of acyclovir for viral TK is approximately 200 times greater than for human TK. The monophosphate then undergoes two additional host cell enzyme-mediated phosphorylations to acyclovir triphosphate (acycloguanosine triphosphate), which preferentially inhibits viral DNA polymerase, competitively and through chain termination. The higher concentrations of the activated form in infected cells and its affinity for viral polymerases result in low toxicity to normal host cells.

Valacyclovir is the L-valyl ester prodrug of acyclovir. Addition of the L-valyl ester fosters greater oral absorption, after which valacyclovir is converted to acyclovir; the prodrug provides three to five times greater bioavailability than oral acyclovir.

Clinical Uses

Acyclovir and valacyclovir are used principally to treat infections caused by herpes simplex virus (HSV; Chapter 382) and varicella-zoster virus (VZV; Chapter 383). Depending on country, acyclovir is available in a topical ointment and cream, oral capsules, and intravenous and ophthalmic formulations. Valacyclovir is available only as an oral capsule.

Oral acyclovir or valacyclovir decreases the duration of symptoms by approximately 50% and reduces the duration of viral shedding by about 90% in initial episodes of genital herpes. Two or 3 days of therapy appears to be sufficient for recurrent genital herpes. Chronic suppression is highly effective in reducing clinical and viral recurrences, and valacyclovir reduces the risk of transmission of genital HSV between heterosexual partners by 48%. For herpes labialis (cold sores), 1 day of therapy with oral valacyclovir improves time to healing and reduces pain, whereas acyclovir ointment has no consistent clinical benefit.

Parenteral acyclovir is indicated for the initial treatment of mucosal or cutaneous HSV infection in immunocompromised patients, neonatal HSV infections, and disseminated or organ-invasive infections in immunocompetent patients. A subsequent switch to oral valacyclovir is possible in some circumstances. High-dose parenteral acyclovir is the therapy of choice for treatment of HSV encephalitis.

Acyclovir is also effective treatment of VZV infections, although higher doses are needed than for mucosal HSV infections (see Table 368-1). In adults treated within 24 hours of the development of a varicella rash, acyclovir decreases the severity of disease and number of lesions, but oral valacyclovir may be more effective than oral acyclovir. Intravenous acyclovir is warranted for initial treatment of varicella and zoster in immunocompromised hosts. Both acyclovir chemoprophylaxis and valacyclovir chemoprophylaxis reduce the incidence of recurrent HSV in recipients of stem cell and solid organ transplants, but valacyclovir is superior for prevention of cytomegalovirus (CMV) disease.

Toxicity

Acyclovir and valacyclovir have excellent safety profiles and are generally well tolerated. Common side effects include nausea, vomiting, and headaches. Major adverse effects include renal dysfunction and central nervous system (CNS) toxicity. Dehydration and preexisting renal dysfunction predispose to the development of renal impairment. Neurologic side effects include tremor, myoclonus, confusion, lethargy, agitation, and hallucination. Renal dysfunction predisposes to the development of neurotoxicity. Neutropenia and other signs of bone marrow toxicity have also been reported rarely.

Antiviral Resistance

Despite widespread use of acyclovir, the development of HSV resistance in immunocompetent subjects is uncommon (prevalence <1%). However, antiviral resistance is higher in immunocompromised subjects, including those with HIV infection (prevalence of 5%) or bone marrow transplants (prevalence of up to 30%). Drug-resistant, refractory VZV infections can occur in highly immunocompromised patients. Intravenous foscarnet or cidofovir may be effective for infections caused by acyclovir-resistant viruses.

Penciclovir and Famciclovir

Penciclovir is an acyclic guanine analogue that unlike acyclovir is not an obligate chain terminator and may be incorporated into DNA. Penciclovir is phosphorylated by viral TK to penciclovir monophosphate, which is then converted to penciclovir triphosphate. Penciclovir demonstrates in vitro activity against VZV and HSV comparable to that of acyclovir. The bioavailability of penciclovir after oral administration is less than 2%. In contrast, famciclovir is an oral prodrug that is deacetylated and oxidized in the liver to form penciclovir; the bioavailability of penciclovir averages 77% after administration of famciclovir.

Clinical Uses

Penciclovir and famciclovir are used to treat HSV and VZV infections. Penciclovir is available as a topical cream and in some countries as an intravenous formulation. Famciclovir is available as a capsule.

Frequent applications of topical penciclovir reduce herpes labialis pain and lesions by about 1 day. Famciclovir is approved for the treatment of recurrent HSV labialis and genital infections and for herpes zoster, for which it is as effective as valacyclovir. It is also as effective as acyclovir when it is used to treat initial genital HSV infection.

Toxicity

Penciclovir is well tolerated as a topical cream; the majority of adverse reactions are local irritation and mild erythema. Adverse effects of oral famciclovir include headache, dizziness, nausea, and diarrhea.

TABLE 368-1 ANTIVIRALS FOR HERPESVIRUS INFECTIONS

VIRAL INFECTION	DRUG	ROUTE	USUAL ADULT DOSAGE
HERPES SIMPLEX VIRUS			
Genital herpes			
First episode	Acyclovir	PO	400 mg tid or 200 mg 5 times/day for 7-10 days
	Famciclovir	PO	250 mg tid for 7-10 days
	Valacyclovir	PO	1 g bid for 7-10 days
Recurrent	Acyclovir	PO	800 mg tid for 2 days, or 400 mg tid or 200 mg 5 times/day for 5 days
	Famciclovir	PO	1000 mg bid for 2 doses
	Valacyclovir	PO	500 mg bid for 3 days or 1 g/day for 5 days
Suppression	Acyclovir	PO	400 mg bid or 200 mg tid
	Famciclovir	PO	250 mg bid
	Valacyclovir	PO	500 mg/day or 1 g/day (10 or more episodes/year)
Orolabial herpes	Penciclovir 1%	Topical	Apply cream every 2 hr while awake for 4 days
	Acyclovir 5%	Topical	Apply cream 5 times/day for 4 days
	Docosanol 10%	Topical	Apply cream 5 times/day until healing
	Valacyclovir	PO	2 g q12h × 2 doses
	Acyclovir	PO	400 mg 5 times/day for 5 days
	Famciclovir	PO	1500 mg single dose
Mucocutaneous disease	Acyclovir	IV	5 mg/kg/8 hr for 7-14 days
	Acyclovir	PO	400 mg 5 times/day for 7-14 days
	Valacyclovir	PO	500 mg or 1 g bid for 7-10 days
Encephalitis	Acyclovir	IV	10 mg/kg/8 hr for 10 days
Neonatal	Acyclovir	IV	10-20 mg/kg/8 hr for 14-21 days
Keratoconjunctivitis	Trifluridine	Topical	1 drop of 1% solution q2h up to 9 drops/day
	Vidarabine	Topical	½-inch ribbon of 3% ointment 5 times daily
Acyclovir-resistant HSV	Foscarnet	IV	40 mg/kg q8-12 h until healed.
CYTOMEGALOVIRUS			
CMV retinitis	Ganciclovir	IV	Induction: 5 mg/kg/12 hr for 14-21 days (maintenance: 5 mg/kg/day)
	Valganciclovir	PO	Induction: 900 mg bid for 21 days (maintenance: 900 mg/day)
	Cidofovir	IV	5 mg/kg once weekly × 2, then every other week (maintenance: 5 mg/kg q2wk)
	Foscarnet	IV	60 mg/kg/8 hr or 90 mg/kg q12h for 14-21 days (maintenance: 90-120 mg/kg daily)
	Fomivirsen	Intravitreal	330 µg q2wk × 2, then q4wk (maintenance: 330 µg every month)
HIV infection, CMV colitis or esophagitis	Ganciclovir	IV	5 mg/kg/12 hr for 14-28 days (until symptoms resolved)
Prophylaxis (transplantation)	Ganciclovir	IV	5 mg/kg/12 hr for 7-14 days, then 5 mg/kg IV once a day
	Valganciclovir	PO	900 mg qd
Prophylaxis (advanced HIV infection)	Ganciclovir	IV	5 mg/kg daily
VARICELLA-ZOSTER VIRUS			
Varicella	Acyclovir	PO	800 mg qid for 5 days
Varicella in immunocompromised hosts	Acyclovir	IV	10 mg/kg/8 hr for 7-10 days
Herpes zoster in immunocompromised hosts	Acyclovir	IV	10 mg/kg/8 hr for 7-10 days
Herpes zoster in normal hosts	Acyclovir	PO	800 mg 5 times daily for 7-10 days
	Valacyclovir	PO	1 g tid for 7 days
	Famciclovir	PO	500 mg tid for 7 days

TABLE 368-2 MECHANISMS OF EXCRETION AND THRESHOLDS FOR DOSE ADJUSTMENT

	MAJOR ROUTE OF ELIMINATION	THRESHOLD FOR ADJUSTMENT IN RENAL INSUFFICIENCY OR FAILURE	ADJUSTMENT FOR HEPATIC FAILURE	ADJUSTMENT FOR OBESITY
Acyclovir IV	Renal	CrCl < 50 mL/min	No adjustment	Dose by ideal body weight
Acyclovir PO	Renal	CrCl < 25 mL/min	No adjustment	Dose by ideal body weight
Valacyclovir	Renal	CrCl < 50 mL/min	No adjustment	Unknown
Famciclovir	Renal	CrCl < 60 mL/min	No adjustment	Unknown
Foscarnet	Renal	CrCl < 1.4 mL/min/kg	No adjustment	Unknown
Ganciclovir IV	Renal	CrCl < 70 mL/min	No adjustment	Unknown
Valganciclovir	Renal	CrCl < 60 mL/min	No adjustment	Unknown
Cidofovir	Renal	CrCl < 55 mL/min	No adjustment	Unknown

Antiviral Resistance

Penciclovir resistance in HSV has been uncommon in immunocompetent subjects but, like acyclovir resistance, more frequent in immunocompromised hosts (2.1%). Most acyclovir-resistant HSV isolates are cross-resistant to penciclovir.

Ganciclovir and Valganciclovir

Ganciclovir is an acyclic deoxyguanosine analogue with antiviral activity against multiple herpesviruses, including HSV, VZV, CMV (Chapter 384), Epstein-Barr virus (EBV; Chapter 385), and human herpesvirus 8. It is much more active than acyclovir against CMV and EBV.

TABLE 368-3 DRUG-DRUG INTERACTIONS

	COADMINISTERED DRUG	RISKS OR TOXICITIES	POSSIBLE MECHANISM
Acyclovir	Fosphenytoin	Decreased phenytoin plasma concentration	Decreased phenytoin absorption
	Meperidine	Increased risk for CNS stimulation and excitation	Increased meperidine metabolites
	Mycophenolate	Increased plasma concentration of acyclovir	Competition for renal secretion
	Valproic acid	Decreased valproic acid plasma concentration	Decreased valproic acid absorption
	Varicella vaccine	Decreased varicella vaccine effectiveness	Inhibition of VZV
	Zidovudine	Increased lethargy and fatigue	Unknown
Valacyclovir	Mycophenolate	Increased risk for neutropenia	Unknown
Ganciclovir	Didanosine	Increased didanosine toxicity (neuropathy, diarrhea, pancreatitis)	Increased didanosine bioavailability
	Imipenem	Increased risk for CNS toxicity (seizures)	Unknown
	Mycophenolate	Increase in plasma concentration of ganciclovir	Competition for renal secretion
	Probenecid	Increase in plasma concentration of ganciclovir	Competition for renal secretion
	Tacrolimus	Increased risk for nephrotoxicity	Additive nephrotoxicity
	Zidovudine	Increased risk for hematologic toxicity (anemia, neutropenia)	Unknown
Valganciclovir	Probenecid	Increase in plasma concentration of ganciclovir	Competition for renal secretion
	Zidovudine	Increased risk for hematologic toxicity (anemia, neutropenia)	Unknown
Cidofovir	Aminoglycosides	Nephrotoxicity	Additive nephrotoxicity
	Foscarnet	Nephrotoxicity	Additive nephrotoxicity
	Pentamidine	Nephrotoxicity	Additive nephrotoxicity
Foscarnet*	Drugs that prolong QRS	Torsades de pointes	Additive toxicity, prolongation of QRS
	Renal toxic drugs	Nephrotoxicity	Additive nephrotoxicity
Idoxuridine	Boric acid	Eye irritation	Formation of precipitate

*Many classes of drugs have added toxicity when they are administered with foscarnet. Consult a pharmacologist if you are uncertain about possible interactions.

TABLE 368-4 SIGNIFICANT ADVERSE EFFECTS (U.S. FDA BLACK BOX WARNING)

DRUG	BLACK BOX SYNOPSIS
Cidofovir	Renal impairment, including renal failure; prehydrate and use probenecid Neutropenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia
Foscarnet	Nephrotoxicity; prehydrate Seizures related to minerals and electrolyte disturbances
Ganciclovir	Neutropenia, anemia, thrombocytopenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia
Valganciclovir	Neutropenia, anemia, thrombocytopenia May be carcinogenic and teratogenic and may cause hypospermia or aspermia

The bioavailability of oral ganciclovir is less than 10%. After the oral administration of valganciclovir, which is an L-valyl prodrug of ganciclovir, bioavailability of ganciclovir averages 60%.

Clinical Uses

Ganciclovir is available as an oral capsule, a parenteral injection, and an ocular implant; valganciclovir is available only as a tablet. Ganciclovir and valganciclovir are effective for treatment of CMV retinitis, for which they are comparably active. In the absence of immune reconstitution, long-term suppression therapy is necessary.

They are also used for life-threatening CMV diseases in patients with acquired immunodeficiency syndrome (AIDS) and other immunocompromised conditions and for prevention of CMV disease in transplant patients. For immunocompromised patients with organ-invasive CMV infections, intravenous ganciclovir provides clinical response rates of 70 to 90%, although response rates are lower for CMV pneumonitis after stem cell transplantation or CMV encephalitis in patients with AIDS. Oral valganciclovir provides long-term outcomes similar to those of intravenous ganciclovir for the treatment of CMV disease.[2]

Long-term prophylaxis with ganciclovir or valganciclovir reduces the incidence of CMV disease after solid organ and stem cell transplantation, but this therapy has substantial side effects, including bone marrow suppression. These drugs can also be used as preemptive therapy for patients who have CMV viremia or antigenemia. In the prevention of CMV disease, preemptive valganciclovir therapy may be equally effective to chronic valacyclovir prophylaxis.[3] Intravenous ganciclovir is the recommended agent for treatment of herpesvirus B infections, particularly those involving the CNS.

Toxicity

The most common adverse effect with ganciclovir and valganciclovir is bone marrow suppression, particularly neutropenia and thrombocytopenia, which occur in up to 50% of patients given intravenous ganciclovir. Fever, edema, phlebitis, headache, neuropathy, disorientation, nausea, anorexia, rash, and myalgias have also been reported with ganciclovir therapy. Intravitreal ganciclovir implants may cause vitreous hemorrhage and retinal detachment.

Antiviral Resistance

Ganciclovir resistance secondary to mutations in CMV kinase and sometimes DNA polymerase is related to the length of ganciclovir exposure and the degree of immunosuppression. Resistance may be associated with progressive disease during continued ganciclovir use; foscarnet and cidofovir are alternative treatments.[4]

Cidofovir

Cidofovir, which is an acyclic phosphonate derivative of cytosine, is phosphorylated to its active diphosphate form by host cellular enzymes. Cidofovir diphosphate competitively inhibits viral DNA polymerase and viral DNA synthesis. Despite a short serum half-life, the antiviral effects are protracted because of prolonged intracellular concentrations of the phosphorylated metabolite.

Clinical Uses

Cidofovir is commercially available as an intravenous infusion. Investigational uses have included topical gel and intravitreal and intralesional injection.

Intravenous cidofovir is indicated in AIDS patients for CMV retinitis for which ganciclovir or foscarnet therapy is failing. Limited data suggest that intravenous cidofovir may be effective in other CMV infections (pneumonitis, gastroenteritis), acyclovir- or foscarnet-resistant HSV infections, certain forms of human papillomavirus disease, invasive adenoviral infections in transplant recipients, and possibly BK virus infection in renal transplant patients. In addition, in vivo and animal data suggest efficacy of cidofovir against smallpox, vaccinia, and monkeypox infections, although clinical trials are lacking.

Toxicity

Dose-related nephrotoxicity, characterized by increased serum creatinine, proteinuria, and tubular dysfunction, is the main side effect of intravenous cidofovir. Adequate hydration and concomitant oral probenecid reduce the

risk. Other common side effects include diarrhea, asthenia, nausea, vomiting, neutropenia, fever, and rash. Iritis, intraocular pressure changes, loss of visual acuity, and uveitis have been reported with intravenous cidofovir. Intravitreal cidofovir is effective but locally toxic.

Antiviral Resistance

Sustained exposure to cidofovir does not easily induce resistance, although resistance has infrequently been described in HSV and CMV.

Foscarnet

Foscarnet is a pyrophosphate analogue that acts as a noncompetitive inhibitor of many viral RNA and DNA polymerases. When a nucleotide is incorporated into a DNA or RNA strand by a polymerase, pyrophosphate is released. Foscarnet directly inhibits viral polymerases without phosphorylation, so TK-deficient acyclovir-resistant HSV and VZV are susceptible to this agent.

Clinical Uses

Foscarnet is as effective as ganciclovir for the treatment of CMV retinitis in patients with AIDS, and combination therapy with ganciclovir may be superior to monotherapy with either agent for recalcitrant retinitis. For extraretinal CMV disease, foscarnet has demonstrated efficacy similar to that of ganciclovir. The choice of agent may be dictated by the side effect profile. Foscarnet is also effective for the treatment of acyclovir-resistant HSV and VZV infections.

Toxicity

Nephrotoxicity with azotemia and proteinuria is dose limiting and occurs in more than a third of patients. A slow infusion rate and saline hydration reduce the risk. Other common side effects include anemia (30 to 50% of patients), granulocytopenia, diarrhea, nausea, vomiting, fever, seizures, paresthesias, headache, and genital ulcers. Marked electrolyte disturbances may develop, including hypophosphatemia, hypocalcemia, hypokalemia, and hypomagnesemia. Foscarnet can prolong the QT interval and be associated with cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes.

Antiviral Resistance

The development of CMV resistance to foscarnet as a result of mutations in viral DNA polymerase is uncommon, except after prolonged administration. In AIDS patients with retinitis, foscarnet resistance is detectable in 13% of patients at 6 months and in 37% at 12 months.

Fomivirsen

Fomivirsen, which is an antisense oligonucleotide that inhibits CMV replication, is currently available as an intravitreal injection that is effective for both newly diagnosed CMV retinitis and CMV retinitis failing usual therapies, although direct comparisons with other agents are lacking. Intravitreal administration of fomivirsen may cause increased intraocular pressure, iritis, vitreitis, and cataracts in 10 to 20% of patients.

Brivudine

Brivudine, also known as bromovinyldeoxyuridine, is a thymidine analogue that is currently licensed for the treatment of herpes zoster in several European Union countries but not in the United States. Its efficacy is comparable to that of acyclovir, with similar time to crusting and cessation of pain. Common side effects include nausea, vomiting, abdominal discomfort, and anorexia.

Docosanol

Docosanol, which is a 22-carbon saturated fatty alcohol that inhibits intracellular penetration of lipid enveloped viruses, is approved as a cream for the treatment of herpes labialis. Frequent topical applications have shown reductions in time to cessation of pain and healing, but direct comparison to other agents is lacking. Local reaction, rash, and pruritus are common side effects.

Idoxuridine and Trifluorothymidine

Idoxuridine and trifluorothymidine (trifluridine) are thymidine analogues that are phosphorylated by both viral and cellular TKs to active triphosphate derivatives that inhibit both viral and cellular DNA synthesis. The result is antiviral activity but also host cytotoxicity, which prevents safe systemic use. However, the tolerability of these compounds is adequate for topical use. Both idoxuridine and trifluorothymidine are available as ophthalmic formulations and are licensed for the treatment of herpetic keratitis. In direct comparison, trifluridine appears to be the more efficacious of these compounds. In addition, idoxuridine in dimethyl sulfoxide has been used topically in some countries for treatment of mucosal herpes infections. The most frequent adverse effects with trifluridine are transient burning or stinging on instillation and palpebral edema. Irritation and punctate corneal defects have been reported with idoxuridine.

Vidarabine

Vidarabine, an adenosine analogue, is now available only as an ophthalmic ointment indicated for acute keratoconjunctivitis and recurrent epithelial keratitis secondary to HSV. Its clinical activity appears to be superior to that of idoxuridine. Toxicities of the ointment include conjunctival injection, burning, and irritation.

ANTIVIRALS FOR INFLUENZA VIRUS INFECTIONS

Adamantanes (Amantadine, Rimantadine)

Amantadine and rimantadine are symmetrical tricyclic amines with activity against many influenza A viruses (Chapter 372). By inhibiting the ion channel function of the M2 protein of influenza A, they interfere with uncoating of the virus and release of the viral genome.

Clinical Uses

Amantadine and rimantadine (Tables 368-5 to 368-7) decrease the length and severity of uncomplicated influenza A virus infection by susceptible strains if they are initiated within the first 2 days after the onset of symptoms, but it is uncertain whether they reduce the risk for complications. Both drugs are formulated for oral administration: capsules for amantadine and tablets for rimantadine as well as pediatric syrups. In recent years, marked increases in antiviral resistance in community isolates have limited the utility of these drugs.

Both rimantadine and amantadine are effective when they are used for prophylaxis against influenza A illness (overall 66% average for rimantadine and 74% for amantadine). In persons who take the drug for prophylaxis, subclinical infections may still develop and elicit immune responses that will protect them when they are exposed to antigenically related viruses.

Amantadine is also used in the treatment of parkinsonism, for drug-induced extrapyramidal reactions, and in the management of multiple sclerosis symptoms.

Toxicity

Amantadine causes CNS side effects in 10 to 30% of healthy young adults who take the standard adult dose of 200 mg/day; the frequency is significantly lower with rimantadine. Neuropsychiatric side effects include anxiety, nervousness, insomnia, and, particularly in the elderly or those with renal insufficiency, hallucinations, confusion, disorientation, and psychosis or coma. Amantadine or less often rimantadine is associated with an increased risk for seizures. Both drugs cause gastrointestinal side effects. Orthostatic hypotension occurs in 1 to 5%. Anticholinergic side effects, including dry mouth, occur in amantadine recipients.

TABLE 368-5 ANTIVIRALS FOR INFLUENZA VIRUS INFECTIONS

VIRUS	DRUG	ROUTE	USUAL ADULT TREATMENT DOSAGE
Influenza A and B virus	Oseltamivir	PO	75 mg bid for 5 days
	Zanamivir	Inhalation	10 mg bid by inhaler for 5 days
Influenza A virus	Amantadine	PO	100 mg bid or 200 mg qd for 5 days
	Rimantadine	PO	100 mg bid for 5 days

TABLE 368-6 MECHANISMS OF EXCRETION AND THRESHOLDS FOR DOSE ADJUSTMENTS

	MAJOR ROUTE OF ELIMINATION	THRESHOLD FOR ADJUSTMENT IN RENAL INSUFFICIENCY OR FAILURE	ADJUSTMENT FOR HEPATIC FAILURE	SPECIAL ADJUSTMENT FOR THE ELDERLY
Amantadine	Renal	CrCl < 50 mL/min	No adjustment	>65 yr: 100 mg daily
Rimantadine	Hepatic and renal	CrCl < 10 mL/min/1.72 m^2	100 mg daily	100 mg daily
Oseltamivir	Renal	CrCl < 30 mL/min/1.72 m^2	No adjustment	
Zanamivir	Renal	No adjustment	No adjustment	

TABLE 368-7 DRUG-DRUG INTERACTIONS

	COADMINISTERED DRUG	RISKS OR TOXICITIES	POSSIBLE MECHANISM
Amantadine	Anticholinergics	Dry mouth, constipation, decreased urination, sedation, blurred vision	Additive anticholinergic effect
	Benztropine	CNS toxicity (confusion, hallucinations)	Unknown
	Bupropion	Nausea, vomiting, excitation, restlessness, postural hypotension	Unknown
	Triamterene	Incoordination, agitation, visual hallucinations	Decreased amantadine clearance
	Trimethoprim	CNS toxicity (insomnia, confusion)	Decreased amantadine clearance

Antiviral Resistance

Single point mutations in M2 confer high-level resistance to these drugs and make them ineffective. Such resistant variants emerge commonly during treatment and are transmissible. In 2005-2006, the frequency of resistance in influenza A (H3N2) viruses was as high as 92% in the United States. Resistance is also present in some seasonal H1N1 and many H5N1 and pandemic H1N1 viruses.

Neuraminidase Inhibitors (Oseltamivir, Zanamivir, Peramivir)

Zanamivir, oseltamivir, and peramivir are sialic acid analogues that inhibit influenza virus neuraminidases by competitively interacting with the active enzyme site of influenza A and B viruses, including adamantine-resistant strains. Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin. These drugs inhibit this action, which is essential for release of virus from infected cells, prevention of viral aggregates, and spread within the respiratory tract.

Oseltamivir is administered orally as the phosphate prodrug, which is rapidly absorbed and hydrolyzed to the active form oseltamivir carboxylate. The oral bioavailability of zanamivir is poor, and it is currently licensed to be delivered as an orally inhaled powder. Peramivir, an intravenous neuraminidase inhibitor, is not licensed but was previously made available for use under an emergency use authorization, a mechanism by which the U.S. Food and Drug Administration (FDA) allows the use of an unapproved medical product during certain types of emergencies, such as pandemic influenza.

Clinical Uses

Oseltamivir and zanamivir are effective for the treatment and prophylaxis of acute influenza A and B infections. Early treatment in adults decreases the duration and severity of illness and reduces lower respiratory tract complications, antibiotic use, and, with oseltamivir, hospitalizations. In cohort studies, treatment with oseltamivir has been associated with a significant reduction in death (odds ratio, 0.21). Zanamivir is also effective in alleviating symptoms and decreasing the risk for lower respiratory complications. Both zanamivir and oseltamivir are highly effective for the prevention of influenza. Peramivir may be useful in patients who are not responding to either oseltamivir or zanamivir antiviral therapy.

Toxicity

The most common side effects with oseltamivir are nausea and vomiting. It may also be associated with headache, rash, and possibly abnormal transaminases. Zanamivir is generally well tolerated, but bronchospasm (sometimes severe) has been reported primarily in patients with underlying airway disease. The most common side effects of peramivir are nausea, diarrhea, and mild neutropenia.

Antiviral Resistance

Oseltamivir resistance as a result of neuraminidase mutations has been detected during treatment of seasonal influenza, more often in children than in adults and recently in H5N1- and H1N1-infected patients. In the immunocompromised host, and possibly in individuals with H5N1 or H1N1, the development of resistance is associated with treatment failure. Zanamivir retains clinical effectiveness against the most common oseltamivir-resistant variant.■

TABLE 368-8 ANTIVIRALS FOR HEPATITIS VIRUS INFECTIONS

VIRAL INFECTION	DRUG	ROUTE	USUAL ADULT DOSAGE
Chronic hepatitis C*	PEG-interferon alfa-2a *or* PEG-interferon alfa-2b	SC	180 µg weekly for 48 wk
	plus ribavirin	SC	1.5 µg/kg weekly for 48 wk
		PO	800-1200 mg/day, depending on weight
Chronic hepatitis B	Interferon alfa-2b	SC, IM	5 MU/day or 10 MU 3 times weekly for 16-24 wk
	PEG-interferon alfa-2a	SC	180 µg weekly for 48 weeks
	Entecavir Naive virus	PO	0.5 mg daily; optimal duration of therapy is unknown
	Lamivudine resistant virus	PO	1 mg daily; optimal duration of therapy is unknown
	Lamivudine	PO	100 mg/day
	Adefovir	PO	10 mg/day
	Telbivudine	PO	600 mg/day

*Genotypes 2 and 3 may tolerate shorter treatment.

ANTIVIRALS FOR HEPATITIS VIRUS INFECTIONS

Adefovir

Adefovir, an acyclic analogue of adenosine monophosphate, is administered orally as a prodrug, adefovir dipivoxil, which is rapidly converted enzymatically to adefovir in intestinal epithelium.

Clinical Uses

In chronic hepatitis B (Chapter 151), prolonged administration of adefovir is effective in improving histologic abnormalities of the liver, decreasing hepatitis B virus (HBV) DNA levels, and normalizing biochemical (alanine aminotransferase) markers in patients with hepatitis B e antigen (HBeAg)–positive and HBeAg-negative chronic hepatitis B (Tables 368-8 to 368-11). Adefovir has been shown to be effective against chronic hepatitis B resistant to lamivudine. The combination of lamivudine and adefovir may decrease the emergence of resistant virus but does not have additive or synergistic antiviral activity.

TABLE 368-9 MECHANISMS OF EXCRETION AND THRESHOLDS FOR DOSE ADJUSTMENT

	MAJOR ROUTE OF ELIMINATION	THRESHOLD FOR ADJUSTMENT IN RENAL INSUFFICIENCY OR FAILURE	ADJUSTMENT FOR HEPATIC FAILURE	SPECIAL ADJUSTMENT FOR ELDERLY
Adefovir	Renal	CrCl < 50 mL/min	No adjustment	
Entecavir	Renal	CrCl < 50 mL/min	No adjustment	
Lamivudine	Renal	CrCl < 50 mL/min	No adjustment	
Tenofovir	Renal	CrCl < 50 mL/min	No adjustment	
Ribavirin	Renal	CrCl < 50 mL/min	No adjustment	
PEG-interferon alfa-2a	Renal	CrCl < 50 mL/min	Progressive rise in alanine transaminase	>60 yr: consider reduction
Telbivudine	Renal	CrCl < 50 mL/min	No adjustment	

TABLE 368-10 DRUG-DRUG INTERACTIONS

	COADMINISTERED DRUG	RISKS OR TOXICITIES	POSSIBLE MECHANISM
Lamivudine	Ribavirin	Lactic acidosis	Unknown
	Sulfamethoxazole	Increased risk for lamivudine adverse effects	Competition for renal secretion
	Trimethoprim	Increased risk for lamivudine adverse effects	Competition for renal secretion
	Zalcitabine	Increased zalcitabine and lamivudine exposure	Inhibition of phosphorylation
Tenofovir	Atazanavir	Decreased atazanavir concentration or increased tenofovir levels	Unknown
	Didanosine	Increased didanosine plasma concentration and risk for toxicity	Increased didanosine bioavailability
	Lopinavir	Increased tenofovir bioavailability	Unknown
	Ritonavir	Increased tenofovir bioavailability	Unknown
Ribavirin	Nucleoside analogues	Lactic acidosis	Unknown
	Interferon alfa-2b	Worsening mental depression, anger, and hostility	Unknown
Interferon alfa-2	Angiotensin-converting enzyme inhibitors	Hematologic abnormalities (granulocytopenia, thrombocytopenia)	Unknown
	Colchicine	Decreased interferon alfa-2a effectiveness	Unknown
	Theophylline	Theophylline toxicity (nausea, vomiting, palpitations, seizures)	Unknown
	Ribavirin	Worsening mental depression, anger, and hostility	Unknown

TABLE 368-11 SIGNIFICANT ADVERSE EFFECTS (U.S. FDA BLACK BOX WARNING)

DRUG	BLACK BOX SYNOPSIS
Adefovir	Severe acute exacerbations of hepatitis B may occur with cessation of therapy Nephrotoxicity may occur in patients at risk for or undergoing renal dysfunction Lactic acidosis and severe hepatomegaly with steatosis
Entecavir	Lactic acidosis and severe hepatomegaly with steatosis; severe acute exacerbations of hepatitis B may occur with cessation of therapy
Lamivudine	Severe acute exacerbations of hepatitis B may occur with cessation of therapy Lactic acidosis and severe hepatomegaly with steatosis
Ribavirin	Monotherapy for hepatitis C is not effective Hemolytic anemia Teratogenic and embryocidal
Interferon alfa	May cause or aggravate neuropsychiatric, autoimmune, ischemic, and infectious disorders
Telbivudine	Severe acute exacerbation of hepatitis B may occur with cessation of therapy Lactic acidosis and severe hepatomegaly with steatosis

Toxicity

The major adverse effect is nephrotoxicity, manifested by increased serum creatinine and sometimes hypophosphatemia, both of which are usually reversible with discontinuation of the drug. Common side effects include asthenia, headache, nausea, vomiting, and diarrhea. In addition, severe exacerbations of hepatitis B have been observed after cessation of therapy.

Antiviral Resistance

Adefovir resistance secondary to point mutations in HBV polymerase develops in about 6% of patients after 3 years of adefovir therapy. Lamivudine generally retains activity against adefovir-resistant variants.

Entecavir

Entecavir, which is a deoxyguanosine nucleoside analogue with specific antiviral activity for hepadnaviruses, is more potent than lamivudine and also retains some activity against lamivudine-resistant HBV variants. It is well absorbed after oral administration, and its prolonged half-life (128 to 149 hours) allows once-daily dosing.

Clinical Uses

Entecavir is approved for the treatment of chronic hepatitis B in adults with evidence of active viral replication and either persistent elevations in serum aminotransferases or histologically active disease. Compared with lamivudine, entecavir is more efficacious in reducing HBV DNA levels and normalizing serum aminotransferases as well as in improving histologic abnormalities.[368] Higher doses and longer durations of therapy are indicated for lamivudine-resistant infections. Entecavir is not recommended in patients who have HIV/HBV coinfection and who are not receiving concurrent highly active antiretroviral therapy because of the risk of resistance to HIV nucleoside reverse transcriptase inhibitors.

Toxicity

Adverse effects reported during entecavir therapy include headache, fatigue, dizziness, nausea, abdominal pain, rhinitis, fever, diarrhea, cough, and myalgia. Lactic acidosis and severe hepatomegaly with steatosis have been reported. Severe exacerbations of hepatitis B have been observed after cessation of therapy.

Antiviral Resistance

Entecavir resistance, caused by specific mutations in HBV polymerase, appears to be uncommon, with no evidence after more than 1 year of drug exposure.

Lamivudine

Lamivudine is a deoxycytidine nucleoside analogue active against retroviruses and hepadnaviruses. The triphosphate inhibits HBV polymerase, and its incorporation into viral DNA results in termination of the DNA chain.

Clinical Uses

Prolonged lamivudine administration to patients with chronic hepatitis B suppresses viral replication, improves histologic abnormalities of the liver, reduces progression of fibrosis, and decreases the risk for late complications, but monotherapy with lamivudine appears to be inferior to monotherapy with interferon for sustained control of HBV replication. Combination therapy with lamivudine and interferon has shown inconsistent benefit compared with either drug alone.

Toxicity

Adverse effects of lamivudine include diarrhea, headache, and elevated liver enzymes. Severe post-treatment exacerbations of hepatitis B, including fatalities, have occurred with discontinuation of lamivudine, more commonly in patients coinfected with HBV and HIV.

Antiviral Resistance

Lamivudine resistance, caused by mutations in HBV polymerase, is common during prolonged treatment of hepatitis B and emerges in about 20% of treated patients annually. Resistance is associated with increases in viral replication and aminotransferases.

Tenofovir

Tenofovir is a nucleotide analogue of adenosine monophosphate. The commercially available agent, tenofovir disoproxil fumarate, is an ester prodrug of tenofovir and gives an effective tenofovir bioavailability of 25%.

Clinical Uses

Treatment with tenofovir is more effective than adefovir in producing histologic improvement and viral suppression in patients with HBeAg-negative or HbeAg-positive chronic hepatitis B.■ In HBV-HIV coinfection, combination antiretroviral therapy that includes tenofovir leads to significantly reduced HBV DNA levels compared with combination therapy with adefovir.

Toxicity

Tenofovir is generally well tolerated; the most common side effects are nausea, diarrhea, vomiting, and anorexia. Lactic acidosis with hepatic steatosis has been reported, primarily when it is used in combination with other nucleoside analogues. Acute exacerbations of hepatitis B have been reported after discontinuation of tenofovir in patients who are coinfected with HIV and HBV.

Antiviral Resistance

Mutations in HBV polymerase that confer reduced susceptibility to tenofovir occur during prolonged use (>12 months), although the clinical significance of these mutations remains to be defined.

Telbivudine

Telbivudine is a synthetic thymidine nucleoside analogue with activity against HBV, including some lamivudine-resistant variants. The triphosphate form competitively inhibits the HBV DNA polymerase (reverse transcriptase).

Clinical Uses

Telbivudine is used for the treatment of chronic hepatitis B. In comparative trials against lamivudine or adefovir, telbivudine demonstrated greater virologic response at week 52 (60% vs. 40% of subjects HBV DNA negative by polymerase chain reaction analysis).

Toxicity

Common side effects include headache, nausea, and vomiting. Severe acute exacerbations of hepatitis B have been reported in patients who have discontinued anti-HBV therapy. Myopathy, manifested by muscle aches or weakness with increased creatine kinase, has rarely been reported.

Ribavirin

Ribavirin is a purine nucleoside with antiviral activity against some DNA viruses and many RNA viruses, including influenza A and B, parainfluenza, measles, respiratory syncytial virus (RSV), retroviruses, arenaviruses such as Lassa virus, and some hantaviruses.

Clinical Uses

Monotherapy with ribavirin for chronic hepatitis C (Chapter 151) has been shown to decrease serum alanine aminotransferase but not hepatitis C virus RNA levels. However, combination therapy with ribavirin and various interferons, most recently pegylated interferons, is superior to interferon monotherapy, improves viral clearance and liver histologic responses, and reduces complications, including mortality. Ribavirin plus pegylated interferon has become the standard treatment of chronic hepatitis C.

Aerosol administration of ribavirin has been used to treat RSV bronchiolitis and pneumonia in children and to treat influenza A and B infections. Limited benefit has been seen with oral ribavirin in uncomplicated influenza. Aerosol ribavirin combined with intravenous immune globulin, particularly with the anti-RSV monoclonal antibody palivizumab, appears to reduce the mortality of RSV infection in bone marrow transplant and other highly immunocompromised patients.

Systemic ribavirin reduces the mortality associated with Lassa fever and Asian (Korean) hemorrhagic fever with renal syndrome (Chapter 389), although not mortality in patients with hantavirus-associated cardiopulmonary syndrome. It appears to have activity in Congo-Crimean hemorrhagic fever and in Nipah virus infections. Ribavirin is often recommended as treatment of hemorrhagic fevers of unknown etiology or secondary to arenaviruses or bunyaviruses in the event that these viruses are used as biologic weapons.

Toxicity

Aerosol delivery may cause bronchospasm. Systemic ribavirin is frequently associated with hemolytic anemia (in up to 61% in some series) and sometimes with electrolyte abnormalities, including hypocalcemia and hypomagnesemia. Arrhythmias, pruritus, rash, nausea, and myalgia have been reported, as have neurologic side effects, including insomnia and irritability. Ribavirin is gonadotoxic and teratogenic in multiple species.

Emtricitabine

Emtricitabine is an analogue of cytidine. It is currently licensed only for the treatment of HIV infection. However, in a large study of patients with chronic hepatitis B, monotherapy with emtricitabine led to significantly better histologic response (62% vs. 25%) and virologic suppression (54% vs. 2%) at 48 weeks compared with placebo.

Interferons

Interferons are glycoprotein cytokines with a complex array of antiviral, immunomodulating, and antineoplastic properties. Interferons are currently classified as α, β, or γ; the natural sources of these classes, in general, are leukocytes, fibroblasts, and lymphocytes, respectively. Each type of interferon can now be produced through recombinant DNA technology. Although the full mechanism of interferon's action is not defined, interferons generally induce synthesis of new cellular RNA and proteins that mediate antiviral effects through multiple different mechanisms.

Interferons generally require administration daily or several times per week. However, the combination of interferon with polyethylene glycol to form pegylated interferon significantly prolongs absorption, decreases elimination, and provides higher, more sustained plasma levels that enable administration once weekly.

Clinical Uses

In chronic active hepatitis B, treatment with interferon alfa leads to loss of HBV DNA and biochemical and histologic improvement in about 25 to 40% of patients. Administration of PEG-interferon alfa-2a or alfa-2b for 48 weeks converts about 30% of patients to seronegative status after 6 months of treatment. Combination therapy with interferon and lamivudine is not clearly superior to interferon alone.

In contrast to hepatitis B, combination therapy is the mainstay of treatment of hepatitis C. Subcutaneous administration of PEG-interferon alfa-2a plus daily ribavirin for 48 weeks results in a sustained virologic response in about 55% of treated patients, compared with less than a 30% response with interferon monotherapy. Patients with hepatitis C genotype 1 have lower levels of response than do patients with genotype 2 or 3 (46% vs. 76%). Patients with genotypes 2 and 3 may need only 24 weeks of combination therapy. Shorter durations of therapy (14 weeks) have lower sustained virologic response.

Toxicity

Common side effects of interferon administration include influenza-like symptoms (fever, chills, headache, and malaise), but these symptoms usually become less severe with repeated treatments; tolerance develops in most patients within several weeks. Major toxicities have included bone marrow

suppression, primarily granulocytopenia, and thrombocytopenia, which are generally reversible when therapy is discontinued. Neuropsychiatric disturbance may be manifested by depression, anxiety, somnolence, confusion, and behavioral disturbance. Other side effects include profound fatigue and anorexia, weight loss, hypothyroidism or hyperthyroidism, alopecia, and cardiotoxicity with arrhythmias and reversible cardiomyopathy.

OTHER ANTIVIRALS

Imiquimod

Imiquimod and the related compound resiquimod are topical immune response modifiers that lack direct antiviral effects. Instead, these agents induce activation of immune cells (monocytes, macrophages, natural killer cells) to produce antiviral cytokines, particularly interferon-α and tumor necrosis factor-α.

Topical imiquimod cream is approved for the treatment of anogenital warts (Chapter 381). In immunocompetent patients, imiquimod leads to complete clearance of warts in 37 to 52% of patients. It may also be beneficial in patients with refractory cutaneous leishmaniasis (Chapter 356) and for molluscum contagiosum (Chapter 380). It is administered as a topical cream three times weekly for a maximum of 16 weeks and is washed off 6 to 10 hours after application.

Side effects are primarily local and include erythema, irritation, tenderness, and, less often, erosion. The side effects usually resolve with cessation of the drug.

369

THE COMMON COLD

RONALD B. TURNER

DEFINITION

The common cold is an upper respiratory syndrome of rhinorrhea and nasal obstruction, frequently accompanied by sore throat, sneezing, and cough. This viral syndrome is among the most common illnesses of humankind.

The Pathogens

The rhinoviruses cause at least half of all common cold illnesses. The rhinoviruses, which are RNA viruses that infect the respiratory epithelium, have long been known as common cold viruses, but they also are important causes of exacerbations of chronic bronchitis and asthma. More recent data suggest that rhinoviruses may also be associated with bronchiolitis in young children.

The coronaviruses (Chapter 374), parainfluenza viruses (Chapter 371), respiratory syncytial virus (Chapter 370), metapneumoviruses, adenoviruses (Chapter 373), and influenza viruses (Chapter 372) may also cause common cold illnesses (Table 369-1). Bocavirus has recently been associated with the common cold, but these viruses are also frequently isolated from healthy control subjects, so their role as pathogens is uncertain. Bacterial pathogens such as *Bordetella pertussis* (Chapter 321) and group A streptococcus (Chapter 298) are occasionally associated with rhinorrhea, but these illnesses are generally readily distinguished from the common cold.

EPIDEMIOLOGY

The incidence of common colds decreases with age, from at least six episodes per year in young children to approximately two episodes per year in adults. The incidence of illness is higher in adults who have occupational or household exposure to children and in children who are cared for in childcare centers. Common cold illnesses occur year-round in temperate climates but have a substantially increased incidence between the early autumn and late spring. This common cold "season" consists of sequential outbreaks caused by the different respiratory viruses. In tropical climates, colds occur year-round without defined seasonality.

PATHOBIOLOGY

Respiratory pathogens are spread from person to person by direct contact with either infected individuals or contaminated objects in the environment, by large-particle aerosols, or by small-particle aerosols. The rhinoviruses appear to be spread most efficiently by direct contact. Respiratory syncytial virus (Chapter 370) may be spread by either direct contact or large-particle aerosols, and influenza (Chapter 372) may be spread by small-particle aerosols.

Regardless of the route of spread, the common cold syndrome is initiated by infection of the nasal epithelium. Influenza and adenovirus produce obvious damage to the respiratory epithelium. Rhinovirus and respiratory syncytial virus, in contrast, have little or no detectable impact on the epithelium. Regardless of the histopathology, all of these viruses stimulate a nonspecific host inflammatory response that appears to be responsible for many of the symptoms associated with the common cold (Fig. 369-1).

The nasal obstruction of the common cold appears to result primarily from increased nasal blood flow and pooling of blood in the capacitance vessels of the nose. The increase in nasal secretion associated with the common cold may also contribute to the nasal obstruction. Rhinorrhea is primarily a result of increased vascular permeability with leakage of serum into the nasal secretions. Increased mucus production contributes to the secretions during the later stages of the illness.

Multiple factors may play a role in the pathogenesis of cough. Cough may be related to infection of the lower airway, irritation of upper airway receptors with neurologically mediated airway reactivity, or postnasal drip with pharyngeal irritation.

The risk of infection after exposure to the respiratory viruses is primarily dependent on the presence of specific neutralizing antibodies. Antibody responses to the rhinoviruses, adenoviruses, and influenza viruses are

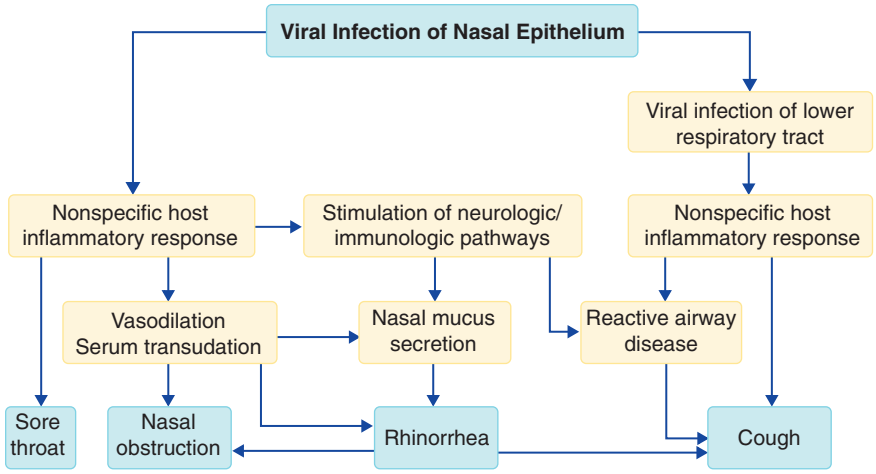

FIGURE 369-1. **Proposed pathogenesis of common cold symptoms.** (Modified from Richmond D, Hayden FG, Whitley R, eds. *Clinical Virology*, 3rd ed. Washington, DC: ASM Press; 2009:1073.)

protective against subsequent infection. The frequency of infection with these viruses is a result of the large number of distinct serotypes of rhinovirus and adenovirus and the ability of the influenza viruses to behave as though there are multiple virus serotypes by virtue of the rapid mutation of the antigens presented on the surface of the virus. The parainfluenza viruses, respiratory syncytial viruses, and metapneumoviruses do not produce protective immunity, so reinfection is common although preexisting antibody moderates the severity of illness.

Mannose-binding lectin deficiency has been associated with an increased incidence of common colds in young children. Protection by this innate response may become less important as children experience a variety of infections and develop specific immunity. Polymorphisms that enhance inflammatory cytokine responses may be associated with more severe respiratory illness.

CLINICAL MANIFESTATIONS

The incubation of common cold illness is generally short, ranging from 2 to 8 days, although the adenoviruses may have an incubation of as long as 13 days. A sore or scratchy throat is frequently reported as the first manifestation. Sneezing is also a common early symptom. Nasal obstruction and rhinorrhea develop rapidly and, by day 2 or 3 after the onset of illness, are the most bothersome symptoms. Cough generally develops later in the illness and frequently is the most bothersome symptom as the cold resolves. Common cold illnesses generally persist for about 1 week, although about 25% may persist for as long as 2 weeks.

Physical findings are restricted to the upper respiratory tract. Increased nasal secretion may be obvious to the examiner. A change in the color or consistency of nasal secretions is common during the course of the illness and is not indicative of sinusitis or bacterial superinfection.

DIAGNOSIS

The differential diagnosis of the common cold includes noninfectious disorders as well as other upper respiratory tract infections. Allergic rhinitis (Chapter 259) has a symptom complex similar to that of the common cold, although the presence of nasal or conjunctival itching suggests allergic disease. Most patients can reliably differentiate these illnesses.

Sinus involvement is present in uncomplicated cold illnesses, and superimposed bacterial sinusitis (Chapter 434) is difficult to differentiate from an uncomplicated cold. Rhinorrhea that persists without improvement for more than 10 days may suggest the presence of bacterial sinusitis that will respond to antibiotics.

Routine laboratory studies are not helpful for the diagnosis or management of the common cold. Although the viral pathogens associated with the common cold may be detected by culture, antigen detection, polymerase chain reaction, or serologic methods, these studies are of little value unless treatment with an antiviral agent is contemplated.

TREATMENT

Rx

Specific antiviral therapy is generally not useful for the treatment of common cold illnesses. The neuraminidase inhibitors oseltamivir and zanamivir (Chapter 368) have a modest effect on influenza virus infections, but the difficulty of distinguishing influenza from other common cold pathogens and the need to start treatment early in the illness for maximum benefit are practical limitations to the use of these agents for mild upper respiratory infections. Antibacterial therapy is of no benefit in the treatment of the common cold.

Management of the common cold relies on symptomatic remedies. Treatments for nasal obstruction, rhinorrhea, and sore throat have demonstrated efficacy in adults but are not clearly beneficial in children and are not recommended for children younger than 4 years.

TABLE 369-2 TREATMENTS FOR THE COMMON COLD

DRUG	DOSE AND DURATION	SIDE EFFECTS
Topical adrenergic agents: oxymetazoline	2-3 sprays of 0.05% soln every 12 hr as needed for up to 3 days	Rebound nasal congestion with prolonged use Nasal stinging or burning
Oral adrenergic agents: pseudoephedrine	60 mg every 4-6 hr up to 240 mg/day as needed for nasal congestion	Insomnia Agitation
Antihistamines: chlorpheniramine	4 mg orally every 4-6 hr up to 24 mg/day as needed for rhinorrhea or sneezing	Sedation
Anticholinergics: ipratropium bromide	2 sprays per nostril of 0.06% soln every 6-8 hr as needed for rhinorrhea	Nasal dryness

Nasal Congestion

Both topical and oral adrenergic agents (Table 369-2) are effective nasal decongestants. Although direct comparison has not been performed in the common cold, it is generally accepted that topical agents, such as intranasal xylometazoline, are more effective than oral drugs for nasal congestion.[1] Nevertheless, oral pseudoephedrine, 60 mg as a single dose or repeated for 3 to 5 days, is superior to placebo for relief of nasal congestion[2,3] and is safe. A 30-mg dose, however, may be no better than placebo.[4] Prolonged use of the topical adrenergic agents should be avoided to prevent the development of an apparent rebound effect when the drug is discontinued. Systemic absorption of oxymetazoline and xylometazoline has rarely been associated with bradycardia, hypotension, and coma. The antihistamines have no effect on nasal congestion.

Rhinorrhea

The treatment of rhinorrhea is primarily by blockade of cholinergic stimulation of glandular secretion. Intranasal ipratropium bromide reduces rhinorrhea in colds by 22 to 31% compared with placebo, and it can be used as a combined spray with xylometazoline to relieve both rhinorrhea and nasal congestion.[1] The most common side effects of intranasal ipratropium are nasal irritation and bleeding.

The first-generation (sedating) antihistamines reduce rhinorrhea by approximately 25% compared with placebo. The second-generation or "nonsedating" antihistamines have had no effect on common cold symptoms[5] in a limited number of studies. These observations, the absence of histamine in the secretions of most subjects with colds, and the similarity of the response to ipratropium and first-generation antihistamines suggest that any effect of antihistamines on rhinorrhea is related to their anticholinergic rather than

their antihistaminic properties. The major side effects associated with the use of the antihistamines are sedation and drying of the eyes, mouth, and nose.

Cough

Cough during colds is produced by several different mechanisms, and treatment should be directed at the most likely underlying cause. If cough is caused by nasal obstruction or postnasal drip, it may respond to treatment with an antihistamine or antihistamine-decongestant combination. If a more persistent cough is the result of virus-induced reactive airway disease or viral infection of the lower airways, patients may benefit from bronchodilator therapy (Chapter 87). Cough that persists after the resolution of other cold symptoms or that persists in association with unremitting rhinorrhea may be due to sinusitis and may respond to antibiotic therapy (Chapter 434). Nonspecific cough suppression with codeine or dextromethorphan hydrobromide has not been demonstrated to be efficacious, and expectorants such as guaifenesin are not effective antitussive agents.

Other Remedies

Many patients have a variety of other symptoms. Nonsteroidal anti-inflammatory agents are effective for headache, ear pain, and muscle and joint pain; however, they do not relieve nasal congestion, rhinorrhea, or cough.[6]

Zinc, which is an inhibitor of rhinovirus 3C protease that is essential for virus replication, does not have a significant antiviral effect and has shown either no or relatively modest effects in reducing the severity of the common cold.[7] This uncertain benefit must also be viewed in light of zinc's side effects; oral zinc lozenges may be associated with sore mouth and occasional nausea, whereas intranasal zinc may cause nasal irritation.

Echinacea has not been shown to be beneficial in reducing symptoms of the common cold in several studies.[8] Given the variation in echinacea products, however, it is possible that echinacea preparations with different phytochemical profiles might be helpful. The accumulating evidence, however, suggests that it is prudent to assume that echinacea has no beneficial effect until positive evidence of a treatment effect is produced.

PREVENTION

Chemoprophylaxis or immunoprophylaxis is generally not available for the common cold. Immunization or chemoprophylaxis against influenza (Chapter 372) may be useful for prevention of colds caused by this pathogen, but influenza is responsible for only a small proportion of all colds. Vitamin C, even in megadoses, is of no benefit.[9] Other nonpharmacologic interventions touted as effective prophylaxis for the common cold but of unproven benefit include zinc, vitamin E, echinacea, ginseng, probiotics, exercise, and handwashing. Handwashing and exercise have undeniable benefits for health in general and can be recommended despite the paucity of evidence specific to common cold prevention. Other interventions, although probably safe, have no demonstrable benefit and simply contribute to the unnecessary health care expenditures related to the common cold.

PROGNOSIS

The common cold generally has little medical significance. However, these illnesses are frequently complicated by otitis media (Chapter 434) or sinusitis (Chapter 434) that may be a direct result of the viral infection or may be due to bacterial superinfection. Exacerbations of asthma (Chapter 87) and chronic bronchitis (Chapter 88) are also important complications of the common cold.

370 RESPIRATORY SYNCYTIAL VIRUS

EDWARD E. WALSH

DEFINITION

Respiratory syncytial virus (RSV), which causes yearly winter outbreaks, remains the single most important cause of bronchiolitis and pneumonia in young infants and a common cause of illness in older children and young adults. RSV can cause serious illness in elderly people, adults with underlying cardiopulmonary disease, and the severely immunocompromised.

The Pathogen

RSV is a single-stranded RNA enveloped virus of the family Paramyxoviridae, genus Pneumovirus; it is related to human metapneumovirus. Two major transmembrane glycoproteins (G, attachment protein; F, fusion protein) carry neutralizing epitopes, and two nonstructural proteins (NS1 and NS2) block the antiviral activity of interferon-α, whereas a secreted form of G contains a CX3C chemokine motif that may be important in modulating immune responses to infection. Two major virus groups (A and B), each with four to five subgroups, are distinguishable.

EPIDEMIOLOGY

In the United States, epidemics generally begin in the southern states in late fall, move steadily north, and peak in February and March in colder climates. RSV annually causes approximately 100,000 hospitalizations and accounts for 60% of cases of bronchiolitis and 25% of cases of pneumonia in infants. Mortality is relatively low in U.S. infants, with an estimated 250 deaths annually; however, deaths are more common in underdeveloped countries. About 70% of infants become infected in their first winter and the remainder in the following year. RSV is transmitted principally by direct contact with large-particle fomites of respiratory secretions rather than by small-particle aerosolization.

Approximately 1 to 3% of primary infections result in hospitalization, but lower socioeconomic status, underlying prematurity, congenital cardiac abnormalities, bronchopulmonary dysplasia, and immunosuppression increase the risk for serious disease. Severe disease is associated with specific polymorphisms in the promoter regions of cytokine genes. Hospitalization is most frequent between the ages of 1 and 6 months, with a median age of 2 months. Reinfection occurs frequently throughout life, although subsequent illness is less severe and hospitalization is infrequent, except for persons with underlying cardiac or pulmonary conditions.

Though often not considered in adults, RSV infection is common and may be severe in the elderly. In a British study, RSV accounted for 17% of medically attended respiratory illnesses in persons older than 45 years. In a U.S. study of community-acquired pneumonia in adults (Chapter 97), RSV ranked third behind pneumococcus and influenza. RSV infection is implicated in about 10% of hospitalizations for acute pulmonary symptoms in the winter among community-dwelling elderly persons, a rate similar to that for influenza.

PATHOBIOLOGY

In naturally acquired infection, the virus most commonly enters through the nose or eye and then spreads from the upper to the lower respiratory tract. Pathologic findings include a lymphocytic peribronchiolar infiltration with edema, obstruction, and necrosis. Bronchiolitis, with multiple areas of atelectasis, and pneumonia, with interstitial infiltration of mononuclear cells and

alveoli that are filled by edema and necrosis, develop in infected patients. Naturally acquired immunity is incomplete and not lifelong. Repeated infections are common, but severe disease is unusual in adults unless they are immunocompromised.

CLINICAL MANIFESTATIONS

After an incubation period of 2 to 8 days, infants experience upper respiratory symptoms of conjunctival injection, mucopurulent nasal discharge, cough, and low-grade fever. Otitis media occurs commonly, generally in association with bacteria. After several days, lower respiratory tract symptoms appear in 25 to 50% of infants, with cough, wheezing, tachypnea, use of accessory muscle, and cyanosis developing as the disease progresses. Expiratory wheezes, rhonchi, and fine rales are the most common findings on lung examination. Sudden apnea may develop in the youngest infants. Mortality is rare in otherwise healthy infants but can reach 37% in infants with cardiac disorders. Hyperinflation and diffuse interstitial pneumonitis are the most frequent radiographic findings. High-titer virus shedding lasts 7 to 10 days, although immunocompromised infants may excrete virus for a month or longer, even when asymptomatic. Coinfection with other respiratory viruses is not uncommon but is not clinically discernible.

Illness in young adults generally continues for 1 week, typically with upper respiratory symptoms. Many have lower respiratory symptoms, especially wheezing, and may miss work while seeking medical attention. Low-titer virus shedding persists for 3 to 5 days. In elderly persons, RSV attack rates approximate 5% annually; wheezing is more common than with influenza (Chapter 372), whereas a high fever is less common. In frail elderly persons or in patients with underlying chronic obstructive pulmonary disease or heart failure, severe disease can develop. Attack rates in nosocomial nursing home outbreaks average 10 to 15%, with rales and wheezes evident in a third of patients and radiographically confirmed pneumonia in approximately 10%. The precise incidence of bacterial superinfection is unknown but is probably similar to that seen with influenza virus infection.

RSV infection has been documented in up to 10% of bone marrow transplant recipients, patients with acute leukemia, and heart/lung transplant recipients during the winter months. Upper respiratory symptoms frequently lead to lower respiratory tract symptoms.

DIAGNOSIS

In infants, a presumptive diagnosis is suggested by typical symptoms during the epidemic season, but the diagnosis is often not considered in adults. In infants the sensitivity of viral culture is about 75%, and rapid tests that rely on detecting viral antigen in respiratory secretions, such as immunofluorescence or enzyme immunoassay (EIA), have a sensitivity of approximately 80%. Reverse transcription–polymerase chain reaction (RT-PCR) is considerably more sensitive than culture. In immunocompromised adults, RSV antigen is found in only 15% of nasal secretions but in 90% of bronchoalveolar lavage specimens.

In adults, viral culture has a sensitivity of 30%, but RT-PCR detects infection in three quarters of culture-negative cases that would be seropositive with testing of acute and convalescent serum. Immunofluorescence and EIA are not useful in adults. In immunocompromised patients, chest radiographs demonstrate diffuse interstitial and alveolar infiltrates. A useful clinical clue to the presence of RSV is the almost universal presence of radiographically proven sinusitis. The presence of upper respiratory tract symptoms distinguishes this illness from cytomegalovirus pneumonia (Chapter 384).

TREATMENT

Rx

Therapy for hospitalized infants includes hydration, oxygen, bronchodilators, and occasionally specific antiviral medication. The effectiveness of nebulized bronchodilators is variable, but a subset of infants respond. Glucocorticosteroids have not been shown to have benefit. Specific antiviral therapy is limited to inhaled ribavirin (20-mg/mL solution administered by aerosol, typically for 6 hours three times a day for 3 to 5 days). High-dose (2 g at 60 mg/mL), short-duration (2 hours three times daily) treatment is considered equivalent. The majority of infants do not require therapy, but ribavirin treatment appears to benefit infants and children at high risk for serious disease and those who are severely ill.

No placebo-controlled studies of the effect of inhaled ribavirin have been conducted in adults with severe RSV disease, but the evidence accumulated suggests benefit in immunocompromised adults with RSV pneumonia (2 g at 60 mg/mL for 10 days), especially if begun before respiratory failure.

Studies using monoclonal antibody (palivizumab, 15 mg/kg once) combined with inhaled ribavirin suggest benefit in the treatment of RSV pneumonia in immunosuppressed adults, although conclusive randomized studies have not been published. Bacterial superinfection can develop, with *Streptococcus pneumoniae* (Chapter 297) and *Haemophilus influenzae* (Chapter 308) being the most frequent organisms. For such patients, appropriate antimicrobial treatment (Chapter 97) is mandatory.

PREVENTION

Adherence to standard infection control principles (e.g., gloves, gowns, and frequent handwashing) substantially reduces nosocomial spread. A vaccine is not available. Parenteral humanized RSV monoclonal antibody (palivizumab, 15 mg/kg monthly during the RSV season) has demonstrated benefit when administered prophylactically to high-risk infants with underlying cardiopulmonary disease or prematurity in this setting.

PROGNOSIS

RSV infection in severely immunocompromised adults, such as bone marrow transplant recipients (Chapter 181) and those with acute leukemia (Chapter 189) undergoing cytotoxic chemotherapy, carries a 60% mortality rate when pneumonia develops. Risk factors for a poor outcome include the degree of lymphopenia and, in one study, the use of cord blood as a source of allogeneic stem cells (Chapter 181). A link between severe bronchiolitis and the subsequent development of asthma remains unresolved. In otherwise normal hosts the outcome is generally good.

PARAINFLUENZA VIRAL DISEASE

GEOFFREY A. WEINBERG AND KATHRYN M. EDWARDS

DEFINITION

Human parainfluenza viruses (hPIVs) are important causes of a wide spectrum of respiratory illnesses. In infants and young children, they produce acute upper and lower respiratory tract infections ranging from the common cold (Chapter 369) and otitis media (Chapter 434) to severe croup, bronchiolitis, and pneumonia (Chapter 97). In older children and adults, hPIV infections are usually limited to the upper respiratory tract (Chapter 96), although immunocompromised individuals may develop fatal respiratory failure.

The Pathogen

The hPIVs are enveloped, single-stranded, nonsegmented RNA viruses that belong to two genera in the family Paramyxoviridae. Members of this family also include respiratory syncytial virus (RSV; Chapter 370), human metapneumovirus (Chapter 369), measles virus (Chapter 375), mumps virus (Chapter 377), Hendra and Nipah viruses, and the animal pathogenic viruses of Newcastle disease, canine distemper, and rinderpest. The hPIV genome

encodes six structural proteins. The hemagglutinin-neuraminidase (HN) and fusion (F) proteins, which are exposed on the bilayered lipid envelope surrounding the helical nucleocapsid–RNA complex, mediate both attachment to host sialic acid–containing glycoproteins and penetration of the virus into susceptible mammalian cells. These proteins have retained their antigenic stability for many years, unlike the antigen "drift and shift" of the influenza viruses. The four serotypes of hPIV are called types 1 to 4, including two subgroups (A and B) of type 4 virus.

EPIDEMIOLOGY

The hPIVs are ubiquitous, with a worldwide geographic distribution. Their transmission is principally by large-particle fomites and close person-to-person contact. Parainfluenza virus activity displays both endemic and epidemic patterns, with each serotype favoring different age groups and distinct clinical syndromes but with enough overlap to preclude specific diagnosis based solely on clinical and epidemiologic grounds.

Primary infection with hPIV occurs early in childhood. Among the parainfluenza viruses, type 3 (hPIV-3) generally infects infants first, such that 50 to 67% of infants demonstrate serologic evidence of infection by 1 year of age. Parainfluenza viruses 1 and 2 (hPIV-1 and hPIV-2, respectively) most commonly infect children between 2 and 5 years of age. Parainfluenza virus 4 (hPIV-4) less commonly causes symptomatic respiratory infections.

Until the early 1960s, hPIV-1 caused endemic annual disease in the United States, but for the past several decades, it has been associated with biennial outbreaks in the fall of odd-numbered years. Infections with hPIV-2 largely follow this same curious pattern but occur much less commonly than hPIV-1 infections. Infections with hPIV-3 have remained endemic throughout the year, with peaks in the late spring. The incubation period for all serotypes of hPIV is 3 to 6 days in experimentally infected adults but appears to be 2 to 4 days in natural infections in children.

The hPIVs are second only to RSV as the cause of acute upper and lower respiratory tract infections in young children in the United States. In a population-based study of children younger than 5 years hospitalized with fever or acute respiratory tract infection, 7% had laboratory-confirmed hPIV infection (by cell culture and molecular amplification techniques), compared with 19% with RSV and 6% with influenza A or B virus infections. The hospitalization rate for hPIV infection in children younger than 5 years was 1.02 per 1000 children per year. Extrapolating to the entire U.S. population, these data suggest that approximately 23,000 hPIV annual hospitalizations occur in children younger than 5 years. The rates of emergency department and outpatient health care visits attributable to hPIV infections in young children are 10- to 50-fold greater. Further, immunity to hPIV infection is neither complete nor durable, so older children and adults can exhibit symptomatic infection, sometimes leading to office visits and hospitalization.

CLINICAL MANIFESTATIONS

Primary Infection

Illness associated with primary hPIV infection varies by age and viral serotype. Underlying medical conditions, such as cardiopulmonary compromise and immune disorders, increase the severity of disease. Large cohort and longitudinal family studies have shown that hPIV infections are responsible for about 65% of croup, 20 to 40% of lower respiratory infection, and 20% of upper respiratory infection in young children. The majority of children have experienced primary hPIV infection by the time they enter elementary school. Thus, although hPIV also causes upper respiratory infections in adults, these are reinfections rather than primary infections (see later). In general, hPIV-1 and hPIV-2 are most commonly associated with croup, whereas hPIV-3 infection often presents as undifferentiated febrile illness, bronchiolitis, or pneumonia.

Infection typically begins with upper respiratory signs and symptoms, notably coryza, rhinorrhea, pharyngitis without cervical adenopathy, and low-grade fever. Symptoms, which typically persist for 3 to 5 days, may be unpredictable and can result in sudden respiratory failure. In approximately 15 to 25% of infected children, signs of lower respiratory tract disease develop, usually presenting as croup but sometimes as bronchiolitis or pneumonia, indistinguishable from RSV infection. When croup develops, the child has a raspy, barking cough with notable inspiratory stridor, dyspnea, and respiratory distress. These symptoms, which are generally spasmodic, result from subglottic inflammation and edema. On occasion, severe stridor may develop and make differentiation from epiglottitis caused by *Haemophilus influenzae* type b (Chapter 308) difficult, although epiglottitis is much less common in the United States since universal Hib vaccination became routine in 1990.

Croup is very rare in adults but has been associated with hPIV in isolated case reports. Epiglottitis is seen more often in adults, but it is more commonly associated with staphylococcal or streptococcal infection. Epiglottitis is a medical emergency for patients of all ages and must be distinguished from croup to allow proper therapy, including emergent intubation of the airway (Chapter 437). The differences between these two entities are clearly shown in lateral neck radiographs, on which subglottic edema and narrowing are seen with croup, and swelling of the epiglottis is seen with epiglottitis (Figs. 371-1 and 371-2). Children with bronchiolitis or pneumonia caused by hPIV have cough, rales, and wheezing associated with hypoxia, and their chest radiographs often exhibit air trapping.

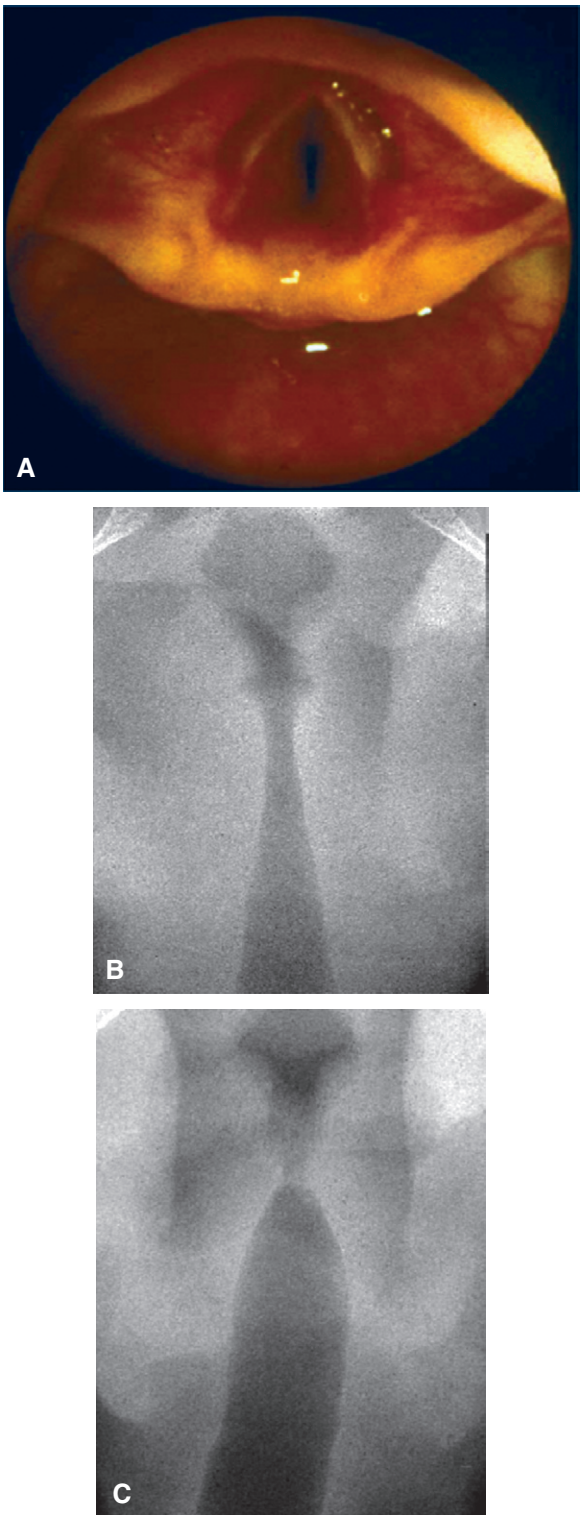

FIGURE 371-1. Subglottic edema. Endoscopic view of subglottic edema in viral croup (**A**). Radiologic presentation of subglottic edema in viral croup causing narrowing ("steeple sign") of the tracheal air shadow (**B**) compared with a normal tracheal air shadow (**C**). (From Hammer J. Acquired upper airway obstruction. *Paediatr Respir Rev.* 2004;5:25-33.)

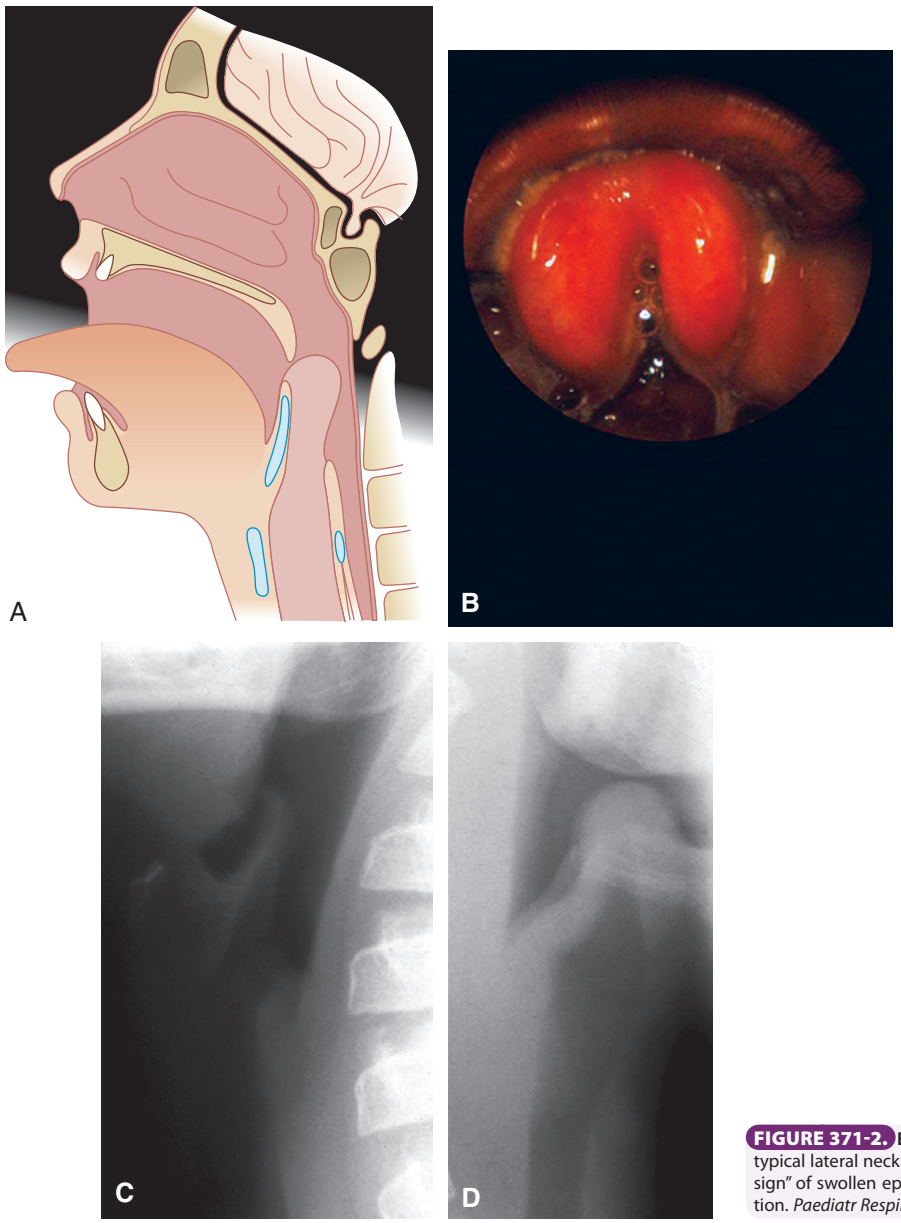

FIGURE 371-2. Epiglottitis. Schematic (**A**) and endoscopic view (**B**) of epiglottitis. The typical lateral neck radiographs of a normal child (**C**) and a child with epiglottitis (**D**; "thumb sign" of swollen epiglottis) are displayed. (From Hammer J. Acquired upper airway obstruction. *Paediatr Respir Rev.* 2004;5:25-33.)

Reinfection

Reinfection with hPIV is less severe and typically causes cold symptoms in normal children and adults. Reinfection with hPIV is estimated to account for 1 to 15% of all acute respiratory illnesses in adults, the majority of whom present with simple upper respiratory tract infections. However, as with RSV, some adults may develop severe disease that requires hospitalization and even ventilatory support. In such patients, fever, cough, dyspnea, and wheezing are common. Radiographic changes, primarily lobar or interstitial infiltrates, are seen in more than 50% of adults hospitalized with hPIV infection.

Elderly and Immunocompromised Patients

Nursing home outbreaks of hPIV infection may include a high incidence of pneumonia, just as hPIV infections often cause severe pneumonia in immunocompromised children and adults. Among healthy elderly residents of long-term care facilities, hPIV infections are as common as infections caused by influenza A virus, influenza B virus, or RSV. In a large study of hematopoietic stem cell transplant recipients, 7% developed hPIV infections, with about 90% of those due to hPIV-3. Although nearly 80% of these cases were community acquired, nosocomial outbreaks occurred even in stem cell transplant units.

Approximately 25% of hPIV-infected stem cell transplant recipients develop lower respiratory disease, mostly in the first 100 days after transplantation, when lymphopenia is most pronounced. The strongest identified risk factors for any hPIV infection and for severe infection in this setting are allogeneic transplantation from unrelated or nonmatched sibling donors and the use of corticosteroids, especially at higher doses. Fever, cough, dyspnea, and sputum production are the most common symptoms. Coinfection, especially with *Aspergillus* (Chapter 347), may occur in hematopoietic stem cell transplant recipients with pneumonia.

DIAGNOSIS

Although hPIV may be suspected on clinical and epidemiologic grounds, specific diagnosis requires isolation of the virus or detection of viral antigen or RNA in respiratory secretions. Reverse transcription–polymerase chain reactions (RT-PCR) are highly sensitive and specific for diagnosis. Alternatively, cultures of monkey kidney or human embryonic kidney cells can be used to grow the virus, with cytopathic effects detected in 5 to 10 days (except for hPIV-4, which requires up to 3 weeks). Rapid direct or indirect immunofluorescence tests are less sensitive than culture but still are used in many clinical laboratories.

Definitive diagnosis of parainfluenza infection in adults, even by RT-PCR, may be more difficult than in children, presumably because less virus is shed by partially immune adults. However, virus can usually be recovered from the nasopharyngeal secretions or bronchoalveolar lavage fluid in hematopoietic stem cell transplant recipients with pneumonia.

TREATMENT

Rx

Specific antiviral treatment of hPIV infection is currently unavailable. Aerosolized ribavirin, approved for use in RSV infection, has in vitro activity against hPIV, but studies in immunocompromised children and adults with severe hPIV pneumonia have shown no benefits even when it was administered with concomitant intravenous immune globulin.

For previously healthy children with croup, general comfort, which usually means sitting in the lap of a parent or caregiver, is widely recommended. Humidified air (mist) repeatedly has been shown to have no benefits and actually has associated adverse effects, including anxiety, difficulty with monitoring, and bacterial and fungal contamination of both hot and cold mist humidifiers. Oxygen may be given by holding the end of the tubing near the nose and mouth ("blow-by" oxygen).

Children with mild to moderate croup (i.e., without stridor or significant chest wall indrawing at rest, or with stridor and indrawing but without agitation) may be given oral dexamethasone, 0.6 mg/kg body weight, and observed; if they improve, they may be discharged to home. Children with severe croup (stridor, chest wall indrawing, and agitation) may benefit from blow-by oxygen, inhaled racemic epinephrine (0.05 mL/kg body weight of a 2.25% solution of racemic epinephrine for nebulization, up to a maximum dose of 0.5 mL[■]; if racemic epinephrine is not available, the equivalent effects can be achieved by nebulizing 0.5 mL/kg of 1:1000 L-epinephrine, up to a maximum dose of 5 mL), and dexamethasone. Children should be admitted to the hospital if no significant clinical improvement is seen after several hours of observation and therapy.

Oral dexamethasone is as effective as intramuscular dexamethasone or nebulized budesonide, and it is easier to administer. Corticosteroids decrease the need for hospitalization and return visits,[■] decrease length of stay both in emergency departments and after hospital admission,[■] and decrease the need for intubation for mechanical ventilation. In general, there are no reasons to institute either antibiotic therapy or short-acting bronchodilator therapy in children with croup.

PREVENTION

Clinical trials of live attenuated hPIV vaccines are ongoing. At least one vaccine candidate under study combines hPIV-3 and RSV in an attempt to prevent both of these common infections in young children.

TABLE 372-1 ANTIGENIC SUBTYPES OF INFLUENZA A VIRUS ASSOCIATED WITH PANDEMIC AND PANDEMIC-LIKE INFLUENZA

YEAR	INTERVAL (YR)	SUBTYPE DESIGNATION	EXTENT OF ANTIGENIC CHANGE IN INDICATED SURFACE PROTEIN*	SEVERITY OF PANDEMIC (MORTALITY)
1889	?42-59	H3N?	H+++N?	Severe
1918	18	H1N1†	H+++N+++	Very severe
1957	39	H2N2	H+++N+++	Severe
1968	11	H3N2	H+++N–	Moderate‡
1977	9	H1N1	H+++N+++	Negligible§
2009	32	H1N1	H++N++	Mild-moderate§

*Compared with antecedent or cocirculating virus.
†Formerly designated H0N1 (swine virus prototype) or Hsw1N1.
‡The population had some immunity to N2 neuraminidase.
§The older population was largely immune because of previous infection with earlier circulating, antigenically identical (1977) or related (2009) viruses; those born after 1957 were primarily affected. The impact of the 2009 pandemic virus, based on estimated years of life lost, was comparable to that observed in the 1968 pandemic in the United States.
+ = Minor change; ++ = moderate change; +++ = major change; – = no change.

372

INFLUENZA

FREDERICK G. HAYDEN

DEFINITION

Influenza is an acute febrile respiratory illness that occurs in annual outbreaks of varying severity and commonly in unpredictable worldwide epidemics (pandemics). The causative virus infects the respiratory tract, is highly contagious, and typically produces prominent systemic symptoms early in the illness. Influenza virus infection can produce various clinical syndromes in adults, including nonfebrile common colds, pharyngitis, tracheobronchitis, and pneumonia. Conversely, infections with other respiratory viruses, such as respiratory syncytial virus (Chapter 370) or adenovirus (Chapter 373), may produce influenza-like illness. Influenza A viruses have caused five pandemics of varying severity within the past 120 years (Table 372-1). The pandemic in 1918 to 1919 caused at least 500,000 deaths in the United States and more than 40 million worldwide, whereas the 2009 H1N1 pandemic was associated with substantially less mortality. Seasonal epidemics may cause enormous morbidity, economic loss, and often substantial mortality. Recent epidemics have caused on average more than 24,000 respiratory- and circulatory-related deaths and more than 200,000 hospitalizations in the United States alone.

The Pathogen

Influenza viruses belong to the family Orthomyxoviridae and are divided into three types (A, B, and C) distinguished by their internal and external proteins (Table 372-2). The virion (Fig. 372-1) is a medium-sized, enveloped, pleomorphic particle covered with two types of surface glycoprotein spikes, the trimeric hemagglutinin (H or HA) and the tetrameric, mushroom-shaped neuraminidase (N or NA). The envelope is composed of a lipid bilayer overlying the matrix (M1) protein that surrounds the viral genome consisting of eight segments of single-stranded RNA. Influenza C viruses have seven segments and only a single surface glycoprotein. Whereas influenza B and C viruses are principally human pathogens, influenza A viruses primarily infect aquatic birds and sometimes other animal hosts, including other avians, swine, horses, marine mammals, felids, and dogs. Influenza A viruses are further classified into subtypes on the basis of their HA and NA glycoproteins. Sixteen HA and nine NA subtypes are currently recognized in nature, but only three HAs (H1, H2, and H3) and two NAs (N1 and N2) have been documented thus far in epidemic and pandemic human influenza A viruses. Each strain is identified by type, subtype if influenza A, site, sample number, and year of isolation.

EPIDEMIOLOGY

Antigenic and Genetic Variation

Influenza viruses are unique among the respiratory viruses with regard to their extent of genetic and antigenic variation, epidemic behavior, and frequent association with excess mortality during community outbreaks. The changing antigenicity of the surface glycoproteins largely accounts for repeated influenza epidemics in humans. Antibody to HA neutralizes viral infectivity and is thus the major determinant of immunity. Anti-NA antibody limits viral replication and probably reduces the severity of infection. Variation involves either relatively minor (antigenic drift) or major (antigenic

TABLE 372-2 INFLUENZA VIRUS PROTEINS

DESIGNATION	LOCATION (APPROXIMATE NO. PER VIRION)	FUNCTION	OTHER
Hemagglutinin (HA)	Surface (500)	Cell attachment and penetration; fusion activity	Type-, subtype-, and strain-specific antigens; key antigen in inactivated vaccine
Neuraminidase (NA)	Surface (100)	Virus release and spread; enzymatic activity	Type-, subtype-, and strain-specific antigens; activity linked to risk for pneumonia; site of action of zanamivir, oseltamivir carboxylate
Membrane or M1 matrix	Internal (3000)	Major structural envelope protein; virus assembly	Type-specific antigen
M2	Surface (20-60)	Virus uncoating and assembly; ion channel	Influenza A only; site of action of amantadine/rimantadine
Nucleoprotein (NP)	Internal (1000)	Associated with RNA and polymerase proteins	Type-specific antigen
Polymerase proteins (PB1, PB2, PA)	Internal (30-60)	RNA replication and transcription	Determinant of replication efficiency; probable site of action of ribavirin
NS1	Nonstructural (infected cells)	Regulation of virus replication	Interferon antagonist
NEP	Internal (130-200)	Nuclear export factor	Formerly NS2
PB1-F2	Nonstructural (infected cells)	Proapoptotic factor; proinflammatory effects	Expressed from 1+ reading frame of PB1 of certain viruses

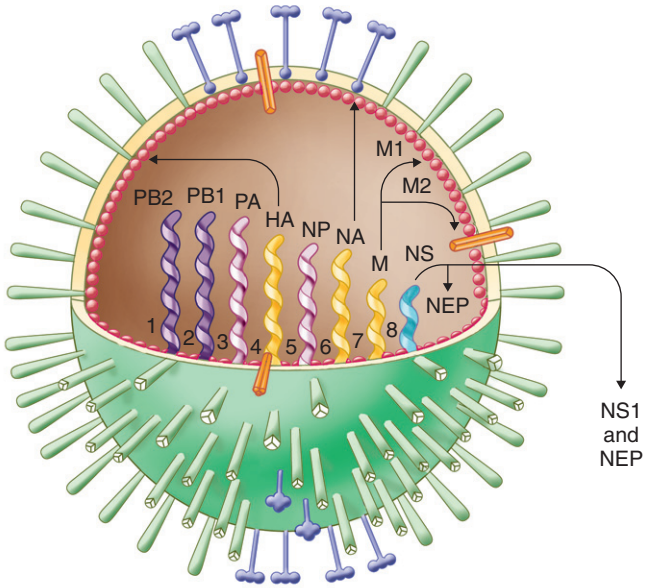

FIGURE 372-1. Diagram of influenza virus structure. Eight segments of viral RNA are contained within the envelope and matrix (M1) shell. Each codes for one or two proteins that form the virus or regulate its intracellular replication. The presumed functions of each are listed in Table 372-2. (Courtesy of Dr. Robert G. Webster.)

shift) changes in antigenicity. Significant antigenic variation is much less frequent with influenza B than with influenza A.

Antigenic drift results from point mutations in the RNA segment that codes for HA, thereby causing amino acid substitutions in at least one of five antigenic sites on HA. Drift can also occur in NA. These mutations occur frequently (every year or every few years) within an influenza A or B virus. For example, the original H3N2 variant, A/Aichi/68, has undergone successive drifts resulting in epidemic strains that include the recent circulation of A/Perth/16/2009–like viruses. Immunologic selection favors transmission of the new variant over the old because of the less frequent presence of antibody to the new virus in the population.

Antigenic shift results from the appearance of an influenza A virus with HA or HA and NA glycoproteins that are new to humans or that reappear after decades of absence. Because of the lack of population immunity, a new strain that is transmissible from person to person can cause pandemic disease (see Table 372-1). The origin of new pandemic strains and the basis for their possible recirculation remain incompletely understood. Avian influenza viruses have served as the reservoir of new genes for human pandemic viruses. Reassortment of gene segments may occur when two influenza viruses simultaneously infect a single cell, and reassortment events in which human viruses acquired avian genes led to both the 1957 and 1968 pandemic viruses. Because swine can support replication of both human and avian viruses, they have been postulated to serve as a mixing vessel for the generation of new strains or as the host in which avian viruses can adapt to mammals. The 2009 H1N1 pandemic virus arose as a quadruple reassortant, which derived gene segments from Asian and North American swine lineage viruses that harbored genes derived from swine, avian, and human viruses. Frequent intra-subtypic reassortment also occurs among seasonal human influenza A viruses and sometimes leads to new antigenic variants. The 1918 pandemic virus was probably a reassortant composed of both human and swine genes, including those of avian origin that underwent mutational adaptation in a mammalian host, perhaps human or swine, before causing the pandemic.

Zoonotic infections occur from swine, poultry, or rarely other animals. Although most avian influenza viruses do not cause infections directly in humans, human infection by avian subtype H5, H7, and H9 viruses has been well documented. Initially recognized by a cluster of human cases in Hong Kong in 1997, an epizootic of avian H5N1 infections has affected many areas of Asia, the Middle East, Europe, and Africa and continues to cause sporadic human illnesses with high mortality.

Epidemic or Interpandemic Influenza

An *epidemic* is an outbreak of influenza confined to one geographic location. In temperate climates, community epidemics of influenza A virus infection often have a characteristic pattern, typically reaching a sharp peak in 2 or 3 weeks after initial recognition and persisting for 6 to 10 weeks. Increased numbers of schoolchildren with febrile respiratory illness are often the first indication of influenza in a community, soon followed by illnesses in adults and, 1 to 2 weeks later, by increased hospital admission of patients with influenza-related complications. Hospitalization rates in high-risk persons increase two- to five-fold during major epidemics (Table 372-3). School and employment absenteeism increases, as does mortality from pneumonia and underlying conditions, especially in older persons during A/H3N2 epidemics. Epidemics occur almost exclusively during the winter months in temperate areas, but inderlying conditions, activity may occur year-round in the tropics or display other patterns. Outbreaks sometimes occur in tour groups (land or ship) and in facilities during summer months, particularly after the appearance of a drift variant. Regional differences in the time and magnitude of occurrence of influenza outbreaks are common. During epidemics, overall attack rates typically range from 5 to 20% in adults. Attack rates of 40 to 50% are not uncommon in closed populations, such as in hospitals and nursing homes, and in highly susceptible age groups such as children. Two different strains within a single subtype, two different influenza A subtypes, two different influenza B lineages, or both influenza A and B viruses may cocirculate or occur sequentially. In addition, simultaneous outbreaks of influenza A

TABLE 372-3 AGE-SPECIFIC RATES FOR ILLNESS AND MORTALITY DURING URBAN INFLUENZA EPIDEMICS

AGE (YR)	PHYSICIAN VISITS PER 100	ACUTE RESPIRATORY DISEASE HOSPITALIZATIONS PER 10,000	PNEUMONIA- AND INFLUENZA-RELATED MORTALITY PER 100,000
<5	28	43	3
5-14	14	5	1
15-44	10	8	1
45-54	9	13	10
55-64	10	21	10
≥65	Not stated	73	104

virus and respiratory syncytial virus or other respiratory viruses occur. Strains circulating at the end of one season's epidemic are sometimes responsible for the next season's outbreak (the so-called herald wave phenomenon).

Pneumonia- and influenza-related deaths fluctuate annually, with peaks in the winter months in temperate climates. When such deaths exceed the expected threshold, the cause is typically influenza A, but influenza B virus or respiratory syncytial virus can occasionally be responsible. Although mortality is usually greatest during pandemics, substantial mortality occurs with epidemics. During seasonal influenza, more than 85% of pneumonia- and influenza-related deaths occur in persons 65 years of age and older. Mortality risk is especially high in those aged 85 years and older. Other cardiopulmonary and chronic diseases also result in increased mortality after influenza epidemics, so the overall influenza-associated mortality is about two- to four-fold higher than pneumonia- and influenza-related deaths.

Pandemic Influenza

Pandemics of influenza A result from the emergence of a new virus capable of sustained person-to-person transmission and to which the population contains no or limited immunity. The virus spreads worldwide, often circulating outside of the usual influenza season, and usually infects persons of all ages. Preexisting immunity due to prior infection with antigenically related viruses can provide partial protection, as occurred in older adults during the 2009 H1N1 pandemic. Pandemics are associated with high morbidity rates, especially in children, and sometimes notably increased mortality rates in pregnant women and young and middle-aged adults. For example, more than 90% of deaths in the 1918 and 2009 pandemics occurred in persons younger than 65 years.

The pandemics of 1957 and 1968 began in mainland China, but the geographic origin of the 2009 H1N1 pandemic virus is uncertain. The interval between pandemics is variable (10 to 40 years) and unpredictable. The most severe pandemics have been associated with major antigenic alterations in both major surface antigens. Depending on population susceptibility and perhaps changes in the virus, one or more waves, sometimes with increased severity, may occur. As the level of immunity in the population increases, antigenic drift within the subtype may cause repeated epidemics in subsequent years, and excess mortality in younger adults may continue for some years.

PATHOBIOLOGY

Influenza virus infection is transmitted from person to person by virus-containing respiratory secretions. Large- and small-particle aerosols over short distances (1 to 2 meters) both appear to contribute, but transmission by other routes, including fomites, may be possible. Infection by avian viruses also can occur after direct contact with infected birds or their excreta, ingestion of contaminated food, and sometimes inoculation into the conjunctiva. Virtually all levels of cells lining the respiratory tract can support viral replication, although receptors for avian viruses appear to be concentrated on cells in the distal bronchioles, alveoli, and conjunctiva. Once the virus initiates infection of the respiratory tract epithelium, successive cycles of viral replication infect large numbers of cells and result in destruction of respiratory epithelium and sometimes pneumocytes through direct cytopathic effects or apoptosis. Virulence, which is a multigenic characteristic with contributions from HA, NA, NS, and polymerase proteins (see Table 372-2), varies among strains and is not necessarily linked to transmissibility.

The incubation period, which averages 2 days and varies from about 1 to 4 days, may be somewhat longer in infections caused by avian viruses. The quantity of virus in respiratory tract specimens generally correlates with the severity of illness and levels of host pro-inflammatory cytokine-chemokine responses, findings that support the importance of ongoing viral replication in producing acute illness. Elevated levels of mediators such as interferon-α, interleukin-6, and tumor necrosis factor-α occur in blood and respiratory secretions and probably contribute to systemic symptoms and fever. The duration of viral replication depends on age, immune status, underlying conditions, and viral strain. In seasonal influenza, upper respiratory viral shedding generally continues for 3 to 5 days in adults and often into the second week in young children, and it may persist for weeks to months in immunocompromised hosts. Higher level and more prolonged viral replication occurs in the lower respiratory tract of patients with viral pneumonia, and excessive cytokine-chemokine responses have been found in severe H5N1 infections and pandemic H1N1 infections. Viremia or extrapulmonary dissemination is rarely detected in typical human influenza, but both occur in some patients with avian H5N1 infections, in whom gastrointestinal replication may also occur.

Nasal and bronchial biopsy specimens from persons with uncomplicated influenza reveal desquamation of the ciliated columnar epithelium. Individual cells show shrinkage, pyknotic nuclei, and loss of cilia. In addition, the lungs in fatal influenza may show necrotizing bronchitis, alveolar edema and hemorrhage, hyaline membrane formation, diffuse alveolar damage, and, later, fibrosis and squamous metaplasia. Secondary bacterial infections develop as a result of altered bacterial flora, damage to bronchial epithelium with depressed mucociliary clearance, decreased polymorphonuclear and alveolar macrophage functions, accumulation of alveolar fluid, and suppression of other host immune responses. Bacterial infections were associated with more than 90% of fatal pneumonias in 1918 and about 20 to 40% in 2009. Neutralizing, hemagglutination-inhibiting (HAI), anti-NA, complement-fixing, enzyme-linked immunosorbent assay, and immunofluorescent antibodies begin to develop in the sera of persons with primary influenza virus infection during the second week after infection and reach a peak by 4 weeks. Secretory antibodies develop in the upper respiratory tract and consist predominantly of IgA antibodies. Cell-mediated immune responses develop by 1 week after infection and are considered important for termination of viral replication. Adaptive immunity to influenza appears to be largely subtype specific and durable for a particular strain. Protection against illness caused by human viruses is generally associated with serum HAI titers of 1 : 40 or greater, serum-neutralizing antibody titers of 1 : 8 or greater, or nasal-neutralizing antibody titers of 1 : 4 or greater.

CLINICAL MANIFESTATIONS

Influenza Syndrome

An abrupt onset of feverishness, chilliness, rigors, headache, myalgia, and malaise is characteristic of influenza but occurs in less than two thirds of cases. Systemic symptoms predominate initially, and prostration occurs in more severe cases. Myalgia, arthralgias, malaise, and headache are usually the most troublesome early symptoms, and their severity is related to the level of fever. Ocular symptoms, including photophobia, tearing, burning, and pain on moving the eyes, are sometimes present. Conjunctivitis is characteristic in avian H7 virus infections. Respiratory symptoms, particularly dry cough and nasal discharge, are typical early in the illness but are overshadowed by the systemic symptoms. Nasal obstruction, hoarseness, and sore throat are likewise common. Pandemic H1N1 2009 illness also was notable for nausea, vomiting, and diarrhea in some adults. As systemic illness diminishes, respiratory complaints and findings become more apparent. Cough is the most frequent and troublesome symptom and may be accompanied by substernal discomfort or burning. Cough, lassitude, and malaise may persist for several weeks before full recovery.

Fever is the most important initial physical finding. The temperature usually rises rapidly to a peak of 38° to 40° C within 12 hours of onset, concurrently with systemic symptoms. Fever is usually continuous but may be intermittent, especially if antipyretics are administered. Typically, the duration of fever in adults is about 3 days, but it may persist from only 1 to 5 or more days. Uncommonly, the fever takes a biphasic course. Early in the course of illness, the patient appears toxic, the face is flushed, and the skin is hot and moist. The eyes are watery and reddened. Clear nasal discharge is common. The mucosa of the nose and throat is hyperemic, but exudate is not

TABLE 372-4 PARTICULAR TARGET GROUPS FOR SEASONAL INFLUENZA IMMUNIZATION*

GROUPS AT INCREASED RISK FOR COMPLICATIONS
Persons 50 years and older
Residents of nursing homes and other chronic care facilities
Patients with a chronic pulmonary (including asthma) or cardiac (except hypertension) disorder
Patients with chronic metabolic (including diabetes), renal, hepatic, hematologic (including hemoglobinopathies), or neurologic (including those that compromise respiratory function or increase aspiration risk) disorder
Patients with immunosuppression (including that caused by medications or HIV infection)
Women who will be pregnant or within 2 works post partum during the influenza season
Persons who are morbidly obese (body mass index ≥ 40)
Persons who are American Indians or Alaskan Natives
Children 6 months through 4 years old
Children and teens receiving long-term aspirin
GROUPS IN CONTACT WITH HIGH-RISK PERSONS
Physicians, nurses, and other health care providers, including those in training†
Employees of nursing homes and chronic care and assisted-living facilities
Household contacts (parents including breast-feeding mothers, siblings) and caregivers of at-risk persons, including children 0-5 years old, adults ≥50 years old, and persons with medical conditions associated with risk of severe influenza complications (above)
OTHER GROUPS
Travelers (including to the tropics, large organized groups, or to the Southern Hemisphere in its winter)
Students, dormitory residents
Anyone wishing to reduce their risk for influenza

*Note: Starting with the 2010-2011 season, routine annual immunization is recommended for all persons aged 6 months or older who do not have contraindications. The risk groups for influenza complications have been expanded because of observations from the 2009 influenza pandemic.
†Trivalent inactivated influenza vaccine is recommended for vaccination of household members, health care personnel, and others who have close contact with severely immunosuppressed persons (e.g., patients with hematopoietic stem cell transplants) during those periods in which the immunosuppressed person requires care in a protective environment.
HIV = human immunodeficiency virus.
Modified from Centers for Disease Control and Prevention. Prevention and control of seasonal influenza with vaccines: recommendations of the Advisory Committee on Immunization Practices, 2010. http://www.cdc.gov/mmwr/.htm.

observed. Small, tender cervical lymph nodes are often present. Transient scattered rhonchi or localized areas of rales are found in less than 20% of cases.

The same pattern of illness occurs with any strain of influenza A or B virus. However, illness is more frequent and severe in smokers. In children, maximum temperatures are often higher; cervical adenopathy may be more frequent, and nausea, vomiting, and abdominal pain are more common. Persons at higher risk for influenza-associated complications and hospitalization (Table 372-4) include pregnant women (especially during the second and third trimesters or early postpartum period), morbidly obese patients, and immunosuppressed persons. Older adults, especially the infirm elderly, develop fever, muscle aches, sore throat, and headache less often but have higher rates of altered mental status and pulmonary complications. Immunocompromised hosts may also have an apparently mild initial illness but often progress to severe lower respiratory tract involvement. In sporadic illness attributable to H5N1 virus, upper respiratory complaints are less frequent, diarrhea is more common, and progressive viral pneumonia with high mortality is much more likely. Influenza C virus generally causes sporadic upper respiratory tract illness or febrile bronchitis.

Respiratory Complications

Three pneumonic syndromes have been described—primary influenza viral pneumonia, secondary bacterial pneumonia, and mixed viral and bacterial pneumonia—but their clinical presentations and courses overlap considerably. Influenza A and B virus infections are often associated with other respiratory tract complications, including exacerbations of chronic bronchitis, asthma, or cystic fibrosis; croup and bronchiolitis in young children; and otitis media, sinusitis, and, rarely, parotitis or bacterial tracheitis. Apparently uncomplicated influenza frequently causes tracheobronchitis and is often accompanied by abnormal tracheobronchial clearance, airway hyperactivity, and dysfunction of small airways lasting weeks. A syndrome mimicking pulmonary embolism with transiently altered perfusion scans has also been described.

Primary influenza viral pneumonia is uncommon during epidemics but accounts for about 20 to 50% of pneumonias during pandemics and has been the principal manifestation of severe pandemic H1N1 or H5N1 illness. It occurs predominantly in persons with underlying pulmonary and cardiac disorders, pregnancy, or immunodeficiency states, although up to 40% of reported cases and almost all patients with H5N1 have no recognized underlying disease. After a typical onset of influenza, there is rapid progression of fever, cough, dyspnea, and even cyanosis. Bilateral pulmonary infiltrates, often consistent with adult respiratory distress syndrome, and hypoxia may evolve rapidly. Gram staining of sputum may show abundant polymorphonuclear leukocytes but scant bacterial flora. Sputum may be bloody. Sputum and endotracheal aspirates usually yield high titers of influenza virus by RNA detection or culture, but upper respiratory samples are sometimes negative.

In patients with classic bacterial superinfection, transient improvement for 1 to 4 days may be followed by recrudescence of fever, increased cough, sputum production, pleuritic chest pain, and a localized area of consolidation; in some patients, fulminant pneumonia develops. Gram staining and culture of sputum most often reveal *Streptococcus pneumoniae* (Chapter 297), *Staphylococcus aureus* (Chapter 296) including community-acquired methicillin-resistant *S. aureus, Haemophilus influenzae* (Chapter 308), or *Streptococcus pyogenes*. Such patients usually respond to specific antibiotic therapy, although staphylococcal infections may be particularly virulent and cause destructive pulmonary lesions. Invasive aspergillosis (Chapter 347) occurs rarely after influenza.

In addition, during an outbreak of influenza, many less distinct syndromes are observed; patients may have viral tracheobronchitis (Chapter 96), milder forms of localized viral pneumonia, or mixed viral and bacterial infection. Many such patients respond to antibiotics. Immunocompromised hosts, including transplant recipients and acute leukemia patients undergoing chemotherapy, may have high rates of pneumonia and mortality after influenza if they are not treated with appropriate antiviral and antimicrobial medications.

Nonrespiratory Complications

Severe influenza, including both pandemic H1N1 and H5N1 disease, may be associated with sepsis syndrome (Chapter 108), acute renal insufficiency (Chapter 122), and multiorgan failure. Lymphopenia and thrombocytopenia are common in severe influenza, and the hemophagocytic syndrome can occur. Myositis with tender leg muscles and elevated serum creatine kinase levels is uncommon, except in children. Rhabdomyolysis (Chapter 115) can be severe, and virus has been recovered rarely from skeletal muscle. Disseminated intravascular coagulation (Chapter 178) develops rarely, as does renal failure related to disseminated intravascular coagulation or myoglobinuria. Reye's syndrome (Chapter 152), which is a well-recognized hepatic and central nervous system complication of influenza A and B virus infections in children and rarely in adults, is associated with salicylate use. Toxic shock syndrome (Chapter 296) caused by respiratory tract infection with toxin-bearing *S. aureus* or *Streptococcus pyogenes* can occur, and outbreaks of meningococcal infection (Chapter 306) have been associated with both influenza A and B virus infections. Myocarditis (Chapter 60) or pericarditis (Chapter 77) occurs uncommonly. Aseptic meningitis (Chapter 420), myelitis, encephalopathy (Chapter 422), and postinfluenzal Guillain-Barré syndrome (Chapter 428) also can develop.

DIAGNOSIS

In an individual case, influenza often cannot be distinguished from infection with a number of other viruses or nonviral pathogens that produce similar clinical manifestations (Chapters 96 and 437). Conversely, when public health authorities report an epidemic of influenza A and B virus infection in a given community and a patient is seen with typical febrile respiratory illness, it is highly likely that these symptoms are caused by an influenza virus infection. In such circumstances, the presence of fever and cough has a positive predictive value of about 80% for laboratory-proven influenza in ambulatory adults. Influenza virus is readily isolated from nasal, sputum, or tracheal secretion specimens in the first 2 or 3 days of illness. Throat samples have lower yield than nasal samples in infections by human viruses but appear to be superior to nasal samples for detection of H5N1 infections. Endotracheal aspirates and bronchoalveolar lavage fluid have higher yields in patients with serious lower respiratory illness. Infectious virus is usually recovered in cell culture within 48 to 72 hours. Immunofluorescence testing of respiratory

cells or inoculated cell cultures (shell vials) can reduce time to detection. Commercially available enzyme immunoassays can detect influenza virus antigens rapidly but have limited sensitivity (<20 to 70%) in adults; some do not distinguish between influenza A and B. The limited specificity of some assays makes their predictive value low, especially outside the influenza season. Detection of viral RNA by reverse transcription–polymerase chain reaction, which is more sensitive and specific than viral culture, is the rapid test of choice for serious illness and for suspected pandemic H1N1 or H5N1 illness. Serologic methods are less useful clinically because they require convalescent serum obtained 14 to 21 days after the onset of infection.

PREVENTION

Vaccination

Inactivated influenza vaccines for persons 6 months of age and older, a high-dose inactivated vaccine for persons 65 years of age and older, and a live attenuated, intranasal vaccine for otherwise healthy persons aged 2 to 49 years are currently licensed in the United States. The target groups for seasonal vaccine have continued to expand; beginning with the 2010-2011 season, immunization is recommended for all persons aged 6 months or older in the United States. However, persons at higher risk for influenza-related complications should continue to be a focus of vaccination efforts (see Table 372-4) during the transition to routine annual immunization or if vaccine shortages occur. Racial and ethnic disparities in influenza vaccination rates persist, and rates for other target groups, including health care workers, remain suboptimal. Immunization of health care personnel can be enhanced by improved access and employer recommendations or requirements.

Seasonal vaccine should be given each year in the fall, preferably October or November, before the influenza season. The antigenic composition of seasonal vaccines is reviewed annually so that these trivalent vaccines contain the most recently circulating strains, usually two subtypes of influenza A (H3N2, H1N1) and an influenza B virus. Both vaccine types are grown in eggs, and episodic production problems have sometimes led to shortages of the inactivated vaccine. For the 2010-2011 season, pandemic 2009 virus has been incorporated as the H1N1 component. Alternative vaccines (cell culture grown; oil-in-water adjuvanted) are available in some countries, and various investigational vaccines (mammalian or insect cell produced; vectored and DNA based; and those directed to conserved antigens) are in clinical study. An intradermal vaccine is approved in Europe.

Inactivated vaccines (Chapter 17) given by intramuscular injection provide about 70 to 90% protection against seasonal influenza illness and reduce work absenteeism, use of health care resources, and antibiotics in adults younger than 65 years when the vaccine is well matched to the epidemic strain.[redacted] Live attenuated vaccines are highly protective against influenza in children but appear less effective in adults compared with inactivated vaccine.[redacted] Immunogenicity and hence protection rates with inactivated vaccine are often lower in elderly persons, particularly infirm nursing home residents, and in immunosuppressed patients. For example, the effectiveness of influenza vaccine for prevention of medically attended acute respiratory illness among the elderly in nursing homes is estimated to be 20 to 40%. In ambulatory high-risk patients, immunization reduces hospitalizations from pneumonia, influenza, and cardiovascular disease as well as all-cause mortality during the influenza season. Higher dose inactivated vaccines (four-fold more HA per strain) and those containing oil-in-water adjuvant are more immunogenic in older ambulatory adults,[redacted] and their comparative effectiveness to standard dose vaccines is under study. Immunization of children appears to reduce respiratory illness in household and community contacts[redacted] and, in one Japanese study, excess deaths in the elderly. Immunization of health care providers reduces the risk of transmission to patients as well as their own risk of infection. Maternal immunization benefits both mother and child. Persons with malignant disease should receive vaccine between courses of chemotherapy.

Nonadjuvanted, inactivated pandemic 2009 H1N1 vaccines were highly immunogenic in older children and adults after one standard 15-μg HA dose, perhaps in part related to preexisting immunity. Oil-in-water adjuvants (e.g., MF-59, AS03) are immunogenic at lower HA doses. For H5 vaccines, two doses of high HA antigen content or coadministration with an oil-in-water adjuvant appears to be necessary for adequate immunogenicity; the latter is also associated with cross-clade immunogenicity.

With inactivated vaccine, fever and systemic symptoms occur at rates comparable to those of adults given placebo but are more common in young children. Among adults, 25% or more may have mild local reactions at the site of injection. Ocular or respiratory symptoms have occasionally been reported within 24 hours after administration, but these symptoms typically are mild and resolve quickly without specific treatment. Injection site reactions and systemic complaints are more frequent after the high HA content[redacted] or oil-in-water adjuvanted inactivated vaccines. Intranasal vaccine causes coryza and sore throat in adults. Hypersensitivity reactions to residual egg proteins or other vaccine components occur rarely, and vaccine is contraindicated in persons with chicken egg anaphylactic hypersensitivity unless the patient has been desensitized. Inactivated vaccine does not cause exacerbation of asthma but might rarely be associated with Guillain-Barré syndrome in older adults.

Medications

Inhaled zanamivir and oral oseltamivir appear to be effective for chemoprophylaxis of both influenza A and B virus infections, including postexposure prophylaxis in households (Table 372-5), with each reducing the risk of symptomatic influenza infections by about 60 to 80%.[redacted] Unimmunized persons can be given prophylaxis when an outbreak develops and be given inactivated vaccine simultaneously with cessation of prophylaxis after 14 days. Alternatively, if vaccine is not available or is a poor match or if the patient is highly immunosuppressed, administration may be continued for the duration of the outbreak. When given to patients and staff alike, these drugs may be helpful in managing nosocomial outbreaks.

Rimantadine and amantadine are 70 to 90% effective in preventing influenza A illness caused by susceptible strains. However, the recent global circulation of adamantane-resistant H3N2 and pandemic H1N1 strains has made use of these agents unreliable. Transmission of resistant virus from drug-treated close contacts (households, nursing homes) may cause failure of prophylaxis and has been associated with failure to terminate nursing home outbreaks.

TABLE 372-5 ANTIVIRAL DOSE RECOMMENDATIONS IN ADULTS

DRUG	ROUTE	TREATMENT	PROPHYLAXIS	DOSE REDUCTIONS	COMMENT
Amantadine	Oral	100 mg bid	100 mg bid	Age >64 yr, Cr_{cl} < 50-80 mL/min	Consider further dose reductions in elderly <70 kg
Rimantadine	Oral	100 mg bid	100 mg bid	Age >64 yr, Cr_{cl} < 10 mL/min or severe hepatic dysfunction	Lower risk of CNS side effects than with amantadine
Oseltamivir	Oral	75 mg bid	75 mg once daily	Cr_{cl} < 30 mL/min	
Zanamivir	Inhaled	10 mg bid	10 mg once daily	Avoid in those with underlying airways disease	Training in use of the inhaler device is important
Peramivir*	Intravenous	600 mg once daily	Not applicable	Cr_{cl} < 50 mL/min	Currently investigational in U.S.
Zanamivir*	Intravenous	600 mg bid	Not applicable	Cr_{cl} < 80 mL/min	Currently investigational in U.S.

*Currently intraverous oseltamivir, peramivir, and zanamivir are in clinical development and are available on a compassionate use/emergency investigational new drug (zanamivir) use basis in the United States. Peramivir is licensed for use in Japan.

The standard duration of treatment in uncomplicated illness is 5 days; a longer duration (e.g., 10 days) should be considered for infections in seriously ill patients, immunosuppressed hosts, or infections caused by novel viruses. Higher doses (e.g., 150 mg twice daily) of oseltamivir have been used in patients with serious lower respiratory illness, immunocompromise, or infections by novel viruses. The duration of prophylaxis depends on the epidemiologic setting; durations of 2 weeks after immunization or 7 to 10 days for postexposure prophylaxis are appropriate. Antiviral prophylaxis may interfere with response to intranasal, live attenuated but not to intramuscular, inactivated vaccine.

CNS = central nervous system; Cr_{cl} = creatinine clearance.

Precautions

Patients hospitalized with human influenza should be managed with standard and droplet precautions. Masks appear to be as effective as respirators in protecting health care workers during seasonal influenza.[7] Patients hospitalized with presumed H5N1 or other novel strains warrant airborne, droplet, and contact precautions, including eye protection. Compliance with masks and hand hygiene also appears to reduce the risk of secondary infections in household contacts.[8]

TREATMENT

Rx

Inhaled zanamivir and oral oseltamivir (see Table 372-5) are active against both influenza A and B viruses. Antiviral treatment is recommended as soon as possible for patients with proven or suspected influenza who manifest severe, complicated, or progressive illness; are hospitalized; or have underlying conditions that increase the risk for complications (Table 372-4), including adults >64 years of age and children <5 years of age (especially those <2 years). Treatment within 2 days of symptom onset may be considered in outpatients with uncomplicated febrile illness. Therapy within 2 days of the onset of febrile illness in ambulatory patients reduces symptoms by 1 to 2 days, time to functional recovery, and risk for lower respiratory complications such as bronchitis and pneumonia.[1] Early oseltamivir therapy also decreases the risk for hospitalization, and even delayed use appears to reduce mortality in hospitalized patients. During therapy, oseltamivir resistance is infrequent but is more common in children and immunocompromised hosts and has developed in H5N1 and pandemic 2009 H1N1 infections owing to a specific mutation (H275Y). Global circulation of oseltamivir-resistant seasonal H1N1 viruses in 2008-2009 highlights the need for ongoing susceptibility monitoring. Zanamivir is inhibitory for most oseltamivir-resistant variants, including those with H275Y. Inhaled zanamivir may be infrequently associated with bronchospasm, sometimes severe, and nebulization of the lactose-containing commercial form is contraindicated in intubated patients. Oseltamivir is associated with nausea, vomiting, rash, and possibly rare neuropsychiatric symptoms.

Oral rimantadine or amantadine shortens the duration of fever and symptoms in uncomplicated influenza A caused by susceptible strains (see Table 372-5). The possible effectiveness of these drugs in preventing or treating the pulmonary complications of influenza is uncertain. Rimantadine carries a lower risk for central nervous system side effects than amantadine does, but both may cause gastrointestinal upset. These agents are ineffective for influenza B infections. Antiviral resistance emerges in 30% or more of treated persons. Circulating H3N2 and pandemic H1N1 as well as increasingly seasonal H1N1 and many H5N1 viruses show high-level resistance to this antiviral class, so these drugs are not recommended for routine use at present.

Symptomatic measures include antipyretics and cough suppressants. Aspirin should not be used, especially in children younger than 16 years, because of its association with Reye's syndrome.

Influenza viral pneumonia, particularly pandemic H1N1 and H5N1 disease, requires intensive respiratory monitoring, often including ventilatory support. Early oseltamivir appears to reduce mortality in such patients.[2] Intravenous formulations of zanamivir and peramivir provide reliable delivery of high drug levels in seriously ill persons and are available for compassionate use in the United States. Oral amantadine or rimantadine combined with a neuraminidase inhibitor is reasonable for susceptible strains. Intravenous ribavirin, aerosolized ribavirin, nebulized zanamivir, and convalescent plasma have been used with uncertain benefit. Systemic corticosteroids have been associated with prolonged viral replication, side effects, and possibly increased mortality. Intensive care unit complications, including ventilator-associated pneumonia, are common. Secondary bacterial pneumonia should be treated with appropriate antibiotics. When studies of sputum do not clearly indicate an infecting bacterium, antibiotics that are effective against the probable pathogens, including methicillin-resistant *S. aureus,* should be used.

PROGNOSIS

The mortality rate from seasonal influenza or pandemic 2009 H1N1 illness has been very low. However, although 90% of seasonal influenza-related deaths occur in persons older than 65 years or at high risk because of comorbid conditions, most pandemic 2009 deaths were in those younger than 65 years. Most patients make a full recovery, but they may require several weeks to return to full function. In patients whose viral pneumonia progresses to respiratory failure, the mortality rate is up to 50% (60% in H5N1) but is reduced by early antiviral therapy and intensive care support.

ADENOVIRUS DISEASES

JOHN J. TREANOR

DEFINITION

The adenoviruses are found in a variety of animal species, including humans, simians, horses, pigs, goats, and dogs. Specific disease syndromes or hosts are often associated with specific adenovirus serotypes (Table 373-1).

The Pathogen

The virus is nonenveloped and has a double-stranded DNA genome. The human adenoviruses are grouped into six subgenera (A to F) on the basis of differences in genome content, pattern of hemagglutination, and ability to cause tumors in experimental animals. In addition, at least 51 distinct serotypes are defined on the basis of neutralization tests. The majority of adenoviruses, like the coxsackieviruses (Chapter 387), use the same cellular receptor called the coxsackievirus-adenovirus receptor. The cell surface marker CD46 has also been identified as a potential receptor for some adenoviruses.

EPIDEMIOLOGY

The adenoviruses can infect and cause disease in a variety of human epithelial tissues, including those of the eye, respiratory tract, gastrointestinal tract, and urinary bladder. Virus may be shed from either the gastrointestinal or respiratory tract for months after acute infection. Most infections in immunologically competent individuals are subclinical.

Many outbreaks of epidemic keratoconjunctivitis have been attributed to contamination of ophthalmologic equipment, such as tonometers. Sterilization of such equipment between patients, good handwashing, segregation of patients, and other infection control procedures are critical in terminating nosocomial outbreaks.

PATHOBIOLOGY

Adenoviruses appear to use multiple mechanisms to circumvent the host's immune response, including inhibition of the antiviral effects of interferons,

TABLE 373-1 ADENOVIRUS SEROTYPES AND ASSOCIATED SYNDROMES

HOST AND DISEASE CATEGORY	EPIDEMIOLOGIC FEATURES	SEROTYPES
IMMUNOCOMPETENT HOSTS		
Pharyngoconjunctival fever	Epidemics in schools, families, and military personnel; associated with swimming pools	3, 7
Epidemic keratoconjunctivitis	Sporadic epidemics in schools, families, and industrial sites; may cause nosocomial outbreaks; more common in fall and winter	8, 19, 37
Endemic upper respiratory disease	Seen predominantly in children, families, and daycare settings	1, 2, 5
Acute lower respiratory tract disease	Most common in military recruits, but other healthy adults can also be affected	3, 4, 7, 14, 21
Acute hemorrhagic cystitis	Male preponderance	7, 11, 21, 35
Gastroenteritis	Predominantly in children <2 yr old	40, 41
IMMUNOCOMPROMISED HOSTS		
Transplantation		7, 11, 31, 34, 35
Acquired immunodeficiency syndrome		Multiple, 35, 42-47

downregulation of the expression of human leukocyte antigen molecules on the surface of infected cells, and inhibition of apoptotic cell death. They are capable of establishing persistent asymptomatic infection in some tissues.

CLINICAL MANIFESTATIONS

DISEASE IN NORMAL HOSTS

Eye Disease

PHARYNGOCONJUNCTIVAL FEVER

The syndrome of pharyngoconjunctival fever is seen predominantly in children and is characterized by bilateral conjunctivitis accompanied by mild pharyngitis without exudate. Fever, myalgias, and malaise may also be present. The eyes are itchy but not painful, with a boggy, hyperemic conjunctiva and watery discharge. Occasionally, the syndrome may be complicated by punctate keratitis.

Pharyngoconjunctival fever is highly contagious (see Table 373-1) and can be spread by contact with the eyes and mouth for 8 to 10 days after the onset of symptoms. The incubation period is 5 to 8 days. The illness is self-limited, with a duration of a few days to as long as 3 weeks. There is no specific therapy.

EPIDEMIC KERATOCONJUNCTIVITIS

In contrast to pharyngoconjunctival fever, epidemic keratoconjunctivitis occurs as unilateral disease in the majority of patients and is not generally accompanied by sore throat, fever, or systemic symptoms. Patients may complain of a mild foreign body sensation with watery tearing but are not in significant discomfort. Physical findings include a swollen eyelid, conjunctival hyperemia with edema and chemosis, and tender preauricular adenopathy. Keratitis eventually develops in about 80% of patients and is usually noted on about the eighth day of illness with the onset of pain, photophobia, lacrimation, and blepharospasm. Visual acuity may be temporarily reduced during the height of illness. Subepithelial corneal infiltrates can be detected in about a third of patients and may take weeks or months to resolve. Some cases of adenoviral conjunctivitis may result in prominent subconjunctival hemorrhage and resemble enteroviral acute hemorrhagic conjunctivitis.

Respiratory Disease

UPPER RESPIRATORY TRACT ILLNESS

Acute pharyngitis is the most common respiratory syndrome attributed to the adenoviruses. Adenoviruses can cause an exudative tonsillitis similar to that caused by group A streptococci (Chapter 298). In children, common associated syndromes include otitis media, coryza, and undifferentiated fever. Overall, adenoviruses are associated with about 7% of acute febrile illnesses in children, with the peak incidence occurring between 6 months and 2 years of age. High secondary attack rates are seen in families or in the daycare setting.

LOWER RESPIRATORY TRACT ILLNESS

Adenoviruses have been etiologically implicated in approximately 10% of childhood pneumonias. Clinical features are nondescript, and findings on chest radiography are similar to those in patients with other forms of viral pneumonia, with the exception that hilar adenopathy is more common in children with adenoviral pneumonia than in those with other forms of viral pneumonia. Mixed bacterial-viral pneumonia is often present and may be suggested by elevations in band forms in peripheral blood.

Adenoviruses can also be responsible for acute, febrile lower respiratory tract disease in healthy adults, seen most commonly in military recruits. The increased incidence in military recruits may be related to the special conditions of fatigue and crowding found in military training. Formerly well controlled by vaccination, adenovirus types 4 and 7 have reemerged as an important cause of acute respiratory illness in recruits after the production of adenovirus vaccine was discontinued in the 1990s. The disease is manifested as an atypical pneumonia syndrome and clinically resembles *Mycoplasma* pneumonia (Chapter 325). Prodromal symptoms of upper respiratory tract infection are reported by most patients, and pharyngitis is often found on initial evaluation. Bacterial superinfection may occur, particularly with *Neisseria meningitidis*. Although the illness is typically mild, more severe disseminated infections and deaths have been reported. Radiographic patterns can include focal infiltrates that resemble acute bacterial pneumonia, as well as large pleural effusions.

Acute, severe lower respiratory tract disease has also been reported in healthy adults in civilian populations in a variety of settings. Nosocomial outbreaks of adenoviral respiratory disease in healthy adults and children in long-term care facilities, psychiatric hospitals, and hospitals have been reported. Recently, outbreaks of severe respiratory disease in normal hosts have been associated with type 14 adenoviruses in the United States and elsewhere.

Because adenoviruses are relatively rare causes of pneumonia in otherwise healthy civilian adults but are frequently shed asymptomatically, isolation of adenovirus from stool or respiratory secretions in normal adults with pulmonary infiltrates should be interpreted with caution.

Urinary Disease: Hemorrhagic Cystitis

Acute hemorrhagic cystitis caused by adenoviruses is seen predominantly in children. The patient complains of gross hematuria and dysuria. The findings may be confused with those of glomerulonephritis, but laboratory tests of renal function remain normal, and fever and hypertension do not occur. Acute hemorrhagic cystitis is generally self-limited.

Gastrointestinal Disease: Gastroenteritis

Although multiple adenovirus serotypes may be shed in stool, only types 40 and 41, referred to as the enteric adenoviruses, have been convincingly associated with acute gastroenteritis. These adenovirus types belong to subgroup F and differ from other adenoviruses in being acid stable and highly restricted in their ability to replicate in conventional cell culture.

Gastroenteritis caused by enteric adenovirus is a disease predominantly of children younger than 2 years. Clinical features include watery diarrhea and vomiting similar to that seen with group A rotavirus infection (Chapter 388). In contrast to gastroenteritis associated with the rotaviruses and astroviruses, adenoviral gastroenteritis has no significant seasonal variability. The frequency of illness is about 5 to 10% of that caused by rotavirus in the same age group. Adenoviruses are rarely causes of acute gastroenteritis in adults.

Other Syndromes Associated with Adenoviruses in Immunocompetent Hosts

Adenoviruses are often isolated in cases of pertussis-like syndrome, but there is no evidence that adenoviruses by themselves are important causes of

whooping cough (Chapter 321). A toxic shock–like manifestation (Chapter 296) of disseminated adenovirus infection in a normal host has been reported. Adenoviruses have occasionally been isolated from cerebrospinal fluid in immunocompetent individuals with meningitis or meningoencephalitis and have been reported to be associated with an acute flaccid paralysis resembling polio (Chapter 423) in children. These viruses have also been implicated in sudden infant death syndrome. Adenoviruses may be detected in mesenteric lymph nodes at the time of surgery for intussusception, and it is postulated that viral infection causes an acute mesenteric lymphadenitis that leads to the development of this condition. Adenoviruses have also been isolated from myocardial biopsy specimens in adults with acute myocarditis (Chapter 60), thus suggesting a role for adenoviruses in its pathogenesis.

DISEASE IN IMMUNOCOMPROMISED HOSTS

In contrast to infection in normal hosts, infection in immunocompromised subjects tends to be disseminated, with virus being isolated from multiple body sites, including the lung, liver, gastrointestinal tract, and urine. The spectrum of serotypes includes those found in immunocompetent individuals and a markedly increased frequency of higher-numbered serotypes rarely found in immunologically normal subjects (see Table 373-1). Because adenoviruses are often isolated from immunocompromised patients in conjunction with multiple other opportunistic pathogens, it is difficult to ascribe specific clinical syndromes to them. The source of infection may be reactivation of latent virus, but nosocomial infection has also been documented.

Adenovirus infections are reported in 3 to 47% of patients undergoing bone marrow transplantation (Chapter 181), usually in association with respiratory disease, gastrointestinal infection, hepatitis, or cystitis. Hemorrhagic cystitis is common and infrequently progresses to disseminated disease. Disseminated disease, defined as involvement of two or more organ systems, generally in association with viremia, is accompanied by high mortality. Symptomatic disease is more common in children and in those with acute graft-versus-host disease.

Adenovirus infections following solid organ transplantation frequently involve the transplanted organ and may become disseminated. Infection may mimic rejection and can lead to graft loss. Infections are more common in pediatric recipients and may be newly acquired or arise endogenously from the donor organ or the recipient.

Adenoviruses are also frequently isolated from the stool and urine of individuals with acquired immunodeficiency syndrome, particularly patients with relatively low $CD4^+$ lymphocyte counts. The most remarkable aspect of this situation is the isolation of a wide variety of serotypes in these patients (see Table 373-1), including new, higher-numbered serotypes isolated for the first time in such subjects. In addition, antigenically intermediate types have been isolated that possibly reflect recombination events made possible by prolonged viral replication in these hosts.

DIAGNOSIS

Adenovirus can be cultured efficiently from conjunctival swabs, respiratory secretions, urine, or stool in as little as 2 days by applying centrifugation culture systems coupled with detection by immunofluorescence. Other widely used methods of directly detecting viral antigen or nucleic acid in clinical specimens include enzyme immunoassays, immunofluorescence tests, and polymerase chain reaction (PCR) techniques. Virus can be detected in the blood of immunocompromised individuals with disseminated disease and in healthy children with primary infections. Assessment of viral load by quantitative PCR techniques may be useful in monitoring the course of disease.

PREVENTION

Live adenovirus vaccines administered orally in enteric-coated capsules provide effective protection against serotypes 4 and 7 but are no longer in production. There is an active program to reintroduce these vaccines in the military. Adenovirus vaccines have not been used in civilian populations, partially because of the plethora of additional serotypes causing severe disease in these populations.

TREATMENT

Rx

Conjunctivitis

Therapy is generally supportive. Corticosteroids should be avoided in patients with mild conjunctivitis (Chapter 431) because the symptoms usually recur when these agents are discontinued. In more severe cases of keratitis, mild topical corticosteroids may be used with cycloplegics as needed for iritis (Chapter 431). Topical antibiotics may be administered to prevent bacterial superinfection. Topical cidofovir may decrease the frequency of severe corneal opacities but is associated with significant local toxicity.

Systemic Infections

No antiviral therapy has been proved to be effective for any systemic adenoviral syndrome. Cidofovir, which is highly active in cell culture, has been used (5 mg/kg intravenously weekly for 2 weeks and then every 2 weeks until three consecutive negative samples are obtained from previously positive sites) to treat disseminated disease in immunosuppressed individuals. The patient should be well hydrated and probenecid (2 g orally 3 hours before the dose and 1 g 2 and 8 hours after the dose) should be given to reduce the risk for renal toxicity. When compared with historical controls, use of cidofovir appears to be associated with decreased mortality, but no controlled trials are available to evaluate its efficacy. The utility of intravenous immunoglobulin for the treatment of adenovirus infection is unclear.

CORONAVIRUSES

LARRY J. ANDERSON AND EILEEN SCHNEIDER

DEFINITION

Human coronaviruses were, until 2003, recognized as a frequent cause of common cold symptoms, occasionally a cause of lower respiratory tract disease, but rarely if ever a cause of serious disease. In 2003, a novel coronavirus was introduced into humans from animals as the etiologic agent of the outbreak of severe acute respiratory syndrome (SARS). The SARS outbreak demonstrated that coronaviruses can be serious human pathogens and led to discovery of other novel human coronaviruses as well as multiple novel coronaviruses in bats, the likely reservoir for SARS coronavirus. The novel non-SARS coronaviruses detected in humans have usually been associated with mild respiratory disease, similar to the clinical syndromes associated with the previously described human coronaviruses 229E and OC43.

The Pathogens

Coronaviruses are members of the family Coronaviridae, which includes two genera, coronaviruses and toroviruses. Coronaviruses are single-stranded, positive-sense RNA viruses with a genome of approximately 30 kD, the largest genome among RNA viruses. These viruses were named coronaviruses because by electron microscopy they have club-shaped surface projections that give them a crownlike appearance. The genome encodes four or five structural proteins (a spike protein [S], a small envelope protein [E], a membrane protein [M], a nucleocapsid protein [N], and sometimes a hemagglutinin-esterase protein [HE]), a varying number of open reading frames scattered among the structural genes, and a polyprotein that is processed into multiple (usually 16) nonstructural proteins. These nonstructural proteins participate in virus replication but are not incorporated into the virion. Coronaviruses have also been isolated from a variety of animals and birds and, in their respective species, cause a wide range of respiratory, gastrointestinal, neurologic, and systemic illnesses. The coronaviruses have traditionally been divided into three antigenic groups; human and animal viruses compose groups I and II and avian viruses group III.

The first two human coronaviruses, 229E and OC43, are members of groups I and II, respectively. SARS coronavirus is a distant member of group II, and the two most recent human coronavirus isolates, NL63 and HK1, are members of groups I and II, respectively. Detection of novel coronaviruses in bats has greatly expanded our understanding of diversity among coronaviruses and suggests that additional groups may be needed to classify these viruses.

EPIDEMIOLOGY

The coronaviruses, which are common pathogens of humans, appear to be transmitted through close contact that probably includes contamination of hands from person-to-person contact or from fomites, followed by autoinoculation to the mucosal surfaces of the mouth, nose, or eyes or inhalation of infectious droplets and possibly aerosols. Symptoms occur 2 to 4 days after infection. The non-SARS coronaviruses are detected in patients with acute respiratory illnesses, most often a mild, upper respiratory tract illness (i.e., the common cold), but also in patients with more serious respiratory illnesses including pneumonia, bronchiolitis, and croup. Coronavirus infections are detected early in childhood, and repeated infections can occur throughout life. About 50% of children have antibodies against OC43 by 3 years of age, and about 70% of adults have such antibodies. Up to 75% of children have antibodies against NL63 and 229E by 3.5 years of age. Studies looking for 229E- and OC43-like infections suggest that coronaviruses are associated with about 15% of cases of the common cold and with up to 10% of cases of acute respiratory illnesses in children and adults. Individually, 229E, OC43, HKU1, and NL63 are detected in less than 1% to 4% of cases, and their individual contributions will vary by location and year. Serious illness has been reported in outbreaks among elderly patients in nursing homes. In one outbreak associated with OC43 infection, for example, 23 residents and 24 staff reported influenza-like illness, and three residents died. The non-SARS coronaviruses can be detected throughout the year, but peak detection is often during fall and winter months in temperate climates. A second respiratory viral pathogen can be detected in 20 to 60% of specimens positive for a non-SARS coronavirus.

Most documented SARS coronavirus infections in humans occurred in persons ill with a SARS-like illness during the 2002-2003 global outbreak. It is likely that wild animal markets in Guangdong Province, China, played a key role in amplifying and introducing the virus into humans, but the original source of the outbreak virus has not been determined. Detection of multiple SARS-like and other coronaviruses in bats suggests that they are a rich source of coronaviruses and likely the source of SARS coronavirus. The parent to the outbreak virus has, however, not yet been detected. Although animals were the original source of human infections, global spread of SARS coronavirus occurred through human-to-human transmission and involved droplet, person-to-person, and fomite transmission and, in some instances, probably small-particle aerosol transmission. Most transmission occurred within households, hospitals, or other health care facilities, and little transmission occurred in the community. The fact that most transmission occurred after the patient's illness had become serious and required hospitalization helps explain the importance of transmission in health care settings and the relative lack of transmission in the community.

PATHOBIOLOGY

The human coronaviruses characterized to date, including SARS coronavirus, infect humans through the respiratory tract. The site of virus replication is determined, at least in part, by which cells express the respective receptors. The receptors for antigenic group I human coronaviruses 229E and the recently described NL63 are aminopeptidase N and angiotensin-converting enzyme 2 (ACE2), respectively. The receptors for the two group II human coronaviruses characterized to date, OC43 and the recently described HK1, have not yet been determined, but OC43 may use several cell surface molecules as receptors, including 9-*O*-acetylated neuraminic acid. The primary receptor for SARS coronavirus is ACE2, but the virus also binds to two C-type lectins expressed on dendritic cells, DC-SIGN and L-SIGN. Aminopeptidase N is expressed in various cells, including respiratory, gastrointestinal, kidney epithelial, and myeloid cells, but 229E is known to infect only respiratory epithelial cells. ACE2 is found in various tissues, including the lung, gastrointestinal tract, heart, and kidneys. The SARS coronavirus has consistently been detected in pneumocytes in the lung and enterocytes in the gastrointestinal tract, and it is occasionally found in other cells, including distal tubular cells in the kidney and macrophages in various tissues. Autopsy studies suggest that infection in the lung leads initially to diffuse alveolar damage and later may lead to a repair process that includes fibrosis in the alveolar walls. It is not known whether NL63, which also uses ACE2 as its receptor, infects sites other than the respiratory tract.

It is likely that the illness associated with SARS and non-SARS coronavirus infections results from both the cytopathic effect of the virus and the host immune and inflammatory response to the viral infection. How this interplay contributes to disease, however, is not understood. The biphasic course of SARS in some patients, with the onset of severe disease in the second week of illness, and the decrease in the number of lymphocytes suggest a role for the host response and virus-induced immune suppression in the disease process.

CLINICAL MANIFESTATIONS

Non-SARS coronavirus infections are commonly associated with acute respiratory illnesses that are usually mild and consistent with the common cold (Chapter 369) but can also result in the full range of acute respiratory illnesses including pneumonia (Chapter 97), croup (Chapter 437), bronchiolitis (Chapter 92), and bronchitis (Chapter 96). The best studied of the non-SARS coronaviruses, human coronaviruses 229E and OC43, cause respiratory symptoms, such as rhinorrhea, nasal congestion, sore throat, and cough, as well as systemic symptoms, including fever, headache, and malaise, when they are inoculated intranasally in adult volunteers. Symptoms develop 2 to 4 days after inoculation, but about 30% of the volunteers who excrete virus had no associated illness. Symptoms usually persist for about 1 week but sometimes for as long as 3 weeks. Previous infection does not induce high levels of protective immunity. Humans can be reinfected with respiratory coronaviruses throughout life, and human volunteers can be symptomatically reinfected with the same strain of coronavirus 1 year after the first infection. As with other infections, the severity of disease varies among individual patients during the same outbreak and among groups of patients during different outbreaks in the same community. Patients with compromised cardiac, pulmonary, or immune systems are at increased risk of more serious lower respiratory tract illness, and outbreaks of human coronavirus infections in elderly patients in chronic care facilities can cause severe lower respiratory illnesses and deaths.

In contrast to the mild illness associated with 229E and OC43, SARS coronavirus infection nearly always results in a serious illness that requires hospitalization, often in an intensive care unit, and a high fatality rate. Radiologic evidence of pneumonia was seen in nearly all SARS coronavirus–infected persons, and acute respiratory distress syndrome (Chapter 104) requiring admission to an intensive care unit and mechanical ventilation developed in 20% or more of patients. Nearly 10% of outbreak-associated patients died. The death rate was especially high, approaching 50%, in elderly patients and patients with underlying illnesses. The initial clinical manifestation of SARS was often systemic symptoms of fever, malaise, and myalgias from 2 to 10 days (rarely longer than 10 days) after exposure. Several days after the onset of systemic symptoms, lower respiratory tract symptoms of nonproductive cough and shortness of breath were noted. Unlike patients with other respiratory virus infections, the majority of patients never experience upper respiratory tract symptoms such as rhinorrhea, sore throat, or nasal congestion (Table 374-1). As with other infections, the expected signs and symptoms with SARS coronavirus infection may be obscured or not present in elderly patients or patients with underlying chronic illnesses. During the course of their illness, most SARS coronavirus–infected patients had elevated liver enzyme levels and lymphopenia, including a substantial drop in numbers of both $CD4^+$ and $CD8^+$ T cells. SARS coronavirus–infected patients with severe complications also often suffered complications associated with intensive supportive care, such as secondary bacterial infections. A more severe illness with infection has been associated with older age, underlying chronic illness, higher liver enzyme values, lower lymphocyte levels and platelet counts, and higher titers of virus or viral RNA. Asymptomatic or mild illness occurred but was uncommon. In studies of exposed health care workers and patients who did not have a SARS-like illness, less than 1% of those tested had definitive serologic evidence of SARS coronavirus infection (i.e., a positive neutralization test result). In general, children had less severe illness than adults did.

Although most survivors of SARS coronavirus infection appeared to achieve full recovery, as many as 25% had abnormal pulmonary findings, such as ground-glass opacities on chest radiograph or abnormal pulmonary function test results (e.g., decreased diffusing capacity), 6 months or more after their illness.

TABLE 374-1 PERCENTAGE OF SARS CORONAVIRUS–INFECTED PATIENTS WITH SELECTED CLINICAL AND LABORATORY FEATURES OF SARS CORONAVIRUS INFECTION

	SARS Coronavirus–Infected Patients with Symptoms or Laboratory Findings	
CLINICAL OR LABORATORY FINDING	**AT HOSPITAL ADMISSION**	**SOMETIME DURING THE ILLNESS**
Fever	90-100%	≈100%
Upper respiratory tract symptoms	10-25%	Not available
Cough or shortness of breath	40-75%	Up to 100%
Diarrhea	20-30%	40-70%
Elevated liver function test results	35-90%	70-100%
Pneumonia on chest radiograph	65-90%	90-100%
Lymphopenia*	50-90%	70-95%

*Both $CD4^+$ and $CD8^+$ lymphocyte counts are decreased.
SARS = severe acute respiratory syndrome.

DIAGNOSIS

Because illness is usually mild and there is no effective treatment, the diagnosis of non-SARS coronavirus infection has not been important to management of patients. The diagnosis of SARS coronavirus infection, however, is critical for the management of individual patients and for the public health response to reemergence of SARS.

Non-SARS Coronavirus Infection

Non-SARS coronavirus polymerase chain reaction (PCR) assays, which can be designed to detect both known and novel coronaviruses, are the assays of choice for diagnosis of infection. Most coronavirus PCR assays are type specific, that is, specific to SARS coronavirus, 229E, OC43, HKU1, or NL63 RNA. Coronavirus diagnostic assays have not been generally available and may have to be obtained by special requests from a limited number of sites that perform human coronavirus diagnostics. Presence of the virus can also be inferred by electron microscopy and confirmed by in situ or immunohistologic assays of affected tissues. Positive immunohistologic and in situ hybridization studies document the site of infection and help support a link between the virus and the disease process. A variety of enzyme or fluorescent immunoassays for antibodies have been used successfully to detect infection. Most assays detect IgG antibodies, but virus neutralization antibody assays are more specific. The need to detect a diagnostic rise in antibodies between acute and convalescent serum specimens for non-SARS coronavirus infections means that serologic tests are not helpful for managing the acute care of individual patients, although they are very helpful for epidemiologic studies.

SARS

Three features of SARS cases help guide approach to its diagnosis. First, SARS has occurred only in persons who have some potential exposure, that is, to patients with SARS, to a location with SARS transmission, to a laboratory working on SARS coronavirus, or to a setting where SARS-infected animals might be located (e.g., southern China). Second, nearly 100% of infected patients develop chest radiographic abnormalities by day 10 of their illness. Finally, SARS nearly always developed within 10 days of exposure. Thus, a suspicion of SARS and a diagnostic evaluation can be limited to patients who have a severe lower respiratory tract illness and some potential exposure to SARS within 10 days before the onset of illness.

Laboratory confirmation of SARS coronavirus infection early in the illness proved to be problematic, even with sensitive real-time PCR assays. Unlike in most respiratory viral infections, the highest titer of virus, or viral RNA, was found in clinical specimens from the second week of illness. During the first week of illness, the best way to detect infection is by a sensitive PCR assay or a sensitive enzyme immunoassay for N protein antigen applied to respiratory and serum specimens. During the second week of illness, respiratory and stool specimens are most likely to be positive for viral RNA. Because most populations are negative for SARS coronavirus antibodies, detection of serum SARS coronavirus antibodies is a reliable indicator of infection. Antibodies were sometimes detected early in the second week of illness but at times were not detected until 4 weeks into the illness. Because antibodies persist in serum, a specimen can be collected late without compromising the ability to detect antibodies. Serologic assays, unlike PCR assays, are not confounded by problems with specimen contamination. Because antibodies to SARS coronavirus were rarely present before the 2003 outbreak, a single positive antibody test result from an ill person could be considered diagnostic of an acute SARS coronavirus infection. However, because the reemergence of SARS coronavirus will have substantial public health, social, and economic impact, and because of occasional cross-reacting antibodies induced by other coronaviruses, a neutralization antibody test and repeated testing by a reference laboratory are required to confirm the diagnosis.

TREATMENT

Rx

There is no virus-specific treatment of non-SARS coronavirus infections, but the illnesses are mild and usually resolve in a few days to a week. Patients require symptomatic therapy or, uncommonly, management of complications of infection.

Treatment of SARS coronavirus infection is more complex. Currently, no antiviral drug has proved to be effective. With the high death rate, fast pace of the outbreak, and no clinical or in vitro data to guide treatment, a combination of ribavirin, steroids, and various mechanical ventilation and oxygenation regimens was often used to treat SARS patients. Later in the outbreak, in vitro data showed little if any antiviral effect with ribavirin and suggested that interferon alfa, SARS convalescent phase immune globulin, and lopinavir plus ritonavir might be useful. Although many people were treated during the outbreak, lack of control groups makes it impossible to determine which if any therapies were beneficial. If SARS reemerges, it is hoped that in vitro and animal studies can provide clearer guidance for treatment.

PREVENTION

A variety of candidate vaccines have been evaluated in animals, and two have entered clinical trials in humans. Handwashing and other infection control measures (Chapter 372) probably decrease the spread of coronaviruses in the home, health care facilities, and other settings. These strategies focus on reinforcing the need for patients with respiratory illnesses to cover the nose and mouth when coughing or sneezing, to use tissues to contain respiratory secretions, and to wash the hands after contact with respiratory secretions. Staff should use good infection control practices.

Within 4 months of the initiation of the 2003 SARS outbreak, the outbreak was contained and human-to-human transmission stopped without a vaccine or effective antiviral therapy but with thorough implementation of the classic public health tools of case finding, isolation, and contact tracing management. The low risk of SARS transmission early in the illness and the very low rate of asymptomatic infection were key factors to the success of these preventive measures.
